November 30, 2022

Abstract

Geologists have documented at least fourteen occurrences of “giant ooids”, a geologically rare type of carbonate allochem, in Neoproterozoic successions at low paleo-latitudes. Recent experiments and modeling demonstrated that ooid size reflects an equilibrium between precipitation and abrasion rates, such that ooid size could be used as a geological proxy for CaCO_3 mineral saturation state (Ω). Here, the documented sizes of Neoproterozoic giant ooids were applied to estimate seawater , which provided a novel approach to constraining temperature, partial pressure of CO_2 , and alkalinity preceding Neoproterozoic glaciations. The results suggest that giant ooid formation was most plausible with seawater alkalinity elevated over its present value by at least a factor of two, and either much warmer (40C) or much colder (0C) climate than modern tropical carbonate platforms, which have important and divergent implications for climate states and ecosystem responses prior to the initiation of each Neoproterozoic glaciation.

5 **Key Points:**

- 6 • Giant ooids are a rare carbonate facies that occur in strata underlying a number of
7 Neoproterozoic glacial deposits.
- 8 • Giant ooid diameter was applied to constrain Neoproterozoic seawater carbonate
9 saturation state, temperature, and alkalinity.
- 10 • Neoproterozoic giant ooids indicate hot or cold, but not moderate, climate at low latitudes
11 preceding the onset of glaciations.

12 **Abstract**

13 Geologists have documented at least fourteen occurrences of “giant ooids”, a geologically rare
14 type of carbonate allochem, in Neoproterozoic successions at low paleo-latitudes. Recent
15 experiments and modeling demonstrated that ooid size reflects an equilibrium between
16 precipitation and abrasion rates, such that ooid size could be used as a geological proxy for
17 CaCO_3 mineral saturation state (Ω). Here, the documented sizes of Neoproterozoic giant ooids
18 were applied to estimate seawater Ω , which provided a novel approach to constraining
19 temperature, partial pressure of CO_2 , and alkalinity preceding Neoproterozoic glaciations. The
20 results suggest that giant ooid formation was most plausible with seawater alkalinity elevated
21 over its present value by at least a factor of two, and either much warmer (40°C) or much colder
22 (0°C) climate than modern tropical carbonate platforms, which have important and divergent
23 implications for climate states and ecosystem responses prior to the initiation of each
24 Neoproterozoic glaciation.

25 **Plain Language Summary**

26 Ooids are a type of calcium carbonate sediment grain composed of a set of concentric layers
27 formed around a small particle. Although most ooids are sand-size grains (<2 mm in diameter),
28 rare cases, referred to as “giant ooids”, are much larger, with some >1 cm in diameter. Geologists
29 have suggested that these giant ooids reflected unusual seawater chemistry, but the exact
30 conditions required for their formation remained unknown. Although giant ooids are geologically
31 rare, a surprising number of occurrences have been described from Neoproterozoic rocks (1000-
32 541 million years old) that underlie sedimentary layers deposited by low paleo-latitude
33 glaciations (i.e., “Snowball Earth” events). This study used the grain diameters of
34 Neoproterozoic ooids to estimate the temperature and composition of seawater when they
35 formed. The results showed that Neoproterozoic seawater must have either been very hot or very
36 cold just prior to these glaciations, a finding that challenges either climate models of this era or
37 conceptual models of common modes of carbonate sediment formation and deposition.

38 **1 Introduction**

39 Neoproterozoic carbonate successions are host to enigmatic and geologically rare
40 carbonate allochems known as “giant ooids”, uncommonly large concentrically-coated carbonate

41 grains (>2 mm in diameter). Sumner and Grotzinger (1993) noted that giant ooids occur more
42 commonly and were generally larger in diameter during Neoproterozoic time than any other
43 period in Earth history; additional observations have confirmed this occurrence pattern (cf. Table
44 3 in Thorie et al., 2018). Geologists have speculated that the formation of giant ooids required
45 exceptionally high calcium carbonate mineral saturation state and higher current velocities than
46 are characteristic of modern ooid shoals (Sumner & Grotzinger, 1993; Swett & Knoll, 1989).
47 Yet, this hypothesis has remained untested and does not clearly explain why giant ooids are not
48 more common in older Precambrian successions.

49 Giant ooids have been documented in Neoproterozoic strata in Greenland, Svalbard,
50 Canada, Alaska (USA), California (USA), Siberia, Mongolia, India, and Australia (Batten et al.,
51 2004; Day et al., 2004; Fromhold & Wallace, 2011; Gutstadt, 1968; Macdonald, et al., 2009a,
52 2009b; Petrov, 2018; Singh, 1987; Srivastava, 2006; Sumner & Grotzinger, 1993; Swett &
53 Knoll, 1989; Teitz & Mountjoy, 1989; Thorie et al., 2018; Trower & Grotzinger, 2010; Zenger,
54 1976). Grotzinger and James (2000) noted that many of these giant ooids closely underlie glacial
55 diamictites and/or cap carbonates (Table 1) associated with prolonged glacial episodes that
56 occurred during the Cryogenian period (the “Sturtian” and the “Marinoan” glaciations), known
57 as “Snowball Earths” because geological evidence indicates widespread glaciation extending to
58 low latitudes (Chumakov, 2007; Evans, 2000; Hoffman et al., 1998, 2017; Kirschvink, 1992;
59 Trindade & Macouin, 2007). Some giant ooid occurrences are directly overlain by glacial strata,
60 while others are separated by ~100-300 m of stratigraphy (in one case, ~1 km) (Table 1). The
61 durations of time elapsed between deposition of giant ooids and glacially-associated sediments
62 are not well-constrained geochronologically (cf. Table 4 in Thorie et al., 2018). There is also
63 evidence of a third glacial episode during the Ediacaran period (the “Gaskiers”), although it
64 appears unlikely that it constituted a Snowball Earth due to the paucity of low-latitude glacial
65 deposits (Hoffman & Li, 2009); it is not clear that the four cases of giant ooids documented in
66 Ediacaran strata precede the Gaskiers glaciation (Table 1). These stratigraphic associations of
67 Neoproterozoic giant ooids suggest that a better understanding of the environmental conditions
68 required for giant ooid formation would provide new constraints for models of the global carbon
69 cycle and climate during this dynamic era.

70 Recent experiment and modeling demonstrated that ooid size reflects an equilibrium
71 between precipitation and abrasion rates (Trower et al., 2017), with the implication that ooid size

72 in the rock record can be used to infer the calcium carbonate mineral saturation state of ancient
 73 seawater, Ω , where $\Omega = \frac{[Ca^{2+}][CO_3^{2-}]}{K_{sp}}$ (K_{sp} is the solubility product constant). These reconstructed
 74 Ω values can then be applied to estimate the other parameters that describe the carbonate system:
 75 the partial pressure of CO₂ (pCO₂), alkalinity (ALK), pH, and the concentration of dissolved
 76 inorganic carbon (DIC). Here, this approach is applied to Neoproterozoic giant ooids to provide a
 77 novel constraint on Neoproterozoic pCO₂, alkalinity, and temperature prior to the initiations of
 78 the Cryogenian Snowball Earths and during the Ediacaran Period.

79 2 Methods

80 Based on the giant ooid occurrences documented by Sumner and Grotzinger (1993), with
 81 the addition of occurrences described more recently (Batten et al., 2004; Day et al., 2004;
 82 Fromhold & Wallace, 2011; Macdonald, et al., 2009a, 2009b; Petrov, 2018; Srivastava, 2006;
 83 Thorleifsson et al., 2018; Trower & Grotzinger, 2010), Neoproterozoic giant ooids range from 2 to 25
 84 mm in diameter (D) (Table 1). Within this range, $D = 5$ mm and $D = 10$ mm were chosen as
 85 representative grain sizes for which to assess characteristic Ω values—the former representative
 86 of a grain diameter observed in the majority of the giant ooid deposits and the latter a
 87 conservative representative of the largest ooids in these deposits (Table 1). Many of these giant
 88 ooid occurrences have been described as having been originally composed of aragonite (Hood
 89 and Wallace, 2018), but additional CaCO₃ minerals were also explored for this analysis.

90 An equilibrium ooid size is the grain diameter, D_{eq} , at which the precipitation rate
 91 $R_{precipitation}$ and the abrasion rate $R_{abrasion}$ are equal (Trower et al., 2017). Abrasion rate can be
 92 estimated from the rock record by measuring D and determining a characteristic bed shear
 93 velocity, u_* (Trower et al., 2017). There are several potential approaches to estimating u_* : the
 94 simplest is to leverage the observation from modern systems that ooids are typically transported
 95 near the threshold of suspension and estimate u_* by assuming Rouse number $P = 2.5$, where
 96 $P = \frac{w_s}{\kappa u_*}$; $\kappa = 0.41$ is the von Kármán constant and w_s is settling velocity calculated following
 97 Dietrich (1982) with grain diameter (D), sediment density (ρ_s), fluid density (ρ_f), and fluid
 98 kinematic viscosity (ν). Alternatively, if bedforms are preserved in the rock record, their
 99 dimensions can be used to estimate u_* (Lapotre et al., 2017; Southard & Boguchwal, 1990).

100 Because bedform dimensions are not well-documented for Neoproterozoic giant ooid
 101 occurrences, $P = 2.5$ was used to estimate a range for u_* corresponding to the range of giant ooid
 102 sizes (Figure S1). Consistent with this choice, most giant ooids have high sphericities, suggesting
 103 that they dominantly experienced collisional abrasion during saltation, rather than frictional
 104 abrasion during rolling and sliding (Sipos et al., 2018). $R_{abrasion}$ can then be calculated following
 105 Lamb et al. (2008) and Trower et al. (2017):

$$106 \quad R_{abrasion} = \frac{\pi A_1 \rho_s Y w_i^3 D^3}{6 k_v \sigma_t^2 H_{fall}} \quad (1)$$

107 where σ_T is tensile strength and Y is Young's modulus of elasticity (1 MPa and 20 GPa,
 108 respectively, following Trower et al., 2017); w_i is impact velocity normal to the bed, calculated
 109 following Lamb et al. (2008); H_{fall} is the typical height particles are transported above the bed,
 110 calculated following Lamb et al. (2008); $k_v = 9 \times 10^5$ is a non-dimensional constant calibrated for
 111 ooid abrasion by Trower et al. (2017); and $A_1 \approx 1/3$ (Sklar and Dietrich, 2004) accounts for the
 112 fact that the time between particle-bed impacts depends on the time for a particle to be
 113 transported from the bed up to H_{fall} , in addition to the time to settle back to the bed. H_{fall} and w_i
 114 both depend on water depth, H . $H = 5$ m was chosen as a representative water depth; sensitivity
 115 tests indicate that varying water depth has a negligible effect on the resulting Ω prediction
 116 (Figure S2). Application of this abrasion model relies on the assumptions (1) that ooid
 117 diminution primarily occurs through abrasion of mud-size (<62.5 μm) carbonate particles rather
 118 than fragmentation of larger particles, which is consistent with experimental observations of
 119 abrasion of carbonate sand (Trower et al., 2019) and limestone pebbles (Attal and Lavé, 2009),
 120 and (2) that abrasion rates calibrated for sand-size carbonate particles (Trower et al., 2017) can
 121 be extrapolated to pebble-size carbonate particles, which is supported by similarity in modeled
 122 rates with experimental rates for limestone pebbles (Attal and Lavé, 2009) (Figure S3).

123 For each combination of (D, u_*) , one can estimate the precipitation rate required to
 124 sustain that D as the equilibrium ooid size: $R_{precipitation} = f \cdot R_{abrasion}$, where $f = (0, 1]$ is
 125 intermittency of movement. For the purposes of this analysis, $f = 0.01$ (i.e., sediment is actively
 126 transported 1% of the time) was chosen as a lower bound on this parameter—resulting $R_{precipitation}$
 127 estimates are therefore minimum values (Figure S4). This intermittency value is somewhat less
 128 than observed in modern ooid shoals— $f = 0.1-0.25$ on Ambergris shoal in the Turks and Caicos

129 Islands (Trower et al., 2018)—but this infrequent active transport could be explained by the large
 130 heights and wavelengths characteristic of gravel bedforms (Carling, 1999). The value of Ω
 131 required for each D_{eq} can be solved for by rearranging the volumetric precipitation rate equation
 132 for the carbonate mineral of interest:

$$133 \quad R_{precipitation} = k(\Omega - 1)^n \cdot \frac{M}{\rho_s} \cdot A_{surface} \quad (2)$$

134 where k is the rate constant ($\mu\text{mol}/\text{m}^2/\text{hr}$), n is the reaction order (dimensionless), M is the molar
 135 mass of the calcium carbonate mineral (g/mol), and $A_{surface}$ is the ooid surface area (m^2).

136 Four scenarios with different mineralogy and/or temperature were simulated, using
 137 estimates for seawater density and kinematic viscosity as a function of temperature (T) and
 138 salinity (S) (Table 2): (1) giant ooids composed of aragonite under conditions similar to modern
 139 carbonate platforms ($T = 25^\circ\text{C}$); (2) giant ooids composed of calcite under the same conditions
 140 as (1); (3) giant ooids composed of aragonite under warmer climate ($T = 40^\circ\text{C}$); and (4) giant
 141 ooids composed of ikaite ($T = 0^\circ\text{C}$). Ikaite is a hydrated calcium carbonate mineral
 142 ($\text{CaCO}_3 \cdot 6\text{H}_2\text{O}$) that precipitates only at cold temperatures ($< 4^\circ\text{C}$) and rapidly dehydrates to
 143 monohydrated calcite, calcite, aragonite, or vaterite at warmer temperatures (timescales of hours
 144 to days) (Bischoff et al., 1993a; Ito, 1998; Shaikh, 1990; Tang et al., 2009) or after any subaerial
 145 exposure (Smoot & Lowenstein, 1991). In theory, due to the rapid and early transformation of
 146 ikaite to aragonite (or other CaCO_3 phases), fabrics interpreted as having been originally
 147 composed of aragonite may not be inconsistent with ikaite as a precursor. The latter scenarios
 148 were predicted to be more amenable to larger equilibrium ooid sizes, either due to higher
 149 precipitation rate at a warmer temperature or due to lower abrasion rate resulting from the low
 150 density of ikaite and high viscosity of cold seawater. Kinetic parameters for aragonite and calcite
 151 precipitation at 25°C , aragonite at 40°C , and ikaite at 0°C were chosen from Zhong and Mucci
 152 (1989), Burton and Walter (1987), and Papadimitriou et al. (2014), respectively (Table 2).
 153 Results for aragonite and calcite at $T = 0^\circ\text{C}$ were not included in the following analysis because
 154 their sluggish precipitation kinetics at low temperature (Burton & Walter, 1987; Lopez et al.,
 155 2009) make them an implausible alternative to ikaite (Figure S5).

156 PHREEQC (Parkhurst & Appelo, 2013) was used to estimate combinations of pCO₂ and
157 ALK required for the Ω values determined for each of the four scenarios (Supplementary Text
158 S1). A range of alkalinity from 2 to 10 meq/L and a range of pCO₂ from 10^{-2.5} to 10⁻⁵ atm
159 (consistent with constraints from Kasting, 1987; Kasting, 1993; and Sheldon, 2006) were
160 explored. The PHREEQC database (Parkhurst & Appelo, 2013) was applied for aragonite/calcite
161 at T = 25°C, 40°C and the FREZCHEM database (Marion et al., 2010) was applied for ikaite at T
162 = 0°C. The concentration of Ca²⁺ was constrained as a function of alkalinity, with either Ca:ALK
163 = 5 (i.e., modern seawater) or Ca:ALK = 0.75, the minimum estimate from Blättler et al. (2016);
164 and the concentration of Mg²⁺ was constrained as a function of [Ca²⁺], with either Mg:Ca = 1 or
165 Mg:Ca = 5, following endmember values from Hardie (2003).

166 3 Results

167 The carbonate mineral saturation states required for giant ooids with D = 10 mm varied
168 substantially depending on mineralogy (aragonite, calcite, or ikaite) and temperature (T = 0°C,
169 25°C, 40°C) (Figure 1). Aragonitic or calcitic ooids of this size under conditions similar to those
170 on modern carbonate platforms (i.e., T = 25°C) required $\Omega_{\text{aragonite}} \cong 19$ or $\Omega_{\text{calcite}} \cong 26$ (Figure
171 1a-b), both of which are notably higher than saturation states observed in modern shallow marine
172 settings (e.g., $\Omega_{\text{aragonite}} = 5$ in the Turks and Caicos Islands, Trower et al., 2018). In contrast,
173 aragonitic giant ooids at T = 40°C required $\Omega_{\text{aragonite}} \cong 10$ (Figure 1c) and ikaite giant ooids at T
174 = 0°C required $\Omega_{\text{ikaite}} \cong 4$ (Figure 1d). Smaller giant ooids (D = 5 mm) required lower saturation
175 states— $\Omega_{\text{aragonite}} \cong 12$ or $\Omega_{\text{calcite}} \cong 17$ for T = 25°C, $\Omega_{\text{aragonite}} \cong 7$ for T = 40°C, or $\Omega_{\text{ikaite}} \cong 2$ for
176 T = 0°C. PHREEQC results illustrated that all cases required ALK > 2 meq/L and pCO₂ ≤ 10^{-2.5}
177 atm (~10x present atmospheric level, PAL) (Figure 2); the lowest minimum ALK values were
178 associated with Ca:ALK = 5, which is most consistent with a minimum constraint of [Ca] ≥
179 9 mM from late Tonian fluid inclusion data (Spear et al., 2014) and constraints from Ca isotopes
180 (Blättler et al., 2020). The Mg:Ca = 5 cases required higher alkalinity and lower pCO₂ than
181 Mg:Ca = 1 cases; Mg:Ca = 5 is most consistent with Hardie's (2003) estimates of Cryogenian
182 and Ediacaran seawater. The ikaite scenario required somewhat higher ALK and lower pCO₂
183 than the other scenarios because ikaite is more soluble than aragonite or calcite. In all cases, most
184 of the combinations of pCO₂ and alkalinity that were consistent with giant ooid formation
185 occurred at pH ≥ 8.2 (Kasemann et al., 2010), although cases with Ca:ALK = 5 allowed giant

186 ooid formation at $\text{pH} \leq 8.2$ at elevated pCO_2 (Figure 2). The model results suggested that giant
187 ooid formation is not consistent with $\text{pH} = 7\text{--}7.2$ (Isson and Planavsky, 2018) (Figure 2).

188 The constraints on $\Omega_{\text{aragonite}}$ and Ω_{calcite} were relatively insensitive to the choice of u_* and
189 therefore transport mode, suggesting that the requirements for $\Omega_{\text{aragonite}}$ and Ω_{calcite} are consistent
190 even for pill-shaped giant ooids (Singh 1987; Hood and Wallace, 2018) associated with transport
191 via rolling and sliding rather than saltation (Sipos et al., 2018). The constraint on Ω_{ikaite} was
192 somewhat more sensitive to the choice of u_* , such that transport via rolling and sliding required
193 higher Ω_{ikaite} than transport via saltation.

194 **4 Discussion**

195 The combinations of elevated ALK and relatively low pCO_2 indicated in all scenarios
196 (Figure 2) could be consistent with drawdown of CO_2 and increased seawater alkalinity due to
197 enhanced weathering prior to the Snowball glaciations (Cox et al., 2016; Donnadieu et al., 2004;
198 Goddériss et al., 2003; Hoffman et al., 1998), while Ediacaran giant ooid occurrences suggest that
199 elevated alkalinity also characterized Ediacaran seawater. However, not all scenarios are equally
200 plausible. The set of carbonate chemistry models with $\text{Ca:ALK} = 5$ and $\text{Mg:Ca} = 5$ are most
201 consistent with constraints from fluid inclusion data (Spear et al., 2014), Ca isotopes (Blättler et
202 al., 2020), and mid-ocean ridge flux modeling (Hardie, 2003) (Figure 2). Although
203 Neoproterozoic carbonate successions have been interpreted to have formed under conditions
204 similar to modern tropical carbonate platforms (e.g., Hoffman et al., 1998), the high Ω values
205 implied by the 25°C scenarios are not particularly plausible solutions. It is unlikely that the Ω
206 values required for $D = 10 \text{ mm}$ ($\Omega_{\text{aragonite}} \cong 19$ or $\Omega_{\text{calcite}} \cong 26$) could be sustained over the >1000
207 year timescales necessary for ooid growth (Beaupré et al., 2015; Duguid et al., 2010). Both Ω
208 values are above the thresholds for homogeneous nucleation of aragonite or calcite, respectively
209 (Morse & He, 1993; Pokrovsky, 1998; Sun et al., 2015); at these Ω values, the respective
210 carbonate mineral would have nucleated rapidly both on available surfaces (heterogeneous
211 nucleation)—including ooid surfaces, particulate organic matter, etc.—and spontaneously within
212 the water column (homogeneous nucleation). Furthermore, the rapid CaCO_3
213 nucleation/precipitation at high Ω values and the relatively slow rate of CO_2
214 hydration/hydroxylation (Zeebe & Wolf-Gladrow, 2001) would both provide strong negative

215 feedbacks on Ω . Although the $T = 25^{\circ}\text{C}$ $\Omega_{\text{aragonite}}$ or Ω_{calcite} values for $D = 5$ mm are more
216 plausible from this perspective, they are not consistent with the observations of ooids with $D > 5$
217 mm. Based on the common occurrence of giant ooids with diameters ≥ 10 mm, it is therefore
218 more likely that Neoproterozoic giant ooids formed under conditions that were either much
219 warmer ($T = 40^{\circ}\text{C}$) or much colder ($T = 0^{\circ}\text{C}$) than modern carbonate platforms.

220 The warmer scenario can explain aragonitic giant ooids under a range of bed shear
221 velocities, but only with infrequent sediment transport (Figure 1, Figure S4). Temperatures \geq
222 40°C at low latitudes are consistent with models of post-Snowball greenhouse climate (Le Hir et
223 al., 2009; Pierrehumbert et al., 2011; Yang et al., 2017), although these models require $\text{pCO}_2 \cong$
224 $400x$ PAL ($\sim 10^{-0.9}$ atm), implying exceptionally high ALK (> 40 meq/L). Due to the reduced
225 solar luminosity during Neoproterozoic time relative to the present (Gough, 1981), models with
226 $\text{pCO}_2 \cong 10^{-2.7}$ atm have predicted a cooler-than-modern climate (i.e., inconsistent with $T =$
227 40°C), and that $\text{pCO}_2 \lesssim$ PAL was sufficiently low to trigger global glaciation (Donnadieu et al.,
228 2004; Hyde et al., 2000; Micheels & Montenari, 2008; Pierrehumbert et al., 2011). This scenario
229 therefore requires that $\text{pCO}_2 > 10^{-2.7}$ atm—and, consequently, $\text{ALK} > 5$ meq/L—but also that
230 $\text{pCO}_2 \ll 10^{-0.9}$ atm, such that Ω could be sufficiently elevated. The occurrences of giant ooids
231 that stratigraphically underlie Marinoan glacial deposits could therefore be indicative of the
232 persistence of greenhouse conditions after the Sturtian Snowball Earth (Mills et al., 2011), but
233 would still have required some drawdown of CO_2 (Figure 2). This scenario would also imply hot
234 low-latitude climate preceding the Sturtian Snowball Earth. Finally, for Ediacaran giant ooid
235 occurrences, this scenario could be consistent with elevated carbonate clumped isotope
236 temperatures from the Ediacaran Nafun Group (Bergmann et al., 2018), but is warmer than 20–
237 25°C temperature estimates from fluid inclusions in Ediacaran halites deposited at equatorial
238 latitudes (Meng et al., 2011).

239 Although the cold scenario requires higher ALK (6–10 meq/L) and lower pCO_2 ($\sim 10^{-4}$)
240 than other cases, it is potentially consistent with several lines of evidence from the rock record.
241 Glendonite—a pseudomorph of ikaite—has been reported in Cryogenian (James et al., 2005) and
242 Ediacaran (Wang et al., 2017) carbonate units deposited prior to glaciogenic sediments. In the
243 former case, glendonites are described in close stratigraphic association with giant ooids; model
244 results demonstrate that aragonitic giant ooids cannot form at the cold temperatures at which

245 ikaite precipitates due to sluggish precipitation kinetics (Figure S5). Ooids formed in cold-water
246 conditions have also been observed adjacent to glaciers in Antarctica (Goodwin et al., 2018; Rao
247 et al., 1998) and in Cryogenian carbonates interpreted as glaciolacustrine deposits (Fairchild et
248 al., 2016), although neither case has been definitively identified as having initially precipitated as
249 ikaite. Furthermore, there is reason to suspect that ikaite might be substantially under-recognized
250 in the rock record due to its rapid transformation to calcite and aragonite at temperatures only
251 modestly above 0°C or after subaerial exposure. Analysis of modern and Holocene carbonates in
252 lakes in California and Patagonia has suggested that most of this carbonate originally
253 precipitated as ikaite before transforming to calcite or aragonite during warmer seasons
254 (Bischoff, et al., 1993b; Council & Bennett, 1993; Oehlerich et al., 2013). In these cases, ikaite
255 had not been recognized as the dominant primary phase until identified via analyses of modern
256 samples because the crystal size of much of the primary ikaite was much smaller than the
257 characteristic glendonite pseudomorphs. It is not yet clear how one might distinguish the
258 petrographic fabrics of finely-crystalline primary aragonite vs. ikaite transformed to aragonite in
259 the rock record. This scenario, if correct, implies that Cryogenian giant ooids are an indicator
260 facies of cold conditions at low-latitudes prior to the delivery of glacially-derived sediment, with
261 the consequence that strata associated with giant ooids could provide a record of ecosystem
262 responses to this extreme cooling. Notably, formation of ooids of any size also requires current
263 transport, so this scenario would also require areas of open water in order for waves to interact
264 with the seafloor. This scenario is less plausible for Ediacaran giant ooid occurrences, given that
265 two of the four occurrences likely postdate the Gaskiers glaciation (Table 1).

266 The results presented here illustrate that Neoproterozoic giant ooids must be reconciled
267 with at least one surprising finding. The T = 40°C scenario requires a hot, high pCO₂ climate not
268 long before the initiation of each Neoproterozoic glaciation and at moderate latitudes during
269 Ediacaran time. These conditions could be consistent with the persistence of post-Snowball
270 greenhouse climate and match the reported aragonitic mineralogy of many giant ooid
271 occurrences (Hood and Wallace, 2018), but are potentially problematic for giant ooids that
272 directly underlie glacially-deposited sediments or that occur in close stratigraphic association
273 with glendonite (James et al., 2005). The T = 0°C scenario requires an original primary
274 mineralogy that is currently considered geologically rare and suggests that low latitude seawater
275 was already cold prior to the onset of glacially-derived sediment deposition. Both scenarios

276 require seawater alkalinity >5 meq/L and infrequent sediment transport. Conditions with more
277 frequent sediment transport cannot produce giant ooids due to the rapid abrasion rates of large
278 particles (Figures S3, S4). Ikaite giant ooids are theoretically possible at lower bed shear
279 velocities and somewhat more frequent sediment transport than aragonite giant ooids (Figure 2,
280 Figure S4). Detailed sedimentological analyses of giant-oooid bearing units (e.g., bedform
281 dimensions, grain-boundary cements) could therefore enable more robust tests of these two
282 scenarios, combined with improved age constraints and a framework for identifying the
283 diagenetic products of finely-crystalline ikaite. The finding that giant ooid formation is most
284 plausible at extreme temperatures—in addition to requiring high alkalinity, strong currents
285 necessary to transport large particles, and infrequent sediment transport—may finally explain
286 why they are so uncommon in the rock record.

287 Acknowledgments, Samples, and Data

288 The author thanks Carl Simpson and Miquela Ingalls for helpful discussions; the author also
289 thanks reviewers Dawn Sumner and Ashleigh Hood for their insightful comments. Data
290 supporting the conclusions are provided in the figures, table, supplementary information, and
291 cited references. Matlab code used to calculate equilibrium ooid sizes is archived at:
292 <https://doi.org/10.5281/zenodo.3601507>

522 **Figure Captions**

523 **Figure 1.** Contour plots of equilibrium ooid size (mm) as a function of carbonate mineral
 524 saturation state (Ω) vs. bed shear velocity (u_*) for four scenarios: (a) aragonite giant ooids at $T =$
 525 25°C , (b) calcite giant ooids at $T = 25^\circ\text{C}$, (c) aragonite giant ooids at $T = 40^\circ\text{C}$, and (d) ikaite at
 526 0°C . Solid bold lines indicate combinations of Ω and u_* consistent with $D_{eq} = 10 \text{ mm}$; dashed
 527 bold lines indicate combinations of Ω and u_* consistent with $D_{eq} = 5 \text{ mm}$. The range in u_* in each
 528 plot is consistent with $P = 2.5$ for grain sizes ranging from 1-10 mm (Figure S1). Notably, D_{eq} is
 529 more sensitive to Ω than u_* in all cases, so an exact constraint on u_* is not necessary to estimate
 530 Ω .

531 **Figure 2.** Contour plots of Ω as a function of $\log_{10}(\text{pCO}_2)$ vs. ALK for each of the four scenarios
 532 with $\text{Ca:ALK} = 0.75$ or 5 and $\text{Mg:Ca} = 1$ or 5. The solid bold black lines indicate the Ω value
 533 necessary for $D_{eq} = 10 \text{ mm}$ and the dashed bold black lines indicate the Ω value necessary for D_{eq}
 534 = 5 mm. The white lines indicate contours of $\text{pH} = 7.5$ (dotted line), $\text{pH} = 8.2$ (solid line), $\text{pH} = 9$
 535 (dashed line), and $\text{pH} = 9.5$ (dash-dot line). $\text{pH} = 8.2$ is used as a benchmark following boron
 536 isotope constraints from Kasemann et al. (2010). Grey boxes illustrate most plausible conditions,
 537 as discussed in main text.

538

539 **Table 1.** Neoproterozoic giant ooid-bearing strata and their relationship with glacial deposits.

540

Giant-ooid-bearing unit	Grain diameters (mm) ^a	Overlying glacial unit and stratigraphic relationship	Paleolatitude range ^b	Reference(s)
Backlundtoppen Formation (Svalbard)	4-9 (maximum 14)	Elbobreen Formation, Petrovbrean Member (Sturtian), separated by ~300 m of carbonate-dominated stratigraphy	S 15-30°	Swett and Knoll (1989)
Beck Spring Dolomite (California, USA)	≤ 10	Kingston Peak Formation, Surprise Diamictite equivalent (Sturtian), separated by unit KP1 (fine-grained siliciclastic rocks interpreted as non-glacial based on	N 0-15°	Gutstadt (1968)

		lack of dropstones; 0-200 m thick—see Smith et al., 2016)		
Grainstone Formation, Little Dal Group (NW Canada)	2-10	Rapitan Group (Sturtian), separated by up to ~500 m of carbonate-dominated stratigraphy	N 0-15°	Batten et al. (2004)
Deoban Limestone (Lesser Himalaya, India)	≤ 6°	Blaini Group (Marinoan), not directly overlying	N 0-15°	Srivastava (2006)
Kataktuk Dolomite unit K1 (Alaska, USA)	> 4	Nularvik Cap Carbonate (Marinoan), directly overlying	S 0-15°	Macdonald, et al. (2009b)
Keele Formation (NW Canada)	≤ 5°	Ice Brook diamictite (Marinoan), separated by > 100m of siliciclastic rocks of the upper Keele Formation	S 0-15°	Day et al. (2004)
Kunihar Formation, Simla Group (Lesser Himalaya, India)	2-24°	Blaini Group (Marinoan), separated by ~1 km thick Sanjauli and Chhaosa Formations, fluvial siliciclastic rocks	N 0-15°	Thorie et al. (2018)
Tayshir Member, Tsagaan Oloom Formation (Mongolia)	> 5°	Khongoryn diamictite (Marinoan), directly overlying	N 0-15°	Macdonald, et al. (2009a)
Trezona Formation (Australia)	≤ 16	Elatina Formation (Marinoan), separated by an unconformity and, locally, siliciclastic rocks of the Yaltipena Formation	N 0-15°	Singh (1987)
Yankanninna Formation and Weetootla Dolomite (Australia)	≤ 10°	Elatina Formation (Marinoan), separated by ~100-200 m of the shale-dominated Amberoola Formation and Enorama Shale	N 0-15°	Fromhold and Wallace (2011)
Byng Formation, Upper Miette Group (Alberta, Canada)	≤ 4.5	Unconformably overlain by Cambrian McNaughton Formation (no clear stratigraphic relationship with Ediacaran	S 30-45°	Teitz and Mountjoy (1989)

		Gaskiers glaciation)		
Johnnie Formation, Rainstorm Member (California, USA)	3.5 (maximum (12) ^c)	Postdates Shuram C isotope excursion and Ediacaran Gaskiers glaciation (cf. Bergmann et al., 2011)	S 30-45°	Trower and Grotzinger (2010)
Kalancho Formation (Patom Basin, Siberia)	≤ 25	Zherba Formation (possibly correlated with Ediacaran Gaskiers glaciation based on C isotope work by Pelechaty, 1998)	S 15-30°	Petrov (2018)
Upper Wyman Formation and basal Reed Dolomite (California, USA)	≤ 5	Contemporaneous with Rainstorm Member?	S 30-45°	Zenger (1976)

541 ^aGrain size data from Sumner and Grotzinger (1993) except where otherwise noted. Some examples listed
 542 in a recent compilation of giant ooid deposits by Thorleifsson et al. (2018) with grain sizes not substantially > 2
 543 mm are not included because those are not giant ooids, by definition, and their relatively small grain sizes
 544 are not useful for differentiating between different scenarios (Figure 1).

545 ^bPaleolatitudes from compilation by Hoffman and Li (2009).

546 ^cGrain size data from reference listed in “Reference(s)” column.

547

548 **Table 2.** Parameters for different model scenarios.

549

	Fluid and mineral properties			Kinetic parameters			Source
	Salinity, S (ppt)	Sediment density, ρ_s (kg/m ³)	Fluid density, ρ_f (kg/m ³) ^a	Fluid kinematic viscosity, v_f (m ² /s) ^a	k (μmol/m ² /hr)	n	
Scenario 1: aragonite, 25°C	35	2800	1025	9.37×10^{-7}	12.88	2.26	Zhong and Mucci (1989)
Scenario 2: calcite, 25°C	35	2700	1025	9.37×10^{-7}	0.783	2.87	Zhong and Mucci (1989)
Scenario 3: aragonite, 40°C	35	2800	1018	6.95×10^{-7}	45.1	2.4	Burton and Walter (1987)
Scenario 4:	50	1800	1040	1.89×10^{-6}	117.5	1.23	Papadimitriou

Introduction

This document includes one supplementary text section (S1) with exemplar PHREEQC input and five supplementary figures (S1 - S2) that provide background for how the range of bed shear velocities was determined (S1), sensitivity of results to water depth (S2), comparison of abrasion rates to Atal and Lavé (2009) (S3), sensitivity of results to transport intermittency (S4), and models of aragonite and calcite giant ooids at 0°C (S5).

Text S1.

Example PHREEQC code for aragonite and calcite supersaturation at T = 25°C, 40°C:

```
DATABASE c:\phreeqc\database\PHREEQC.dat
TITLE Aragonite and calcite supersaturation
SOLUTION 1 Modern-like Neoproterozoic seawater
    units      mmol/kgw
    density   1.024
    temp     40
```

```

pressure    1      atm
Ca        10
Mg        50
Na        459
K         9.7
Cl         536
Si         0.1
Fe        0.00036
B          0.426
Mn        0.00018
P          0.0032
S(6)     27.6 as SO4
C(4)     2.3  as HCO3   CO2(g)      -4.5
Alkalinity 2
END

```

Example PHREEQC code for ikaite supersaturation at T = 0°C:

```

DATABASE c:\phreeqc\database\frezchem.dat
TITLE Ikaite supersaturation
SOLUTION 1 Cold Neoproterozoic seawater
units      mmol/kgw
density    1.05
temp       0
Ca         3
Mg        15
Na        900
K         20
Cl        1000
S(6)     60   as SO4
C(4)     2    as HCO3   CO2(g)      -3.5
Alkalinity 4
END

```

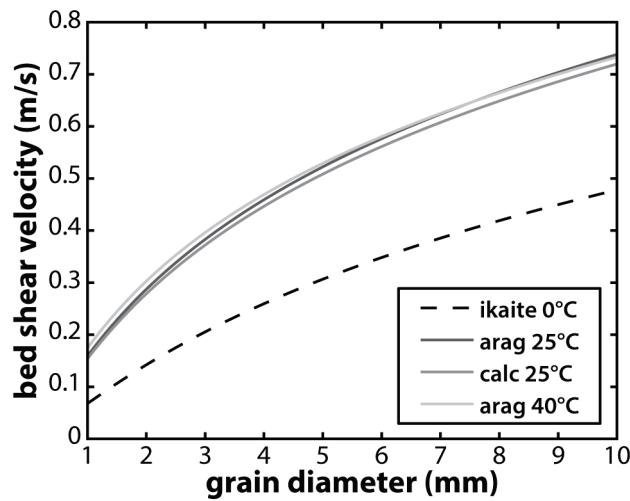

Figure S1. Bed shear velocity (u_s) as a function of grain diameter (D) for $P = 2.5$.

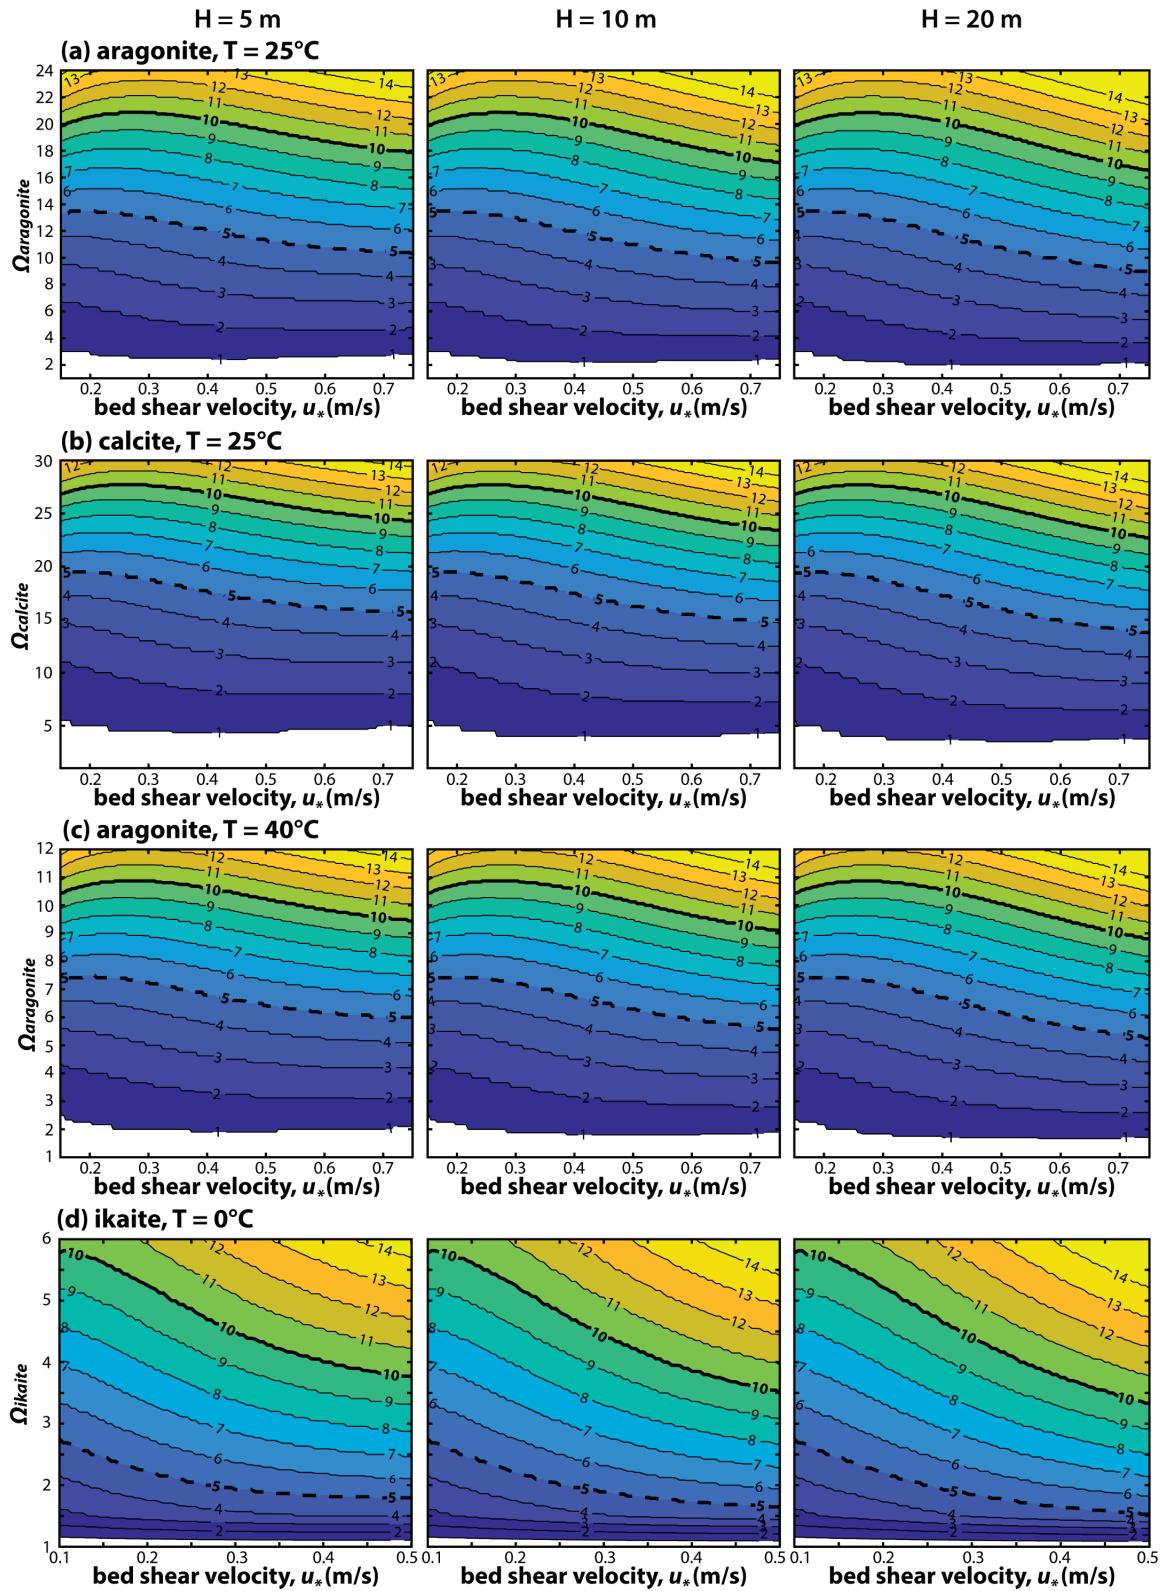

Figure S2. Contour plots of equilibrium ooid diameter (D_{eq}) as a function of carbonate mineral saturation state (Ω) and bed shear velocity (u_*) showing sensitivity to water depth (H) for each

of the four scenarios: (a) aragonite, $T = 25^\circ\text{C}$, (b) calcite, $T = 25^\circ\text{C}$, (c) aragonite at $T = 40^\circ\text{C}$, (d) ikaite at $T = 0^\circ\text{C}$. $H = 5\text{ m}$ (left column) was used for the models in the main manuscript; deeper water depths (middle column, $H = 10\text{ m}$; right column, $H = 20\text{ m}$) require slightly lower Ω values than $H = 5\text{ m}$. Solid bold lines indicate combinations of Ω and u^* consistent with $D_{eq} = 10\text{ mm}$; bold dashed lines indicate combinations of Ω and u^* consistent with $D_{eq} = 5\text{ mm}$.

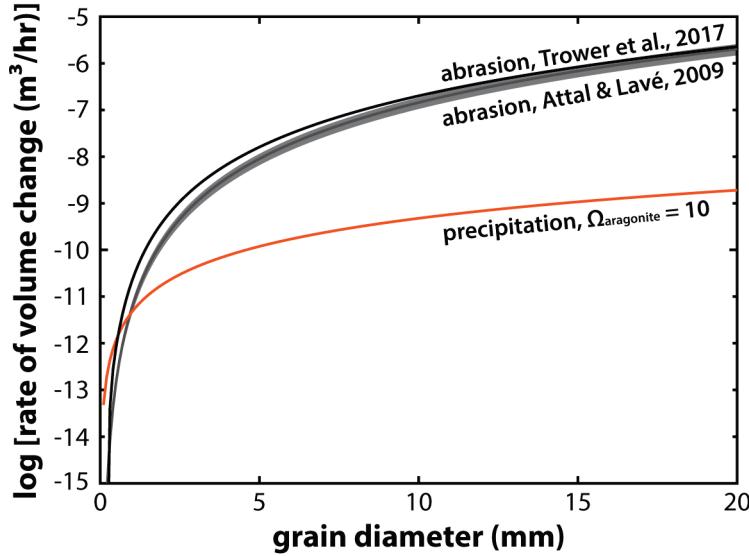

Figure S3. Comparison of abrasion rates estimated using the Trower et al. (2017) model (black line) vs. the Attal and Lavé (2009) model (grey line, with shaded grey area indicating standard deviation). The Trower et al. (2017) model predicts abrasion rates with similar magnitudes as the Attal and Lavé (2009) model. The model predictions diverge somewhat for grain diameters $<10\text{ mm}$, but the Attal and Lavé (2009) model was based on grain diameters $>10\text{ mm}$ and the Trower et al. (2017) model was based on sand-size grains. The Trower et al. (2017) model was based on a bedrock erosion model for both sand- and gravel-size sediment, so this process-based approach was deemed more appropriate for grain sizes $<10\text{ mm}$ than extrapolating the empirical model of Attal and Lavé (2009). Notably, both models predict abrasion rates 2-3 orders of magnitude greater than the rate of growth due to aragonite precipitation at $\Omega_{\text{aragonite}} = 10$, consistent with the requirement of very high saturation states to balance the rapid abrasion rates for giant ooids.

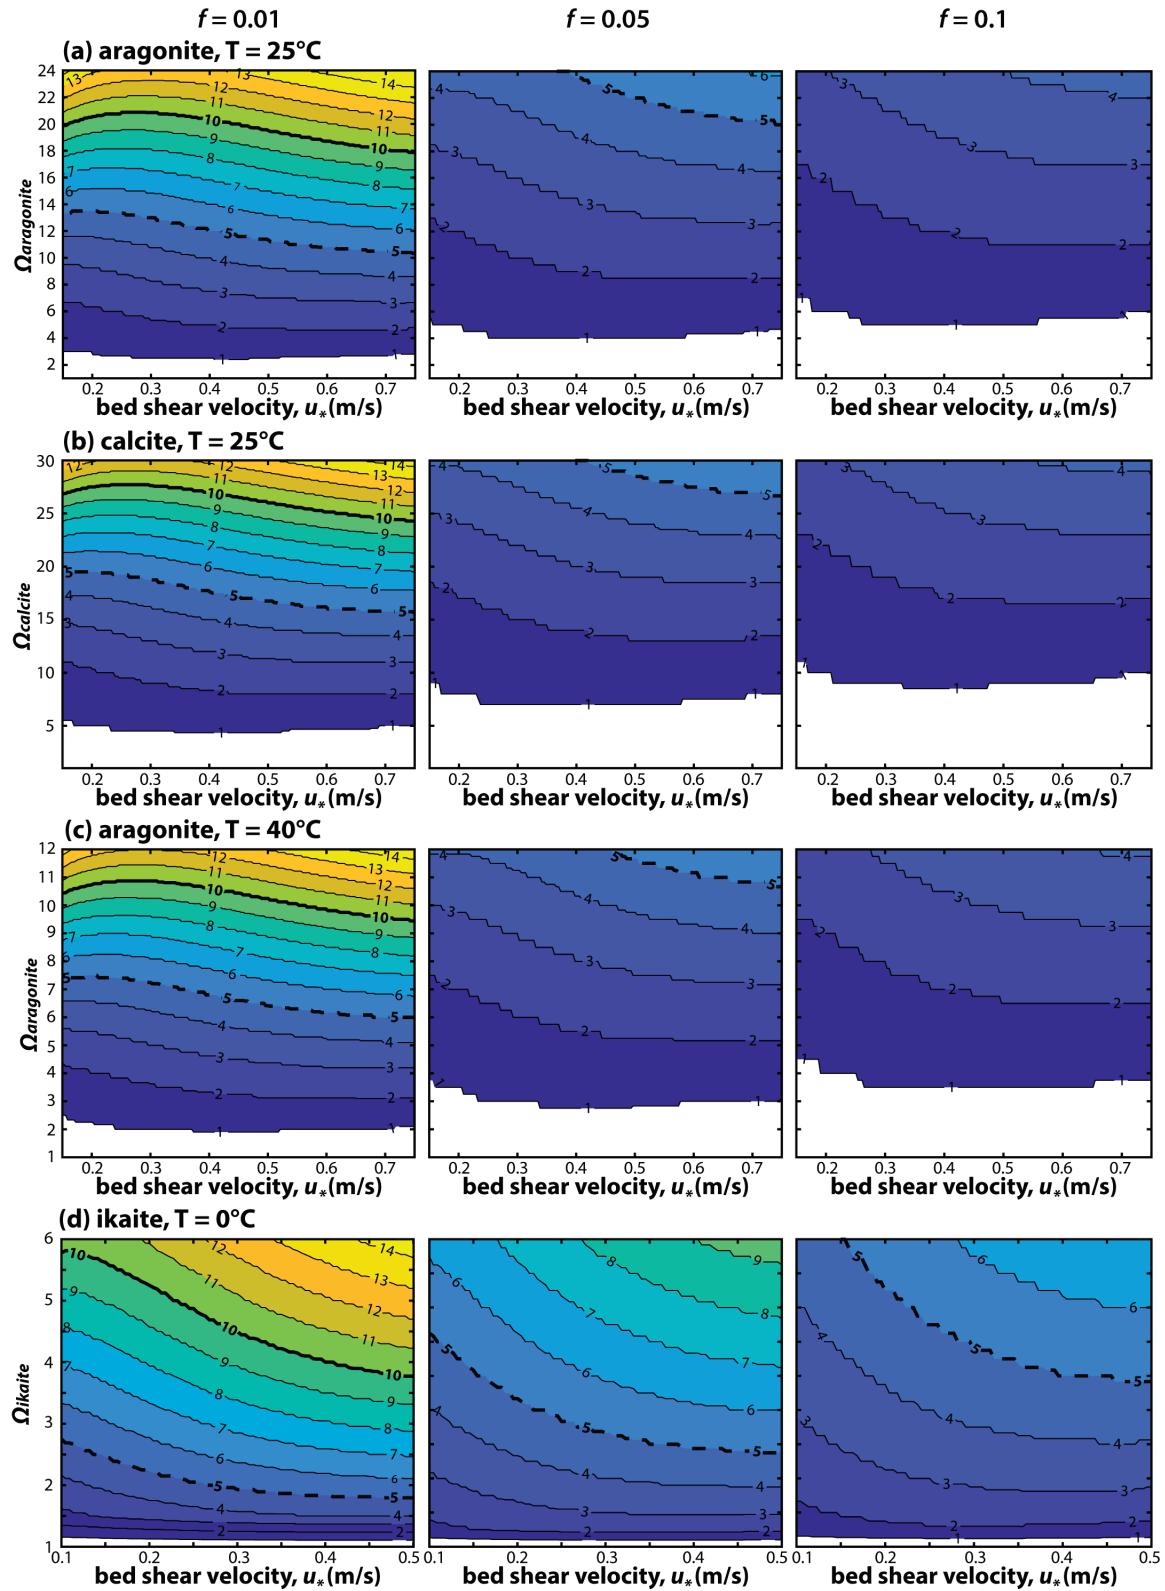

Figure S4. Contour plots of equilibrium ooid diameter (D_{eq}) as a function of carbonate mineral saturation state (Ω) and bed shear velocity (u_*) showing sensitivity to intermittency of

movement (f) for each of the four scenarios: (a) aragonite, $T = 25^\circ\text{C}$, (b) calcite, $T = 25^\circ\text{C}$, (c) aragonite at $T = 40^\circ\text{C}$, (d) ikaite at $T = 0^\circ\text{C}$. For larger values of f (more frequent transport), larger Ω values are required for any particular D_{eq} , indicating that the Ω values estimated for $f = 0.01$ are minimum values.

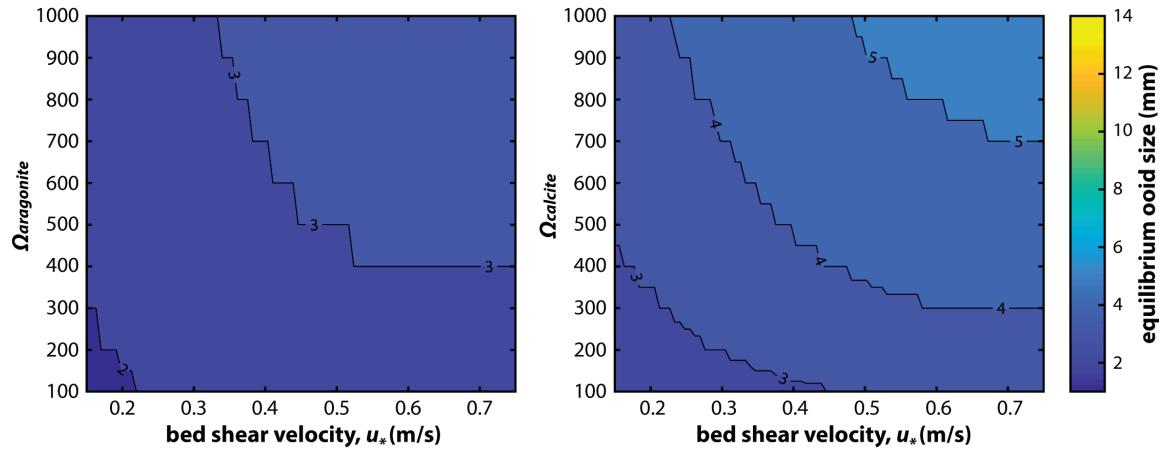

Figure S5. Contour plots of equilibrium ooid size (D_{eq}) as a function of bed shear velocity (u_*) and carbonate mineral saturation state (Ω) for aragonite and calcite at $T = 0^\circ\text{C}$. Even at exceedingly high supersaturations ($\Omega_{\text{aragonite}} = \Omega_{\text{calcite}} = 1000$), aragonite and calcite precipitation rates are not sufficiently rapid to outpace abrasion, so giant ooids with $D_{eq} = 10 \text{ mm}$ are not possible under these conditions.
