Abstract

Carbonyl sulfide (COS) was measured in firn air collected during seven different field campaigns carried out at four different sites in Greenland and Antarctica between 2001 and 2015. A Bayesian probabilistic statistical model is used to conduct multi-site inversions and to reconstruct separate atmospheric histories for Greenland and Antarctica. The firn air inversions cover most of the 20 century over Greenland and extend back to the 19 century over Antarctica. The derived atmospheric histories are consistent with independent surface air time-series data from the corresponding sites and the Antarctic ice core COS records during periods of overlap. Atmospheric COS levels began to increase over preindustrial levels starting in the 19 century and the increase continued for much of the 20 century. Atmospheric COS peaked at higher than present-day levels around 1975 CE over Greenland and around 1987 CE over Antarctica. An atmosphere/surface ocean box model is used to investigate the possible causes of observed variability. The results suggest that changes in the magnitude and location of anthropogenic sources have had a strong influence on the observed atmospheric COS variability.

17 **Abstract.** Carbonyl sulfide (COS) was measured in firn air collected during seven different field
18 campaigns carried out at four different sites in Greenland and Antarctica between 2001 and
19 2015. A Bayesian probabilistic statistical model is used to conduct multi-site inversions and to
20 reconstruct separate atmospheric histories for Greenland and Antarctica. The firn air inversions
21 cover most of the 20th century over Greenland and extend back to the 19th century over
22 Antarctica. The derived atmospheric histories are consistent with independent surface air time-
23 series data from the corresponding sites and the Antarctic ice core COS records during periods
24 of overlap. Atmospheric COS levels began to increase over preindustrial levels starting in the
25 19th century and the increase continued for much of the 20th century. Atmospheric COS peaked
26 at higher than present-day levels around 1975 CE over Greenland and around 1987 CE over
27 Antarctica. An atmosphere/surface ocean box model is used to investigate the possible causes
28 of observed variability. The results suggest that changes in the magnitude and location of
29 anthropogenic sources have had a strong influence on the observed atmospheric COS
30 variability.

31 **1 Introduction**

32 Carbonyl sulfide (COS) is the most abundant sulfur gas in the troposphere. The global
33 average mixing ratio of COS was 480-490 parts per trillion (ppt) during 2000-2006 CE [Montzka
34 et al., 2007]. The atmospheric lifetime of COS is estimated to be about 2 years [Berry et al.,
35 2010]. COS is a precursor of background sulfate aerosol in the stratosphere [Crutzen, 1976],
36 although there is some uncertainty regarding the importance of COS relative to volcanic and
37 anthropogenic SO₂ [e.g. Barkley et al., 2008; Brühl et al., 2012; Chin and Davis, 1995; Myhre et
38 al., 2004; Notholt et al., 2003; Solomon et al., 2011; Vernier et al., 2011]. A recent modeling
39 study suggests COS alone accounts for more than half of stratospheric aerosol during
40 volcanically quiet periods [Sheng et al., 2015], but the net climate-impact of COS may be small
41 because the cooling effect from COS-derived stratospheric aerosol is offset by radiative
42 greenhouse warming from tropospheric COS [Brühl et al., 2012].

43 Atmospheric COS is also of scientific interest because the primary removal mechanism
44 from the atmosphere is uptake by terrestrial vegetation [Goldan et al., 1988; Kesselmeier and
45 Merk, 1993; Kjellstrom 1998; Xu et al., 2002; Sandoval-Soto, 2005]. During photosynthesis,
46 terrestrial plants take up COS along with CO₂ because the carbonic anhydrase enzyme that
47 hydrolyzes CO₂ also efficiently hydrolyzes COS [Protoschill-Krebs and Kesselmeier, 1992;
48 Protoschill-Krebs et al., 1996; Asaf et al., 2013]. Unlike CO₂, COS is generally not produced
49 during plant respiration, although some exceptions have been identified [Gimeno et al., 2017;
50 Wohlfahrt et al., 2017]. Photosynthetic uptake dominates the seasonal variability of
51 atmospheric COS in the northern hemisphere, resulting in a late boreal summer minimum at
52 most NH sites [Montzka et al., 2007]. It is commonly assumed that the removal of atmospheric
53 COS covaries with the globally integrated gross primary productivity (GPP) of land plants
54 [Montzka et al., 2007; Whelan et al., 2018].

55 Direct and indirect emissions from the world ocean constitute the largest source of
56 atmospheric COS [Chin and Davis, 1993; Kettle et al., 2001 and 2002; Ulshofer et al., 1998;
57 Watts, 2000]. In the surface ocean, sulfur-containing organic compounds are photochemically
58 broken down to produce COS and CS₂, which are emitted to the atmosphere via air/sea gas

59 transfer. In the atmosphere, CS₂ is photochemically oxidized with a lifetime of several days and
60 a COS yield of about 50%. Dimethylsulfide (DMS) is another indirect oceanic COS source. It is
61 biologically produced in the surface ocean in large amounts and is the dominant flux of reduced
62 sulfur to the atmosphere [Lana et al., 2011]. Laboratory experiments have identified a small
63 yield of COS (~1%) from gas phase photooxidation of DMS [Arsene et al., 2001]. Because of the
64 very large DMS flux, this source is a significant term in the COS budget.

65 Anthropogenic sulfur gas emissions (CS₂ and COS) from the synthetic fiber, aluminum,
66 and coal industries are thought to be the second most important COS source in the present-day
67 atmosphere [Campbell et al., 2015; Sturges et al., 2001]. Biomass burning is another significant
68 atmospheric COS source, with possible minor emissions from anoxic soils, wetlands, and
69 volcanoes [Berry et al., 2013; Kettle et al., 2002; Suntharalingham et al. 2008; Watts, 2000]. The
70 ocean sources dominate the seasonal variability of COS in the southern hemisphere, resulting in
71 an austral summer maximum in the high latitude SH [Montzka et al., 2007].

72 The first reported measurements of COS in firn air are from one Arctic (Devon Island,
73 Canada) and two Antarctic (Dronning Maud Land and Dome Concordia) sites and imply a
74 decline in anthropogenic COS emissions during the late 20th century [Sturges et al., 2001]. A firn
75 air study from the South Pole revealed a sharp COS increase of up to 200 ppt during the early to
76 mid 20th century, followed by a relatively modest decline during the 1990s [Montzka et al.,
77 2004]. These trends have primarily been attributed to changes in anthropogenic emissions.
78 Campbell et al. [2017] reanalyzed the same trends using updated estimates of sources and sinks
79 and inferred a large growth in terrestrial GPP during the 20th century attributed to the fertilizing
80 effect of increasing atmospheric CO₂ concentrations.

81 In this study, we analyze new COS measurements from 6 firn air sampling campaigns
82 along with the previously published measurements from the South Pole 2001 campaign. Three
83 of the new data sets are from Greenland: two from campaigns at Summit conducted in May
84 2006 and June 2013 and one from a Renland campaign carried out in 2015. The other three are
85 from Antarctica conducted at the South Pole in Dec 2008/Jan 2009 and in Dec 2015, and at
86 Mega Dunes in January 2004. We use established firn air models [Aydin et al., 2011; Buizert et
87 al., 2012] to characterize the age of COS in firn air at each of these sites and perform Bayesian
88 inversions to recover one southern and one northern hemisphere atmospheric history
89 consistent with all firn air COS measurements from Antarctica and Greenland. The inversions
90 are conducted with the Stan probabilistic programming language, which uses a fast Hamiltonian
91 Markov Chain Monte Carlo (MCMC) sampling algorithm [Carpenter et al., 2017]. Antarctic ice
92 core measurements are incorporated in the Antarctic inversions. A coupled
93 atmosphere/surface ocean box model is used to explore the possible causes of the long-term
94 trends in the atmospheric COS records. Implications for the atmospheric COS budget are
95 discussed.

96 **2 Firn air sampling and measurements**

97 Greenland firn was sampled during two different campaigns to Summit in May 2006
98 (SUM06) and in June 2013 (SUM13), and another one to Renland in May 2015 (REN15).
99 Antarctic firn was sampled during three different campaigns to South Pole in Dec-Jan 2001-

100 2002 (SPO01), in Dec-Jan 2008-2009 (SPO08), and in Dec 2015 (SPO15), and another campaign
101 to Megadunes in January 2004 (MD03). The firn air trace gas sampling techniques used in these
102 studies have been described previously [Hmiel et al., 2020; Muhle et al., 2019; Aydin et al.,
103 2011; Montzka et al., 2004]. The firn holes are dry-drilled using either a 3" or a 4" electro-
104 mechanical drill. Once the desired sampling depth is reached, a 4 m-long bladder (natural
105 rubber) is lowered into the hole and inflated in place to seal the bottom ~20 cm of the hole
106 from the overlying atmosphere. There are three lines running from the surface to the bladder.
107 One connects directly to the bladder and is used for inflating it with borehole air. The other two
108 are the waste and sampling lines, which run through the bladder and come out the other end.
109 The waste line is larger in diameter than the sample line (3/8" vs. 1/4") to accommodate higher
110 flow rates. At the bottom of the firn hole, the waste line inlet sits about ~10 cm higher than the
111 sample inlet, with the two inlets separated by an aluminum baffle. A high-flow carbon vane
112 pump is used to draw firn air through the waste line. The sample air is drawn by a metal-
113 bellows pump at lower flow rates to ensure cleanliness.

114 Firn air samples used in COS analysis were collected in 2 L glass flasks with dual glass
115 valves that seal via Teflon o-rings, except for 8 replicate NOAA samples from SUM06 that were
116 collected in stainless steel flasks equipped with dual all-metal bellows valves. The two-valve
117 setup enables flushing of the flasks with firn air before collecting the samples. COS samples are
118 from a single firn hole, except SPO08 where samples are from two holes drilled about 30 m
119 apart. The SPO01, SPO08, and MD03 measurements were conducted at NOAA-GML by the
120 HATS group (www.esrl.noaa.gov/gmd/hats/). The SUM13 and REN15 measurements were
121 conducted at the University of California, Irvine (UCI). The SUM06 and SPO15 measurements
122 were conducted at both UCI and NOAA-GML (Table 1).

123 At NOAA-GML, COS is routinely measured in glass and stainless-steel surface-air flasks
124 collected in pairs for the HATS group as part of their global flask network. Analysis is performed
125 by cryofocusing a barometrically-measured volume of dried air onto an uncoated fused silica
126 tube followed by heating-facilitated transfer of trapped gases onto a gas chromatograph with a
127 mass spectrometer detector. COS was detected at ion $m/z = 60^+$. The NOAA-GML
128 measurements are referenced to the NOAA-GML calibration scale that was originally developed
129 in 2004. For more details see Montzka et al. [2004 and 2007] and the readme files and updated
130 measurement record at: ftp://ftp.cmdl.noaa.gov/hats/carbonyl_sulfide/.

131 At UCI, the firn air samples were analyzed using the same analytical system previously
132 described for ice core air measurements [Aydin et al., 2007; 2008; 2014, and 2016]. COS is
133 preconcentrated on a glass bead trap (glass beads packed inside an 1/8" stainless steel tube)
134 under vacuum at -196°C. The amount of dry bulk air that has been sampled is determined by a
135 pressure measurement in a temperature-controlled volume located downstream of the trap.
136 The trapped gases are thermally injected into an HP 5890 GC fitted with a DB-1 capillary column
137 (0.25 mm ID, 60 m). The GC is programmed to run through multiple isothermal and
138 temperature ramp-up steps starting at -50°C and ending at 150°C. The GC runs in tandem with
139 a dual focusing magnetic sector mass spectrometer (Waters – Autospec) running at a minimum
140 mass resolution of 8000 ($m/\Delta m$) in EI+ mode.

141 The UCI measurements are based on detection of the parent COS ion at $m/z=59.967^+$
142 ($^{12}\text{C}^{16}\text{O}^{32}\text{S}$). A known amount of ^{13}C labeled COS ($^{13}\text{C}^{16}\text{O}^{32}\text{S}$; $m/z=60.970^+$) is mixed into every
143 sample during the preconcentration step as an internal standard and used for quantification of
144 the COS in the sample. The isotope-labeled internal standard is calibrated by ppt-level working
145 standards prepared from multiple high concentration (200-300 ppb) primary standards
146 prepared at UCI in 6 L pacified-aluminum tanks (Aculife – Scott Gas). All COS measurements are
147 reported as dry-air mixing ratios and analytical precision is estimated to be $\pm 1\text{-}2\%$ (1σ).

148 **3 Firn air data**

149 The firn at Summit is about 80 m deep and the full depth was sampled during both the
150 SUM06 and SUM13 campaigns. The SUM06 data include measurements conducted at both UCI
151 and NOAA for 16 sampling depths (Fig. 1). The SUM13 samples were analyzed only at UCI, using
152 two different sets of flasks (UCI and NOAA-CCG). SUM13 measurements from a few depths (3
153 out of 18) were contaminated for multiple trace gases and are not included in the analysis
154 [Hmiel et al., 2020]. Renland firn is about 10 m shallower than Summit and frequent surface
155 melting results in the presence of ice lenses throughout the firn column. Two firn holes were
156 sampled during REN15, but the measurements from the first hole were contaminated. Data
157 from 11 out of the 12 sampling depths from the second firn hole are used in our analysis. The
158 deepest Renland sample is not included in the analysis because we have not been able to
159 successfully model the firn air gas age at this depth due to apparent discrepancies between the
160 CH_4 , CO_2 , and SF_6 measurements.

161 The air in the top 30-40 m of the firn is influenced by seasonal variability in the overlying
162 atmosphere. From 40 m to 65 m, both the SUM06 and SUM13 firn air COS measurements
163 remain at or below 500 ppt (Fig. 1). Below 65 m, the COS mixing ratio increases by
164 approximately 10% before leveling off then slightly declining towards the bottom. This basic
165 pattern is present in all firn air COS profiles from Summit. At Renland, a downhole COS increase
166 is also evident from about 50 m to 70 m with peak COS levels of about 580 ppt; the basal firn air
167 is younger at Renland than it is at Summit. The firn air COS measurements from all Greenland
168 campaigns point to a period of higher COS in the atmosphere sometime in the recent past.

169 At the South Pole (SPO), the firn column is close to 120 m thick, with the top 30-40 m
170 under the influence of seasonal variability in surface air and the bubble close-off starting below
171 100 m (Fig. 2). For all SPO campaigns, COS is 500-550 ppt range with no discernable trend down
172 to about 110 m, with a small offset apparent between the SPO15 data from the NOAA and UCI
173 laboratories. Deeper in the SPO firn, there is a steep decline evident in both the SPO01 and
174 SPO08 data, with COS at or below 400 ppt at the bottom of the firn. At Megadunes, the firn is
175 less than 70 m thick and the bubble close-off zone is confined to below 63 m. The deepest
176 MD03 sample from 67 m measures 372 ppt, which is the lowest COS mixing ratio measured in
177 firn air from any site. It is well established that the basal firn at the South Pole and the
178 Megadunes sites contains older firn air than the Greenland sites [e.g. Battle et al., 1996;
179 Severinghaus et al., 2010]. The Antarctic firn air measurements indicate that atmospheric COS
180 levels were much lower than present-day sometime in the in the beginning of the 20th century

181 or earlier. A precise determination of the timing and the magnitude of atmospheric COS
182 variability based on the firn records requires conducting formal inversions.

183 **4 Ice core data**

184 Previously published ice core COS data sets from Antarctica include measurements from
185 6 different ice cores from the Siple Dome, West Antarctic Ice Sheet Divide, and the South Pole
186 sites in Antarctica (Fig. 3). In Fig. 3, we also present new, previously unpublished measurements
187 from the SPC14 ice core recently drilled at the South Pole as part of the SPICEcore project. All of
188 the ice core COS measurements were made at UCI following published methods and are based
189 on the UCI calibration scale [Aydin et al., 2008; 2014]. Temporally overlapping data from
190 different sites agree within uncertainties. The mean of all the Antarctic data is 347 ± 26 ppt
191 ($\pm 1\sigma$). Ice core COS levels are relatively higher and display more variability prior to 1690 CE.
192 During the period that follows, COS remains in the 320-350 ppt range until 1875 CE, after which
193 there is a gradual rise to about 400 ppt by the middle of the 20th century.

194 The only ice core COS data set from the northern hemisphere is from a small pilot study,
195 consisting of 25 measurements combined from the GISP2B and GISP2D ice cores drilled at
196 Summit, Greenland [Aydin et al., 2007]. The data cover the period from 1681 CE to 1868 CE,
197 averaging 325 ± 23 ppt ($\pm 1\sigma$) (Fig. 3). The overlapping subset of the Antarctic data from 1690 CE
198 to 1875 CE averages 334 ± 14 ppt ($\pm 1\sigma$). The mean analytical error is estimated to be 12 ± 6 ppt
199 ($\pm 1\sigma$) for the Antarctic measurements and 21 ± 4 ppt ($\pm 1\sigma$) for the Greenland measurements.
200 The limited temporal extent and the larger errors associated with the Greenland ice core data
201 limits our ability to determine an inter-polar difference.

202 **5 Firn modeling and firn air age distribution functions**

203 The aging of firn gases is closely linked to the rate of firn densification and it increases
204 non-linearly with depth. At shallower depths where the ice density is lower than a critical limit
205 ($\sim 800 \text{ kg m}^{-3}$), all porosity in the firn is open (i.e. interconnected). This allows the firn air to mix
206 with the overlying atmosphere at relatively fast rates via molecular diffusion, limiting the aging
207 of gases. At densities higher than 800 kg m^{-3} , open porosity declines and tortuosity increases
208 rapidly with depth, leading to a quick decline in gas diffusion rates, a fast increase in the gas
209 ages, and a broadening of the age-distribution. Firn air transport models are used to determine
210 the aging of gases with depth in the firn. These models commonly include a 1-dimensional
211 parameterization of vertical advection and diffusivity as the primary physical processes that
212 control the degree of smoothing in the firn [Battle et al., 2011].

213 In this study, two 1-D firn air models were used: one developed at UCI and the other at
214 CIC Copenhagen [Aydin et al., 2011; Buizert et al., 2012 and 2016]. The UCI firn air model was
215 used for SPO01, SPO08, and MD03 and has fixed snow accumulation rate and vertically variable
216 diffusion. The vertical diffusivity structure is determined empirically by running the model to
217 simulate CO_2 and CFC-12 measured in the firn samples using the known atmospheric histories
218 of these gases. The result of the simulation is compared with the measured CO_2 and CFC-12 firn
219 profiles. The diffusivity parameterization is iteratively adjusted to improve the agreement

220 between simulated and measured firn trace gas profiles. For the MD03 site, the diffusivity
221 tuning of Severinghaus et al. [2010] was used.

222 The CIC Copenhagen firn air model was used to model SUM06, SUM13, REN15, and
223 SPO15. The CIC model uses a steady-state assumption, isothermal firn, downward advection
224 controlled by the firn porosity, and vertically variable diffusion and dispersion tuned via an
225 automated routine to a suite of several trace gases whose concentrations were measured in the
226 firn air samples and for which the atmospheric history is well known. The model uses the
227 porosity parameterization by Mitchell et al. [2015].

228 The vertical diffusivity profiles for both models are adapted to COS using the ratio of the
229 COS molecular diffusivities to the diffusivities of the tune gases. Molecular diffusivities are
230 calculated from empirical relationships [Fuller et al., 1966; Wilke and Lee, 1955]. The models
231 generate firn air age distribution functions that characterize the fractional atmospheric
232 contribution from each year in a range of years to the trace gas composition at a given depth in
233 the firn (Fig. 4). These age distribution functions are used in the inversions (described in
234 section-6) to infer COS atmospheric histories from the firn air measurements. The repeat
235 campaigns at the same site are treated as individual sites; for example, SUM06 and SUM13 are
236 tuned individually to the atmospheric tracers and have different diffusivity profiles.

237 **6 Bayesian inversion framework and results**

238 A hierarchical Bayesian approach is used to analyze the firn air COS data using the Stan
239 probabilistic software package (mc-stan.org), in which all parameters are interpreted
240 probabilistically and updated using Bayes' theorem according to how consistent the parameters
241 are with the data [Carpenter et al., 2017]. The atmospheric mixing ratio (X , ppt) is modeled as
242 an autocorrelated random process:

243

$$244 \quad X_t \sim N(X_{t-1}, \alpha X_{t-1}) \quad (1)$$

245

246 where the probability distribution of X at time step t (X_t) is normally distributed (N) around the
247 mean of X at time step $t-1$ (X_{t-1}) with one standard deviation of αX_{t-1} . The α parameter
248 quantifies how much the atmospheric mixing ratio of COS can change from one year to the
249 next, parameterized as a fraction of the previous year's atmospheric mixing ratio. X_t in (1) is
250 evaluated separately for the atmosphere above Antarctica and Greenland.

251 The measured mixing ratio (M_{mes}) in the firn at a given depth (z) is linked to X by:

252

$$253 \quad M_{mes}(z) \sim N(\gamma f_{AgeD}(z)X, \beta \sigma_M(z)) \quad (2)$$

254

255 where the *gamma* (γ) is a constant parameter that accounts for possible offsets between data
256 sets from different sites that may result from calibration differences or other factors, $f_{AgeD}(z)$ is
257 the firn air age distribution function from the firn model specific to every sampling depth at

258 each site, $\sigma_M(z)$ is the measurement error, and β is a constant scalar parameter for the
259 measurement error. All terms in (2) other than X are site specific and treated separately at
260 each individual site. We use one X (X_{GRN}) in all Greenland inversions and another one (X_{ANT}) for
261 all Antarctic inversions, recovering two independent atmospheric histories. All inversions are
262 conducted with the Stan shell interface (CmdStan) version 2.21.0.

263 The uncertainty estimates for the measurements are based on reproducibility defined as
264 the standard deviation of measurements from the same depth. The reproducibility can be
265 estimated from repeated measurements of the same flask or from measurements of different
266 flasks filled at the same depth, provided there are multiple flasks from the same depth. For all
267 the firn campaigns, the number of replicate data from a given depth is often limited to two
268 (same flask measured twice or two flasks from the same depth each measured once), which is
269 not sufficient for a good estimate of the standard deviation. When all the error estimates for all
270 depths are evaluated together, we find that the standard deviation of replicate measurements
271 and replicate flasks are the same, except in rare cases where replicate flasks display larger than
272 average standard deviation. We exclude such depths as outliers and calculate an average
273 standard deviation for all depths except the outliers. Outlier depths are also included in the
274 analysis, but with a larger average uncertainty based on the replicate data from outlier depths
275 (Figs 1 and 2). One of the reasons why a β parameter is included in (2) is to compensate for the
276 possibility that the calculated average standard deviation may underestimate the true
277 measurement error arising from uncertainties in the sampling and analysis of firn air.

278 The inversion model does not explicitly address the potential uncertainty arising from
279 the dimensionless $f_{AgeD}(z)$ term specific to each site. When simultaneously inverting firn data
280 from multiple sites, site specific errors in the $f_{AgeD}(z)$ should not result in coherent features in
281 the posterior probability distributions of X . However, systematic errors in $f_{AgeD}(z)$ that applies to
282 all Greenland and Antarctic sites can result in features in the posterior distributions that are not
283 real. The β parameter in (2) can also account for errors resulting from f_{AgeD} . If the firn air
284 measurements from different sites are perfectly consistent with the model described by (1) and
285 (2) within the estimated measurement uncertainties, the posterior for β should approximate to
286 1; otherwise, $\sigma_M(z)$ does not specify the absolute uncertainty.

287 The number of elements of X is equal to the total number of years included in the
288 inversion, which is 109 y for the Greenland inversion (from 1907 CE to 2015 CE) and 337 y for
289 the Antarctic inversion (from 1679 CE to 2015 CE). This total number of years is larger than the
290 number of years constrained by firn air at any of the individual firn sites (periods covered by
291 f_{AgeD} shown in Table 1) because we use data from multiple firn campaigns carried out in
292 different years.

293 In (2), data from each firn campaign constrain a different segment of the atmospheric
294 history, but often with considerable overlap. For example, the SUM06 and SUM13 campaigns
295 constrain the Greenland atmospheric history (X_{GRL}) counting 100 years back from 2006 CE and
296 2013 CE, respectively, while REN15 data constrain X_{GRL} counting 70 years back from 2015 CE.
297 This ensures that in the vector multiplication $f_{AgeD}(z)$ times X , both factors have the same
298 number of elements.

299 **7 Monte Carlo sampling and results**

300 Stan uses fast Hamiltonian MCMC sampling [Carpenter et al., 2017] to draw samples
301 from the joint posterior probability for X and all the other parameters in (1) and (2) that are
302 conditioned on the measured firn air mixing ratios and the estimated measurement
303 uncertainties. Parameters are drawn from uniform prior distributions, which can have
304 prescribed upper and lower bounds, and evaluated for their consistency with the observations
305 via the likelihood function (2). The algorithm iteratively samples the parameters with a
306 frequency proportional to the posterior parameter probability. 5000 iterations are conducted
307 using 4 different chains for both the Antarctic and the Greenland inversions. Each chain
308 initializes the search from a different set of randomly drawn parameters. The posterior results
309 include 20,000 iterations total from 4 different chains.

310 The inversions are conducted with lower and upper prior bounds of 10 – 1500 ppt for X .
311 The α and β parameters are positive by definition, with search ranges from 0 to 0.5 and 0 to 5,
312 respectively. X , α , and β draws do not exceed or reach the set bounds of the search, indicating
313 we are not restricting the search by these bounds. The dimensionless site-specific γ parameters
314 are constrained to a $\pm 2\%$ (0.98 to 1.02) range, allowing up to 4% offset between different data
315 sets because we estimate the temporal consistency of the calibration scales to be 3-4% or
316 better. It is possible that the annual mean atmospheric mixing ratio of COS over Renland is
317 somewhat different than it is over Summit because of the elevation difference between the
318 sites, but we do not prescribe a broader prior on the Renland γ parameter. Over Antarctica, any
319 difference in the true atmospheric abundance of COS between SPO and MD is likely small,
320 considering both are East Antarctic sites at similar elevations with no local sources and sinks.
321 The sensitivity of the results to different ranges of γ has been tested. Smaller γ ranges result in
322 larger variability in the inferred atmospheric histories with larger uncertainty estimates; ranges
323 larger than $\pm 2\%$ do not result in smoother atmospheric histories nor do they significantly
324 change the estimated uncertainties (supplemental section-2).

325 **7.1 Antarctic inversions**

326 The Antarctic inversion extends back to 1679 CE due to the long-tailed air age
327 distribution function at the bottom of the Megadunes firn. However, the one MD03 data point
328 from the bottom does not sufficiently constrain the oldest 150-200 years of the Antarctic
329 atmospheric history. Instead, we use the Antarctic ice core measurements from the 1679 –
330 1860 CE period (Fig. 3) to describe the prior distributions using:

331

$$332 \quad X_{1679-1860\text{ CE}}^{ANT} \sim N(334 \text{ ppt}, 14 \text{ ppt}) \quad (3)$$

333

334 given that the mean and 1 stdev of the ice core data from this period are 334 ppt and 14 ppt.
335 We do not use the ice core data after 1860 CE as a prior because the data display a temporal
336 trend and the temporal resolution is low (Fig. 3). Surface air data are not used to constrain the
337 inversions either.

338 Prior to 1860 CE, the posterior results for the Antarctic atmospheric history of COS (X_{ANT})
339 remain within the mean and standard deviation prescribed by (3), resulting in tightest data
340 densities in posterior atmospheric histories for the whole inversion period (Fig. 5). The pre-
341 1860 CE results demonstrate that the ice core data from the 1679-1860 CE period are
342 consistent with the deepest data from MD03 (Fig. 2). After 1860 CE, the posterior distributions
343 at each year widen, reflecting weaker constraints on the inversion from the oldest fir air data.
344 The posterior distributions gradually narrow towards the present day due to the increase in firn
345 air data and narrowing of the age distributions. The regions of densest data and the median of
346 the post-1860 CE posterior distributions are generally consistent with contemporaneous
347 Antarctic ice core data which have not been included in the inversion, providing further
348 evidence that Antarctic firn air and ice core COS measurements are consistent (Fig. 5).

349 SPO01 firn data have previously been used in a single site inversion and the two firn-
350 only (not constrained by surface flask measurements) atmospheric histories from Montzka et
351 al. [2004] fall within the 0.025-0.975 quantile (95% confidence) band of the results from the
352 current multi-site inversion (Fig. 5). The SPO01 firn-only atmospheric histories were based on
353 an inversion with a different firn model output than what has been used here and were
354 reported without formal uncertainty estimates. The ambient air results from both UCI and
355 NOAA also fall within the 95% confidence band of our analysis; this is notable given that the
356 inversion is not forced to agree with either the instrumental record or the surface samples
357 collected during the firn campaigns. However, the earlier part of the flask record from the
358 1990s through the early 2000s do not overlap with the highest likelihood (higher data density)
359 region of the posterior results, suggesting a possible discrepancy during this period.

360 The predominant feature of the Antarctic firn inversions is a rise in COS that starts in the
361 19th century and continues through most of the 20th century (Fig. 5). The averaging of 20,000
362 individual posterior simulations smooths out the high frequency variability that is present in all
363 individual simulations. Some low frequency variability is retained as evidenced by two plateaus
364 during the ramp-up period: one from 1890 CE through 1920 CE and the other from 1955 CE
365 through 1965 CE. The steepest COS rise in the record occurs after 1970 CE, culminating in a
366 maximum in the mid 1980s, followed by a period of decline punctuated by a minimum near
367 2010 CE. The 95% confidence band for the analysis is large early in the 20th century and
368 decreases after 1960 CE until the last few years when it broadens again.

369 The marginal posterior distributions for the parameters (α , β , and γ) are shown in Fig.
370 6. The α parameter has a skewed distribution with a mean of 0.032 and a median of 0.029,
371 meaning the year-to-year change in the inferred atmospheric mixing ratio of COS averages 3%.
372 The β parameter is more symmetrically distributed with a mean and a median of 1.49 and 1.48,
373 indicating the 1σ uncertainty estimates for the data were scaled up by about 50% during the
374 inversion. Most of the site-specific γ parameters display truncated distributions; the sensitivity
375 of results to broader priors on gamma has been tested and found not to impact the results
376 (supplement section-2). Nearly all the γ draws for the SPO01 and SPO08 campaigns are higher
377 than 1, indicating these data are positively biased with respect to the posterior atmospheric
378 history. In contrast, nearly all the draws for the SPO15 UCI data are lower than 1. The γ
379 distributions for the SPO15 NOAA and MD03 data are more evenly distributed across the

380 prescribed $\pm 2\%$ range and display only very small ($<1\%$) negative biases from the posterior
381 atmospheric histories (Fig. 6).

382 Two plausible causes of offsets between different data sets are calibration offsets
383 between the NOAA and UCI labs and changes in calibration scales over time within both
384 laboratories. It is unlikely production or loss processes in the firn are significant contributing
385 factors because the differences between γ parameters are largest between the different
386 campaigns conducted at the same site and such processes are not expected to introduce a
387 constant bias to the entire data set. Contamination during sampling and chemical production or
388 loss in the flasks can result in apparent offsets between data sets, but the nature of the
389 contamination or the chemical processes has to be such that approximately the same amount
390 of COS must be introduced to or removed from all the flasks from the same campaign.

391 The inclusion of the γ parameters allows the inversion to converge to a posterior
392 distribution that is less likely to include artifacts resulting from potential biases between the
393 firn data from different campaigns. However, this does not preclude the possibility that the
394 posterior distribution itself is biased with respect to the real atmosphere. Based on our analysis,
395 the largest bias is between the NOAA SPO01 and the UCI SPO15 data sets (Fig. 6). With 89% of
396 the SPO01 γ posteriors higher than 1.01 and 91% of the UCI SPO15 γ posteriors lower than 0.99,
397 there is at least a 2% offset between the data sets from these two campaigns. Note that we
398 cannot determine an upper limit for this offset; however, the upper limit of potential biases
399 between the data sets is rather inconsequential for the posterior distribution of the
400 atmospheric history as it only slightly augments the uncertainty bounds (see supplement
401 section-2).

402 **7.2 Greenland inversions**

403 The Greenland inversions are conducted for the period from 1907 CE to 2015 CE. There
404 are no Greenland ice core measurements that can be used to constrain the Greenland
405 inversion. The COS atmospheric history in 1907 CE is prescribed a uniform prior distribution
406 ranging from 200 and 1000 ppt. The rest of the Greenland atmospheric history (X_{GRN}) are from
407 the joint posterior distribution defined by equations (1) and (2) using the same priors on α , β ,
408 and γ as the ones used in the Antarctic inversions.

409 Prior to 1940 CE, the posterior range of atmospheric COS is very large and not well-
410 constrained as evidenced by very low data density at the peak of the histograms and a broad
411 95% confidence band around the median (Fig. 7). After 1940 CE, the 95% confidence band
412 narrows and the posterior density is increasingly concentrated around the median, indicating a
413 better constrained inversion. There is a prominent peak in COS mixing ratio that is centered in
414 the mid 1970s CE. The magnitude and timing of this peak is constrained by data from all three
415 Greenland campaigns (Fig. 1). After the peak, COS declines by roughly 100 ppt. This decline
416 continues through the 1990s CE, reaching a minimum in 2003 CE.

417 All annually-averaged NOAA surface flask network data from Summit fall within the 95%
418 confidence band even though the surface flask data are not used to constrain the inversion (Fig.
419 7). However, there seems to be a small bias between the firn air reconstruction and the surface

420 flask network data, with most of the flask data lying below the posterior median. The small late
421 peak in the reconstructed atmospheric history after 2010 CE is not evident in the NOAA flask
422 record. To our knowledge, there is no other published formal COS firn inversion from a
423 northern hemisphere site. The COS data from the Devon Island firn display evidence for a
424 decline in atmospheric COS during the late 20th century [Sturges et al., 2001], which is
425 consistent with the results of our analysis.

426 The marginal posterior probability distributions for the Greenland atmospheric history
427 in 1907 CE (first element of the vector X) and for the constant parameters (α , β , and γ) for the
428 inversion are shown in Fig. 8. The posterior for the atmospheric mixing ratio in 1907 CE shifted
429 from the uniform prior into a non-uniform skewed posterior, indicating that the firn
430 measurements impose some constraints on the Greenland atmospheric history from as early as
431 1907 CE. The distribution of the α parameter is slightly skewed with a mean and a median of
432 0.035 and 0.032. The year to year change in Greenland COS averages 3%, similar to the
433 Antarctic inversion results. The β distribution is minimally skewed with a mean and a median of
434 1.66 and 1.64, indicating the 1σ error estimates based on the reproducibility of measurements
435 were scaled up by over 60%.

436 The γ parameters for the Greenland inversion are generally truncated. The two data sets
437 from the SUM06 campaign display about 1% negative bias (SUM06 UCI) and 1% positive bias
438 (SUM06 NOAA), respectively. Data from the SUM13 and REN15 campaigns are highly truncated,
439 with most posterior distributions displaying either a 2% negative bias (SUM13) or 2% positive
440 bias (REN15). As noted earlier, the Renland site is at lower elevation than Summit and may
441 experience higher ambient COS levels, although we expect the difference to be small based on
442 comparison of instrumental data from other northern hemisphere sites within the NOAA
443 network [Montzka et al., 2007].

444 **7.3 Synthesis of Antarctic and Greenland inversions**

445 The ice core data suggest that preindustrial COS levels over Greenland during the late
446 1700s CE were not higher than those over Antarctica (Fig. 3). The firn air inversions indicate
447 that by the early 20th century, Greenland COS levels were higher than Antarctic levels (Fig. 7).
448 About 90% of the Greenland posteriors from 1907 CE are higher than 422 ppt, which is the
449 average 0.975 quantile of the Antarctic posteriors from 1900 CE through 1920 CE, suggesting
450 the COS levels in the northern hemisphere exceeded the southern hemisphere in the early 20th
451 century, perhaps as a result of anthropogenic emissions. One caveat to this inference is that
452 samples from the base of firn holes can be more prone to contamination during sampling than
453 the samples from shallower depths [Buizert et al., 2012; Hmiel et al., 2020]. If this occurred at
454 the bottom of the SUM06 firn hole, the early Greenland inversion results could be biased high
455 with respect to the true atmospheric levels.

456 For every year from 1907 CE through 1975 CE, roughly 98% (average over 68 years) of
457 the Greenland posterior atmospheric histories are higher than the median of the Antarctic
458 posterior atmospheric histories, and about 81% are higher than the 0.975 quantile. Therefore, it
459 is likely that COS was higher over Greenland than Antarctica for most of the 20th century, and
460 by extension higher in the northern hemisphere than in the south. The most notable difference

461 between the records is the timing of the primary COS maxima in the records with the peaks in
462 median posteriors occurring in 1975 CE and 1987 CE over Greenland and Antarctica,
463 respectively.

464 In the individual posterior histories from 1950 CE to 2000 CE, the COS peak occurs in or
465 after 1981 CE in more than 95% of the posterior histories for Antarctica and it occurs in or
466 before 1980 CE in more than 91% of the posteriors for Greenland. For a lag of 5 years, we find
467 that the COS peak occurs in or after 1984 CE in about 80% of the Antarctic posterior histories
468 and in or before 1979 CE in about 85% of the Greenland ones. After 2010 CE, the COS mixing
469 ratio in both hemispheres remain very close with overlapping uncertainty bands, which is in line
470 with the ambient air results from the NOAA flask network.

471 To test the possibility that the time lag between the late 20th century atmospheric COS
472 peaks over Greenland and Antarctica may be due to inaccuracies in the firn modeling, we
473 conducted inversions for only the SUM06 campaign using both the UCI and CIC firn models and
474 compared the results to the result presented in section-7.2 (supplement section-3). We do not
475 find any indication that the COS peak over Greenland occurred at the same time as Antarctica.
476 Although this sensitivity test does not address all possible uncertainties in the firn modeling, it
477 suggests that if the time lag between the Greenland and Antarctic atmospheric histories is
478 caused by the inaccuracies in the firn modeling, the possible cause is unlikely to be site-specific,
479 rather it must apply to all or most of the sites.

480 **8 Possible causes of atmospheric COS variability**

481 Antarctic ice core measurements imply that atmospheric COS was 300-350 ppt for
482 several millennia preceding the 20th century [Aydin et al., 2014]; this helps constrain the natural
483 background concentrations of atmospheric COS. The general characteristics of the COS
484 atmospheric history over the last 100+ years are suggestive of an emission history dominated
485 by anthropogenic sources (Fig. 7). The late 20th century peak is preceded by a large increase and
486 followed by a rapid decline into a relatively stable period in the 21st century. This pattern is
487 typical for an atmospheric trace gas whose primary emissions are from fossil-fuel production
488 and use, as demonstrated by prior firn air studies of various non-methane hydrocarbons and
489 carbon monoxide [Aydin et al., 2011; Helmig et al., 2013; Petrenko et al, 2013; Worton et al,
490 2012]. In this section, we use a coupled atmosphere-surface ocean box model to examine
491 whether the main features of the Greenland and Antarctic atmospheric histories are consistent
492 with the present understanding of the atmospheric COS budget and the bottom-up estimates
493 of historical anthropogenic COS emissions, assuming constant COS lifetime in the atmosphere.
494 We also discuss the implications of assuming the atmospheric removal rate of COS remained
495 constant.

496 **8.1 Atmospheric COS budget**

497 In earlier budget estimates, atmospheric removal of COS was scaled with net primary
498 productivity (NPP) [Chin and Davis, 1993; Watts, 2000], with model-based top-down estimates
499 converging at 200 – 300 Gg S y⁻¹ of COS uptake by plants [Kettle et al., 2002]. This value roughly
500 matched the observationally-constrained estimates of direct and indirect oceanic emissions and

501 resulted in a near-balanced budget with a lifetime close to 4 years [Kettle et al., 2001; 2002].
502 Using data from the NOAA-GML global flask network, Montzka et al. [2007] showed that
503 atmospheric COS exhibited a strong seasonal minimum at northern hemisphere continental
504 sites that closely followed the summer peak in terrestrial productivity and suggested terrestrial
505 COS uptake should instead be scaled with GPP. Subsequent field and laboratory studies support
506 scaling COS uptake with GPP of land plants [Campbell et al., 2008; Stimler et al., 2010 and 2011;
507 Maseyk et al., 2014; Whelan et al., 2018]. This change had the effect of shortening the
508 atmospheric lifetime and increasing the emissions required to balance the budget.

509 Recent atmospheric modelling-based estimates of the terrestrial COS uptake range from
510 ~500 Gg S y⁻¹ [Suntharalingham et al., 2008] to over 800 Gg S y⁻¹ [Berry et al., 2013; Campbell et
511 al., 2017], resulting in a global average lifetime that may be shorter than 2 years. It has been
512 suggested that the larger terrestrial uptake should be balanced by larger oceanic emissions,
513 with modeling-based estimates ranging from 800 to 1000 Gg S y⁻¹ [Berry et al., 2013; Kuai et al.,
514 2015; Glatthor et al., 2015; Launois et al., 2015]. In contrast, bottom-up estimates of oceanic
515 COS emissions using direct observational constraints suggest no more than 300-400 Gg S y⁻¹
516 combined from direct and indirect ocean sources [Lennartz et al., 2017]. Present-day
517 anthropogenic emissions which were estimated at 200-300 Gg S y⁻¹ [Campbell et al., 2015 and
518 2017] are now updated to about 400 Gg S y⁻¹ [Zumkehr et al., 2018], but the source estimates
519 constrained directly by observations still fall short of what is necessary for a balanced budget.
520 The imbalance in the COS budget can result from an incomplete understanding of the existing
521 budget terms and associated uncertainties, or there may be a missing source. The uncertainties
522 notwithstanding, all existing evidence suggests the major terms in the atmospheric COS budget
523 are oceanic (direct and indirect), anthropogenic, and biomass burning emissions on the source
524 side and terrestrial uptake (plant + soil) and chemical oxidation on the sink side (Table 2).

525 **8.2 The box model**

526 Atmospheric COS is simulated by a box model which was used for atmospheric ethane
527 [Nicewonger et al., 2016]. The atmosphere includes six zonal boxes, each representing a 30°
528 latitude band from 90°N to 90°S. Mass exchange between the boxes occurs via transport
529 parameters calibrated with the global SF₆ distribution [Marik, 1998; Mitchell et al., 2013]. The
530 time-dependent COS mixing ratio X in each box is calculated from (5) using the *MATLAB* ode45
531 fast solver.

$$532 \quad \frac{dX}{dt} = S(t) - kX(t) + EX(t) \quad (5)$$

533 In (5), X is the mixing ratio in each atmospheric box, S is the sum of all sources within a
534 box, k is the cumulative pseudo first-order loss rate constant ($k_{OH} + k_{VEG} + k_S$) in a box, and E
535 represents the exchange between neighboring boxes via transport. The sources are described
536 for 4 tie-points in time chosen to capture the main characteristics of the atmospheric COS
537 variability and are linearly interpolated to time steps chosen by the ODE solver. k and E are kept
538 constant over time.

539 The magnitude of the source terms for each box are adapted from the most recent
540 estimate of the atmospheric COS budget (Table 2), except the direct COS emissions component

541 of the ocean source is calculated dynamically using a 6-box surface ocean model. COS in each
542 surface ocean box equilibrates with the overlying atmospheric box via air/sea gas transfer.
543 Unlike the atmospheric model, there is no exchange between the ocean boxes themselves.

544 The magnitude of the modeled direct ocean COS source is based on the observational
545 estimates for the present-day ocean [Lennartz et al., 2017]. COS is produced in the surface
546 ocean by both dark and light processes and lost via hydrolysis and downward mixing. The
547 parameterization of these processes closely follows previous modeling work on ocean-
548 atmosphere exchange of methyl halides [Butler, 1994; Yvon and Butler, 1996; Verhulst et al.
549 2013]. Dark production is set to published values by Lennartz et al. [2017]. Photoproduction is
550 tuned to match the magnitude and latitudinal distribution of the present-day direct COS source
551 by Lennartz et al. (2017). Loss to hydrolysis in the surface ocean is calculated from published
552 temperature and pH dependent hydrolysis rates [Elliot and Rowland, 1989; Kamyshny et al.,
553 2003]. Air/sea gas transfer is based on the temperature and salinity dependent solubility of COS
554 and a surface-wind-dependent gas exchange coefficient [Lennartz, 2017]. The production terms
555 and the physical parameters that control hydrolysis loss and air/sea gas transfer are assumed to
556 be constant through time. As a result, the ocean acts to buffer the atmosphere against changes
557 in COS due to terrestrial emissions and uptake.

558 The major removal mechanisms for atmospheric COS are uptake by terrestrial
559 vegetation and uptake by soils with first-order rate constants of k_{veg} and k_{soil} , cumulatively
560 accounting for about 90% of COS loss in our model. k_{soil} is explicitly scaled to be 10% of k_{veg} as
561 recommended by Whelan et al. [2018], although this scaling is inconsequential for the analysis
562 conducted in this work. The magnitude of the cumulative terrestrial uptake rate ($k_{veg} + k_{soil}$) is
563 scaled so that the modelled COS in the present-day approximates the observed COS mixing
564 ratios from the NOAA flask network. Chemical degradation of COS in the atmosphere occurs via
565 oxidation by OH based on the global OH fields [Spivakovsky et al., 2000] and the temperature
566 dependent rate constant (k_{OH}) [Burkholder et al., 2015]. Any other loss processes are
567 considered minor and ignored. OH oxidation accounts for the remaining 10% of the
568 atmospheric COS loss. The overall globally-weighted average lifetime of COS in the model is 1.7
569 y; the lifetimes with respect to vegetation, soil, and OH sinks are 2.0 y, 19.3 y, and 19.8 y,
570 respectively.

571 **8.3 Implications for anthropogenic COS emissions**

572 The COS box model is used to estimate the emission changes required to approximate
573 the major features of the COS variability apparent in the Greenland and Antarctic atmospheric
574 histories. In this analysis, oceanic COS production is kept constant and emissions from biomass
575 and biofuel burning are prescribed. The inferred emission changes are presumed to emanate
576 from anthropogenic sources linked to industrial activity and fossil-fuel combustion that are
577 known to emit sulfur containing gases. Two scenarios are explored: 1) low anthropogenic
578 emissions, 2) high anthropogenic emissions.

579 **8.3.1 Low anthropogenic emissions scenario**

580 The low anthropogenic emissions scenario is based on the historic and present-day
581 anthropogenic emission estimates from Campbell et al. [2015] and the B2013 global budget

582 assessment, but with a modification to peak emissions as explained below. The anthropogenic
583 emissions are set to zero in 1880 CE, increased to 500 Gg S y^{-1} in 1975 CE, lowered to 375 Gg S
584 y^{-1} in 1987 CE, and to 250 Gg S y^{-1} at present (2000 CE onward), linearly interpolating between
585 the tie-points to calculate the annual emissions (Table 2, Fig. 9). The historic inventory by
586 Campbell et al. [2015] suggests zero emissions prior to 1880 CE, a peak in the 1970s CE at about
587 300 Gg S y^{-1} , a drop to about 200 Gg S y^{-1} by 2000 CE, followed by a rise to 250 Gg S y^{-1} (Fig. 10).
588 We use anthropogenic emissions of 500 Gg S y^{-1} in 1975 CE instead of the 300 Gg S y^{-1}
589 suggested in the historic inventory so as to have a pronounced COS peak in the model that
590 more closely resembles the firn air atmospheric histories. The more recent global gridded COS
591 emission histories by Zumkehr et al. [2018] suggest emissions of about 400 Gg S y^{-1} for present-
592 day; however, it does not cover the period prior to 1980 CE and the emission estimates in 1980
593 CE are the same as present-day. Following Campbell et al. [2015], we also assume increases in
594 emissions from biofuel and biomass burning to maximize atmospheric COS rise during the 20th
595 century (Table 2); otherwise, a larger increase in anthropogenic emissions are needed during
596 the 1880 CE to 1975 CE period.

597 The geographic distribution of the sources and sinks in the six atmospheric model boxes
598 are shown in Table 3. The balance term in the model (Tables 2 and 3) represents the “missing”
599 COS source attributed to the oceans in B2013. Both the magnitude and the latitudinal
600 distribution of the balance source in our model are calculated, totaling 515 Gg S/y compared to
601 the 600 Gg S/y estimate of B2013 (Table 2). This is because we use the more recent and larger
602 direct ocean estimates by Lennartz et al. [2017] instead of the estimates of Kettle et al. [2002]
603 when calculating the required magnitude of the balance source that will match the magnitude
604 and the distribution of the total direct ocean source in the B2013 budget. The negative fraction
605 in Box 5 for the balance source indicates uptake, implying the direct observational estimates
606 are somewhat larger than the B2013 estimates in this region (Table 3). The negative values for
607 the direct ocean source in boxes 3 and 4 indicate the ocean acts as a small net sink over this
608 region at present day.

609 The resultant COS history for the low anthropogenic emissions scenario captures the
610 general characteristics of the observed variability, but with some notable shortcomings (Figs. 7
611 and 9). The COS levels over Antarctica in the 19th century atmosphere are too high compared
612 with the ice core and firn air records, with Antarctica exceeding Greenland by more than 50
613 ppt. The Antarctic levels stay higher than Greenland during most of the ramp-up period. The
614 model COS peaks in the two hemispheres are only one year apart in contrast to the
615 observations that suggest a larger time lag with Greenland leading Antarctica.

616 8.3.2 High anthropogenic emissions scenario

617 Assuming that anthropogenic emissions are driving the long-term changes in
618 atmospheric COS, the only way to lower both the Antarctic levels and the inter-polar difference
619 during the 19th century is to 1) introduce anthropogenic emissions during the 19th century in
620 the northern hemisphere to bring Greenland and Antarctic levels closer together and 2) change
621 the geographic distribution of present-day anthropogenic emissions by increasing the fractional
622 contribution from low latitude anthropogenic sources so that when they are removed, the COS
623 levels will be lower over both Greenland and Antarctica at the end of the 19th century (Figs. 7

624 and 9). In the high anthropogenic emissions scenario, this is done by introducing new
625 anthropogenic sources that are additive to those in the low anthropogenic emissions scenario.

626 The total anthropogenic emissions increase from about 200 Gg S y⁻¹ at the end of the
627 19th century to about 800 Gg S y⁻¹ during the 20th century peak before dropping to 600 Gg S y⁻¹
628 level at present (Fig. 9). In constructing this scenario, we assume that the balance emissions are
629 primarily anthropogenic in origin and assign them to 25% of their present-day value in 1880 CE
630 (129 Gg S y⁻¹), 50% in 1975 CE (258 Gg S y⁻¹), and 515 Gg S y⁻¹ in 1987 CE. A new (third)
631 anthropogenic source is introduced, all of which is emitted from 30°N-60°N (box 2). This source
632 is set at 230 Gg S y⁻¹ in 1880 CE, decreased to 150 Gg S y⁻¹ in 1975 CE and zeroed in 1987 CE.

633 The high anthropogenic emissions scenario successfully reproduces the main features of
634 the observed COS variability over Greenland and Antarctica (Figs. 7 and 9). The lower inter-polar
635 gradient in the 19th century is achieved by introducing anthropogenic emissions in the mid-to-
636 high latitude northern hemisphere. The time lag between peaks over Greenland and Antarctica
637 is driven by a shift in anthropogenic sources from high northern latitudes to low latitudes in
638 both hemispheres that takes place between 1975 CE and 1987 CE. Note that the anthropogenic
639 emissions are always predominantly in the northern hemisphere. The present-day emissions in
640 the high anthropogenic emissions scenario are less than 20% lower than the peak emissions,
641 suggesting anthropogenic emissions at present can be only marginally lower than peak
642 emissions during the 20th century. In the low anthropogenic emissions scenario, the present-
643 day anthropogenic emissions are at 50% of the peak emissions (Fig. 9).

644 8.3.3 Anthropogenic COS sources

645 The box-model results show that the anthropogenic emissions in the COS historic
646 inventory are insufficient to push atmospheric COS to the peak levels observed during the
647 1970s and 1980s CE. The model results also provide evidence that the anthropogenic emissions
648 are underestimated at present-day and early in the 20th century. Despite not including enough
649 emissions, the COS historic inventory closely matches the temporal evolution of the peak in
650 atmospheric COS during the 20th century (Fig. 10), suggesting there is either an underestimate
651 of emissions from the known anthropogenic sources of COS or there are unidentified
652 anthropogenic sources with emission histories similar to the known sources.

653 Montzka et al. [2004] noted that the atmospheric history of COS during the 20th century
654 resembles historical anthropogenic sulfur dioxide (SO₂) emissions. Despite including emissions
655 from a larger variety of sources compared to the COS inventory, the SO₂ inventory [Smith et al.,
656 2011] also closely follows the atmospheric changes in COS during the 20th century, displaying
657 double peaks during the 1970s and 1980s CE at exactly the same time as the COS peaks over
658 Greenland and Antarctica occur (Fig. 10). The first of the SO₂ emission peaks is linked to
659 maximum emissions from the petroleum and metal smelting sectors while the second one is
660 primarily due to peaking coal emissions. The single broad peak in the COS emission inventory is
661 largely due to CS₂ emissions while the coal emissions are not large enough to cause a secondary
662 peak in the 1980s. The box model results show that the longer than 1 year time-lag between
663 the peaks in the Greenland and Antarctic firn COS histories can be caused by geographic
664 relocation of northern hemisphere sources. The late 20th century is a time period when sulfur
665 mitigation policies were enacted in North America and Europe and emissions started to shift

666 first towards East and South Asia, and later to India, Indonesia and various locations in South
667 Africa and South America [Klimont et al., 2013, Smith et al., 2011; Stern, 2005].

668 While there is qualitative evidence that the anthropogenic sources of SO₂ also influence
669 atmospheric COS levels, the coal sector is the only common major source between the SO₂ and
670 COS anthropogenic emission inventories. The most recent bottom-up analysis by Zumkehr et al.
671 [2018] estimate significantly larger COS emissions from coal at present-day than the earlier
672 historical inventory by Campbell et al. [2015]. Our analysis supports this assessment. We also
673 suggest that the reasons behind entirely omitting the other major SO₂ emitting industries from
674 the COS emission inventories should be reexamined. This might be especially important for
675 periods prior to implementation of regulatory restrictions on use of sulfur containing fuels and
676 sulfur emissions. Co-emissions of COS from all major SO₂ emitting industrial sectors might be
677 the only viable explanation for peak anthropogenic COS emissions on the order of 800 Gg S/y
678 during the 20th century as implied by our top-down analysis.

679 **8.4 Implications of a constant COS lifetime**

680 In the modelling analyses presented in the previous sections, we assumed a constant
681 COS lifetime of 1.7 y based on the contemporary understanding of the atmospheric COS budget
682 and the absence of clear evidence that lifetime has varied. Here, we briefly discuss the
683 implications of assuming a fixed COS atmospheric lifetime, focusing on k_{veg} and ignoring
684 possible changes in k_{OH} and k_{soil} .

685 The assumption of a constant k_{veg} does not necessarily imply that GPP itself remained
686 constant. Stimler et al. [2010] proposed the following relationship between GPP (molC.yr⁻¹) and
687 COS uptake (molCOS.yr⁻¹) based on laboratory chamber studies:

$$688 \quad COS \text{ uptake} = GPP \times \frac{[COS]}{[CO_2]} \times LRU \quad (6)$$

689 where [COS] and [CO₂] are atmospheric mixing ratios of the respective trace gases and LRU is
690 dimensionless normalized leaf relative uptake of COS to CO₂. By substituting COS uptake with
691 k_{veg} (y⁻¹) times the atmospheric mixing ratio of COS, (6) can be rearranged:

$$692 \quad k_{veg} = \frac{GPP \times LRU}{[CO_2]} \times \frac{1}{mAtm} \quad (7)$$

693 where $mAtm$ is the number of moles of air in the atmosphere added for dimensional
694 consistency. Equation (7) implies that the product of GPP and LRU will always scale linearly with
695 atmospheric CO₂ levels if k (1/lifetime) is constant. This implies large increases in $GPP \times LRU$ since
696 the 19th century given the atmospheric CO₂ rise during this period.

697 In other words, both the low and high anthropogenic emissions scenarios in sections
698 8.3.1 and 8.3.2 imply an increase in $GPP \times LRU$ of more than 30% from the 19th century to 2000
699 CE due to CO₂ increasing from 280 ppm to 370 ppm, and an increase of about 45% through
700 2020 CE for an atmospheric CO₂ mixing ratio of 410 ppm. LRU is a leaf-scale parameter that
701 might not have varied much over the last several decades [Campbell et al., 2017], implying
702 most or all of this inferred change can be attributed to the GPP. The 30+% increase in inferred
703 GPP by 2000 CE agrees with the recent analysis of Campbell et al. [2017]. They show that the

704 roughly 30% GPP increase during the 20th century is close to the high-end estimates from the
705 carbon-cycle models. An additional 15% increase in inferred *GPPxLRU* since 2000 CE under a
706 constant lifetime assumption and based on (7) needs to be evaluated against carbon-cycle
707 models.

708 **9 Conclusions**

709 We conducted a simultaneous multi-site inversion of firn air data from Greenland and
710 Antarctica for the first time. The Bayesian framework implemented within the Stan statistical
711 programming language is an efficient method for the inversion of firn air measurements to
712 recover atmospheric histories, allowing quantification of uncertainties arising from sampling
713 and measurement errors as well as addressing possible biases between different data sets that
714 may stem from temporal variability in calibration scales applied to COS measurements. We find
715 that these uncertainties are about an order of magnitude smaller than the long-term changes in
716 the atmospheric history of COS. This method can be expanded in the future to quantify the
717 source and sink changes required to explain the inferred atmospheric variability along with the
718 associated uncertainties within a hierarchical Bayesian framework.

719 Our analysis provides a continuous record of Antarctic atmospheric COS since the 19th
720 century based on ice core and firn air measurements. The Greenland atmospheric history
721 covers most of the 20th century though there is still a 100-year gap between the oldest periods
722 well-constrained by the firn air and the youngest ice core measurements. This gap could be
723 closed by shallow ice core measurements. Both the Greenland and Antarctic records suggest a
724 large COS increase in the atmosphere through the first 70-80 years of the 20th century, followed
725 by a decline leading into a relatively stable period near present-day levels. There is strong
726 evidence that the changes in atmospheric COS did not occur in a smooth and monotonic
727 fashion, and it is likely that the peak levels were reached at different times in the two
728 hemispheres, with the northern hemisphere leading the south.

729 Model simulations are consistent with the changes in anthropogenic emissions being
730 the primary driver of atmospheric COS variability from the late 19th century to present-day. The
731 total anthropogenic emissions required to simulate the COS rise over the past century are
732 larger than the bottom-up estimates. We suggest that some industrial sectors that are sources
733 of SO₂ but not of COS should be considered to be included in the COS inventories. It is likely
734 that co-emissions of COS from industrial sulfur gas emitting sectors are larger than previously
735 thought and changes in the latitudinal distribution of anthropogenic emissions have had an
736 impact on observed COS levels in the polar atmosphere over Greenland and Antarctica. A
737 chemical transport modelling framework is needed to formally determine the historic variability
738 in the anthropogenic COS emissions and their locations. Such work would benefit from
739 independent information on GPP variability to constrain potential changes in the COS lifetime.

740 **Acknowledgments.** We thank Todd Sowers and Trevor Popp for the SPO15 and Jeff
741 Severinghaus for the MD03 firn campaigns. We also thank all the drillers and the field support
742 personnel that contributed to the firn air and ice core campaigns. This research was supported
743 by the National Science Foundation grants ANT-1443470 and ANT-1443472, the U.S. Dept. of

744 Energy grant DE-SC0016539, and Simons Foundation Postdoctoral Fellowship in Marine
745 Microbial Ecology. Antarctic ice core data can be accessed via usap-dc.org/.
746 Arctic ice core data can be accessed via arcticdata.io/. Firn air data will be submitted to a data
747 repository prior to publication (currently in supplement section-4).

976

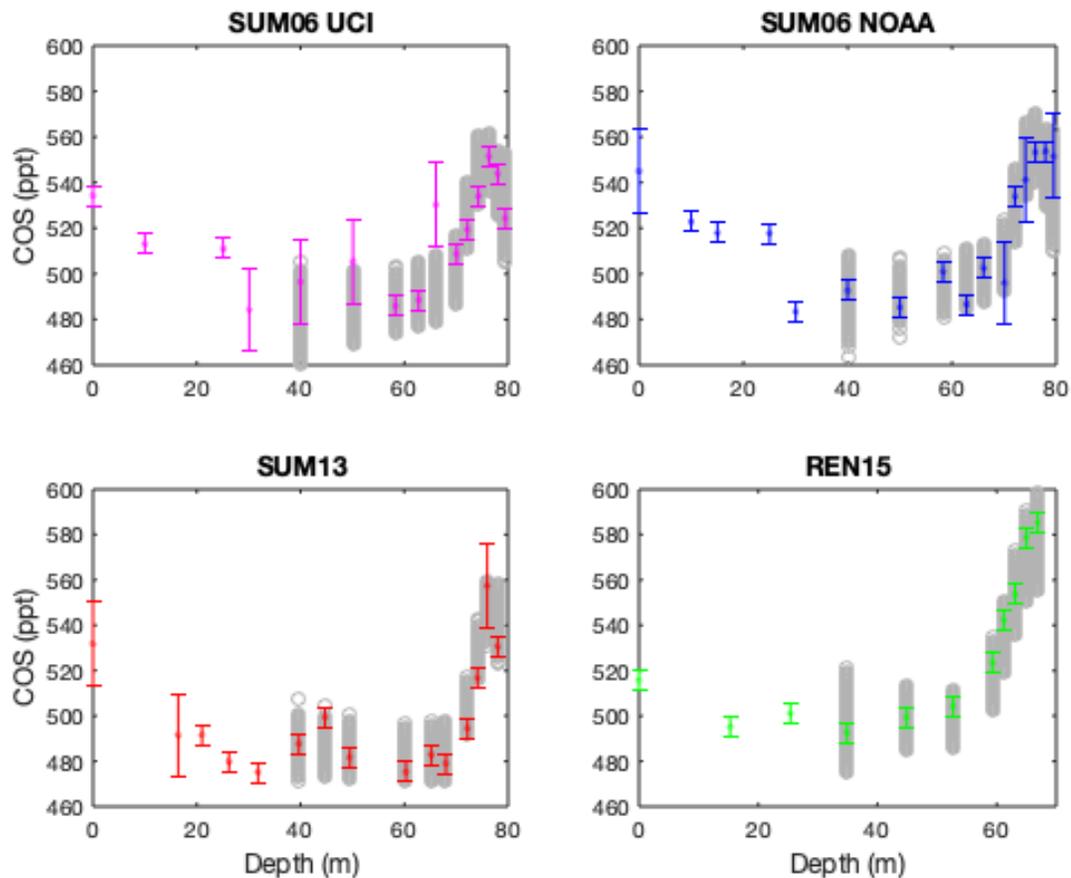

Figure 1. Firn air COS uncertainty estimates ($\pm 1\sigma$) centered around measurement means for Summit and Renland sites in Greenland. SUM06 measurements were conducted at UCI (magenta) and NOAA-GMD (blue) using different sets of flasks. SUM13 (red) and REN15 (green) measurements were conducted at UCI. The gray bands (20,000 circles) represent the firn air COS concentration estimates based on the Bayesian inversion results shown in Fig. 7. Only the firn data from below 35 m are included in the inversions to avoid influence from seasonal variability in ambient air. Neither the data nor the inversion results are corrected for gravitational enrichment in the firn.

977

978

979

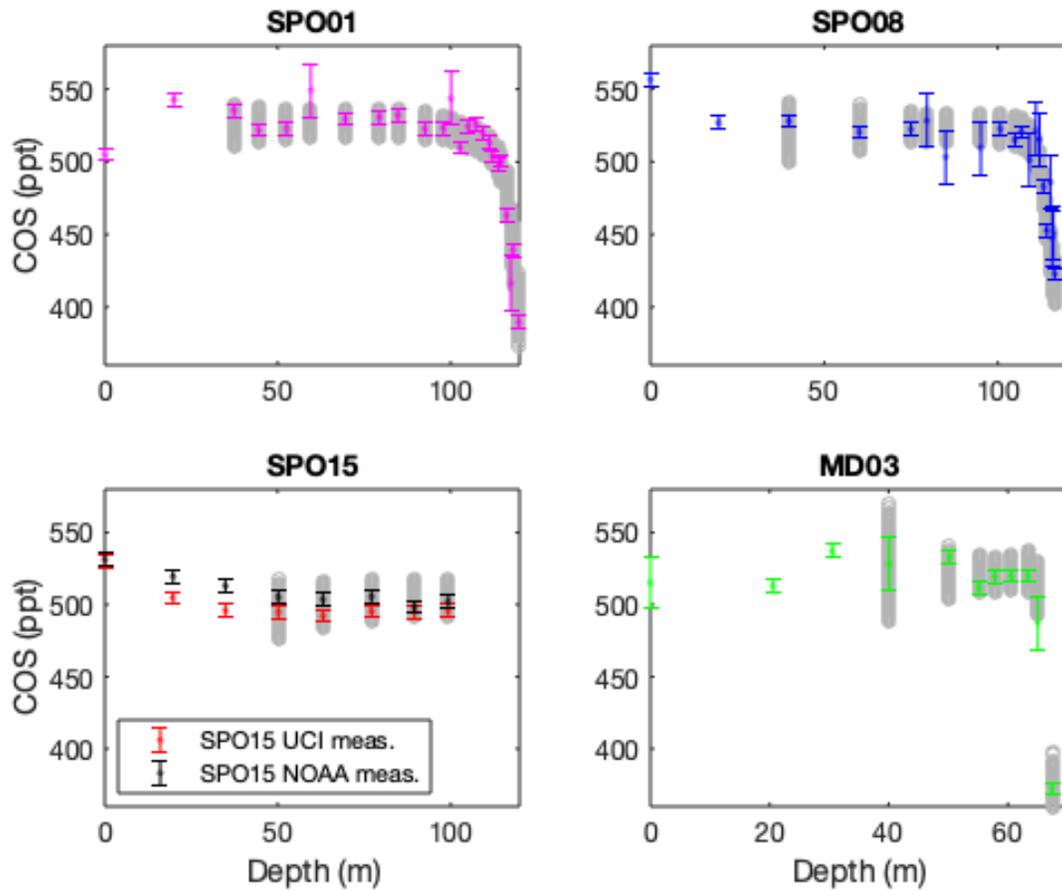

Figure 2. Firn air COS uncertainty estimates ($\pm 1\sigma$) centered around measurement means for the SPO01 (magenta), SPO08 (blue), SPO15 (black and red), and MD03 (green) sites in Antarctica. All Antarctic data are NOAA measurements except one set of SPO15 measurements conducted at UCI (red). The gray bands (20,000 circles) represent the firn air COS concentration estimates based on the Bayesian inversion results shown in Fig. 5. Only the firn data from below 35 m are included in the inversions to avoid seasonal variability in ambient air. Neither the data nor the model inversion results shown in this figure are corrected for gravitational enrichment in the firn.

980

981

982

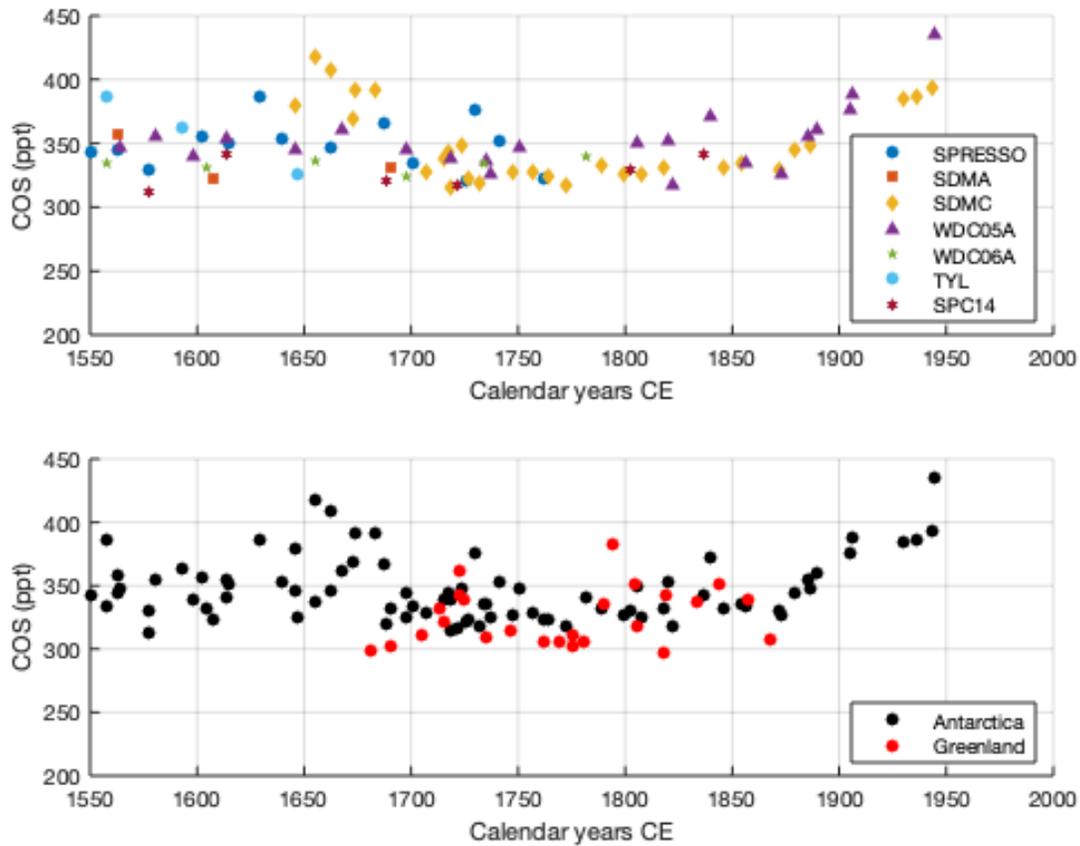

Figure 3. Ice core COS data. **Top)** COS data from various Antarctic ice cores (n=84): SPRESSO (South Pole), SDMA (Siple Dome), SDMC (Siple Dome), WDC05A (WAIS Divide), WDC06A (WAIS Divide), TYL (Taylor Dome), SPC14 (South Pole). Except for the new SPC14 measurements, all data shown here have been published as parts of larger data sets with established chronologies that cover longer periods [Aydin et al., 2002; Montzka et al., 2004; Aydin et al., 2008; Aydin et al., 2014]. The new SPC14 data are on the SP19 chronology [E. J. Brook, personal communication]. **Bottom)** Previously published COS data from the GISP2B and GISP2D ice cores (red circles) from Greenland [Aydin et al., 2007] versus all Antarctic data (black circles) from the top panel.

983

984

985

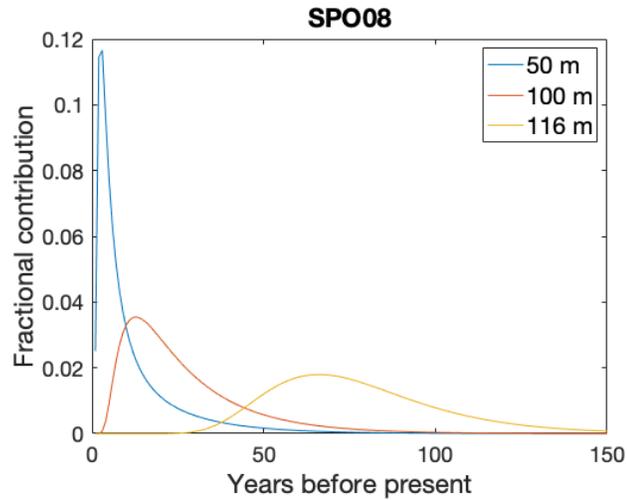

Figure 4. The COS firn air age distribution for the SPO08 campaign at three different depths from the UCI firn model [Aydin et al., 2011]. The integral of the age distribution is equal to one at all depths. The smaller amplitude and broader width at depth results in heavier smoothing of atmospheric variability. Slower accumulation sites preserve air with an older mean age, but the older air is also more heavily smoothed. The degree of smoothing at the bottom of the firn is different at each site.

986

987

988

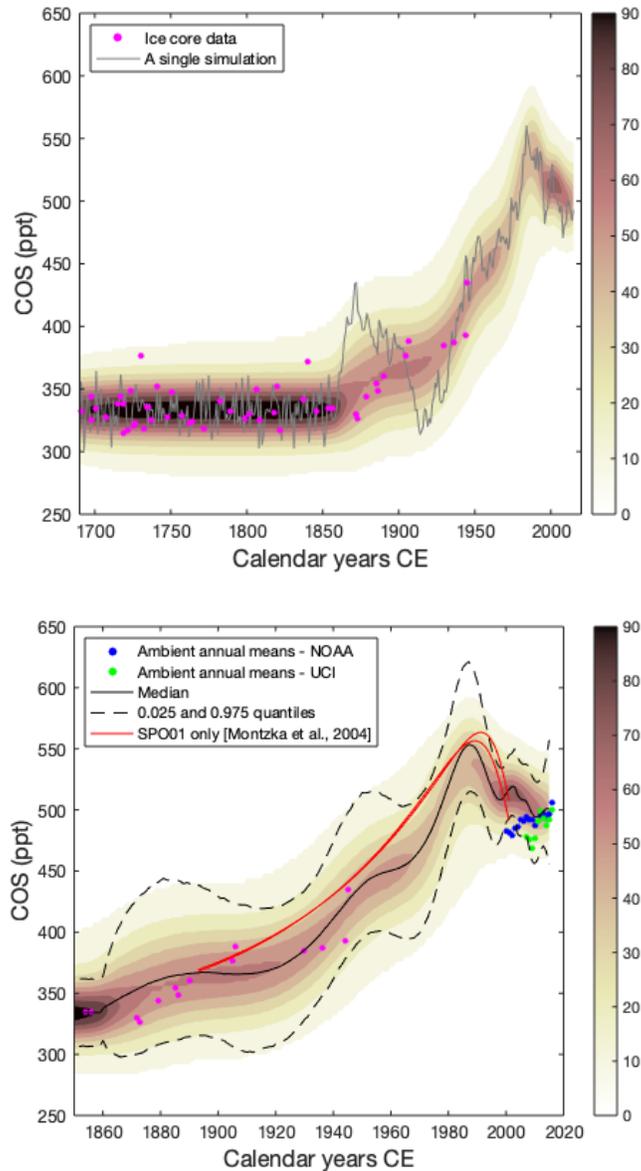

Figure 5. Data density plots (contour plot of histograms) of the Antarctic inversion results, with the resulting firn air concentrations shown in Fig. 2 (see supplement section-1 for the full posterior range). The darkest color contours from 1850 CE to 2015 CE correspond to the periods with highest data density. The darker colors at each year correspond to the concentration range covered by most of the posterior results for that year. **Top** – One random simulation of X (gray line) and the Antarctic ice core data (magenta circles) are also shown. Only the ice core data from before 1860 CE are used in the inversion. **Bottom** – The same as the top but zoomed into the period after 1855 CE. Also shown are the 0.025, 0.5, and 0.975 quantiles of the X_{ANT} posterior (solid and dashed black lines), the previously published COS atmospheric histories based on the SPO01 firn only (red lines – Montzka et al., 2004), and the ambient air annual means from flasks filled at the SPO and Cape Grim, Australia, measured at NOAA (blue circles) and UCI (green circles).

989

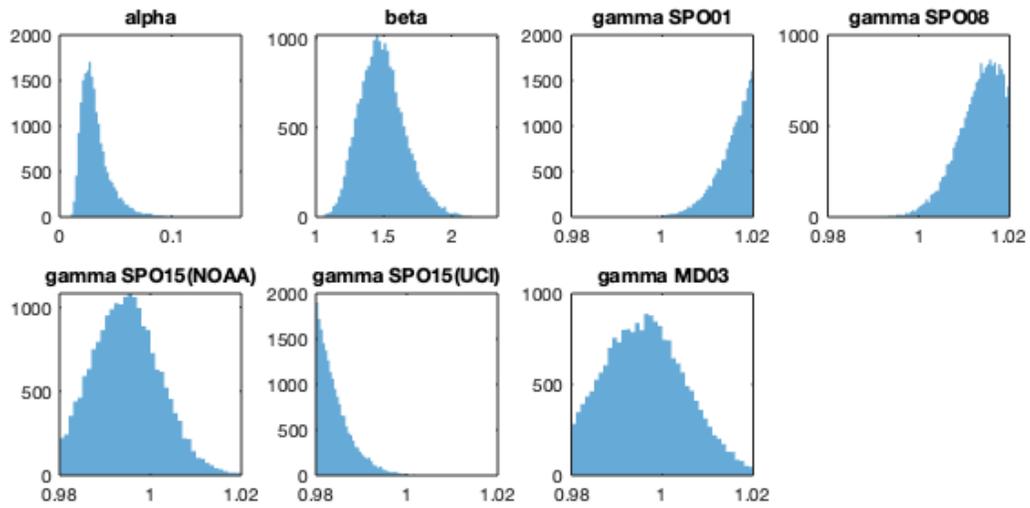

Figure 6. Antarctic posterior probability distributions for the α , β , and the site-specific γ parameters. All γ parameters stay within $\pm 2\%$ of 1 by design (see supplement section-2 for sensitivity of the results to broader γ ranges).

990

991

992

993

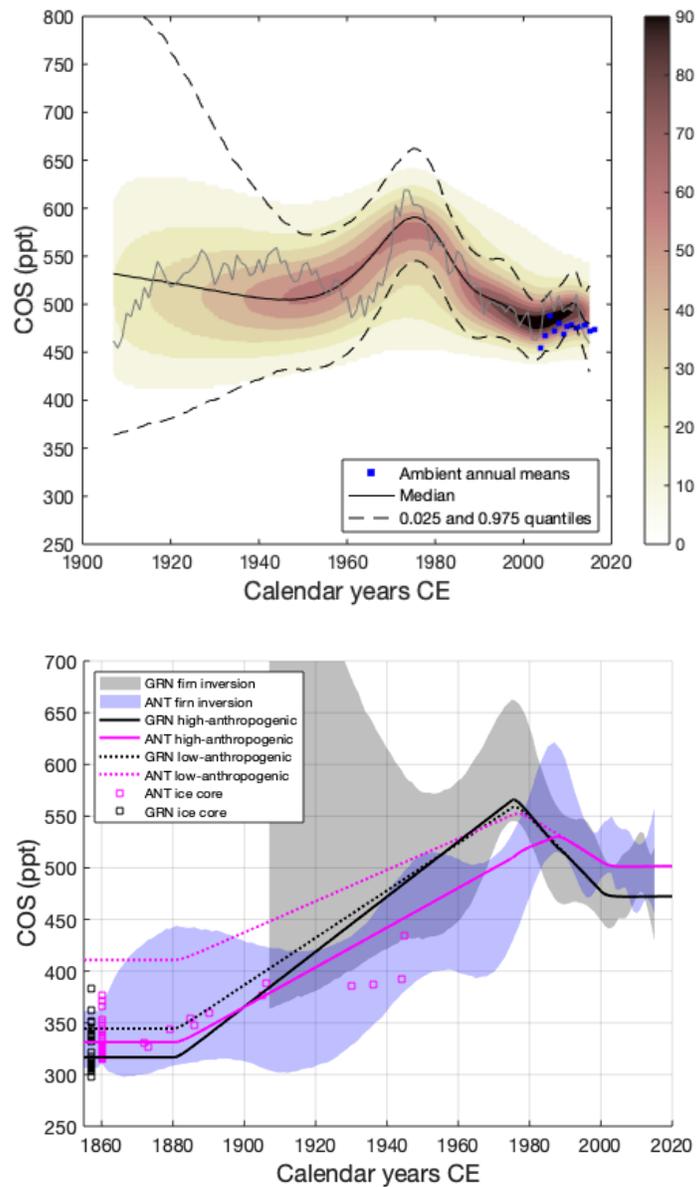

Figure 7. Top – Data density plots (contour plot of histograms) of the Greenland inversion results, with the resulting firn air concentrations shown in Fig. 1 (see supplement section-1 for the full posterior range). Also shown are one random simulation (solid gray line), the 0.025, 0.5, and 0.975 quantiles of the posterior X_{GRN} (solid and dashed black lines), and the ambient air annual means from Summit surface flasks measured at NOAA (blue squares). **Bottom** – The 0.025- 0.975 quantile range for the Antarctic (blue shade) and Greenland (black shade) inversions compared with the box model high (solid lines) and low (dotted lines) anthropogenic emissions scenarios for Antarctica (magenta) and Greenland (black). The ice core data (Fig. 3) from Antarctica (magenta squares) and Greenland (black squares) are also shown, with measurements from before 1860 CE plotted on a collapsed x-axis scale.

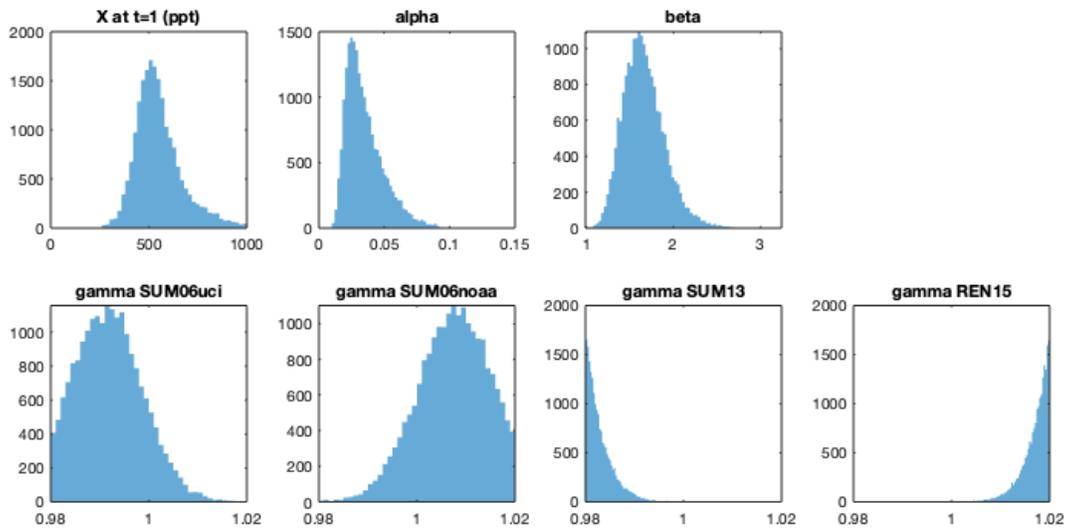

Figure 8. Greenland posterior probability distributions for the α , β , and the site-specific γ parameters, and for the initial atmospheric history (X in 1907 CE). All γ parameters stay within $\pm 2\%$ of 1 by design. Sensitivity of the results to broader γ ranges has been tested (supplement section-2).

996

997

998

999

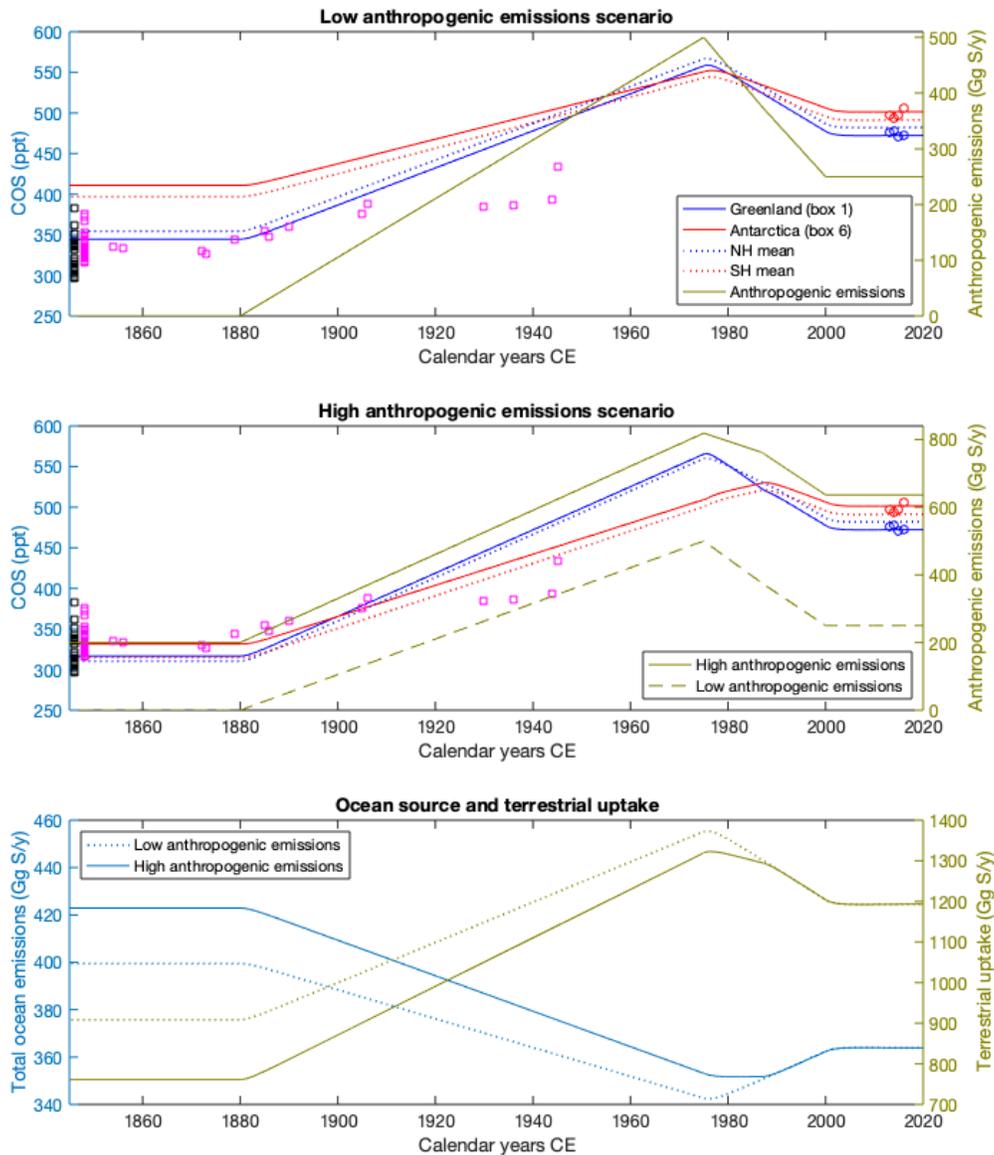

Figure 9. Top: Low anthropogenic emissions scenario model results: COS mixing ratio over Greenland (blue solid line) and Antarctica (red solid line), in the northern (blue dotted line) and the southern (red dotted line) hemispheres are shown on left y-axis along with the ice core data from Antarctica (magenta squares) and Greenland (black squares) and surface flask data from the South Pole (red circles) and Summit, Greenland (blue circles). The ice core data from before 1860 CE are plotted on a collapsed x-axis scale. The total anthropogenic emissions (yellow line) are shown on the right y-axis. **Middle:** Same as the top panel but for the high anthropogenic emissions scenario. **Bottom:** The total (direct + indirect) net ocean emissions (blue lines) for the low (dotted line) and the high (solid line) anthropogenic emissions scenarios are shown on the left y-axis. The total terrestrial (vegetation + soil) uptake (yellow lines) for the low (dotted line) and the high (solid line) anthropogenic emissions scenarios are shown on the right y-axis.

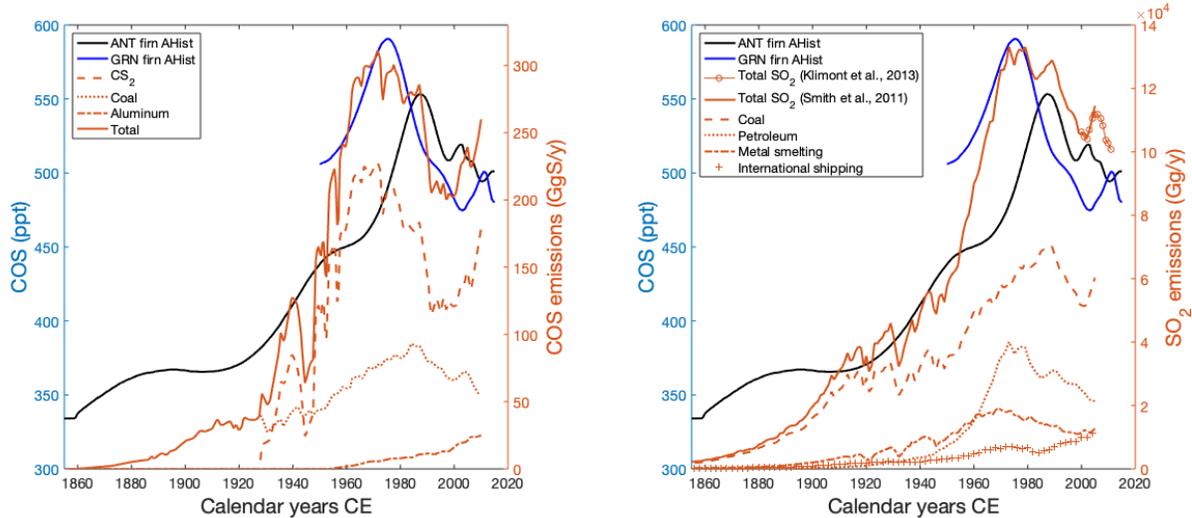

Figure 10. Left: Median X_{GRN} (blue line) and X_{ANT} (black line) are on the left y-axis. The historical anthropogenic COS emissions inventory by Campbell et al. [2015] is on the right y-axis. The total inventory emissions (solid red line) is the sum of emissions from CS_2 (dashed line), coal use (dotted line), and aluminum smelting (dashed dotted line). **Right:** The same as the left panel but COS emission inventory is replaced with the historical anthropogenic SO_2 inventory by Smith et al. [2011]. The major components of the total anthropogenic SO_2 inventory are emissions from petroleum (dashed line), coal (dotted line), metal smelting (dashed dotted line), and shipping (plus sign) sectors. Biomass and biofuel burning emissions are not shown. Emissions from coal are common to both the SO_2 and COS inventories. Metal smelting sector in the SO_2 inventory includes emissions from aluminum smelting, which is the only metal smelting sector accounted for in the COS inventory.

1001
1002

Table 1. Information relevant for different firn campaigns included in the analysis.

Site	Firn depth	Inversion period (CE)	No. of sampling depths ¹	Flask origin and type	Analysis location
SUM06	80 m, 1 hole	1907 - 2006	16	UCI (glass) NOAA (glass and SS)	UCI and NOAA
SUM13	80 m, 1 hole	1914 - 2013	18	UCI (glass) NOAA-CCG (glass)	UCI
REN15	70 m, 1 hole	1946 - 2015	12	UCI (glass)	UCI
SPO01	120 m, 2 holes	1802 - 2001	13 per hole	NOAA (glass)	NOAA
SPO08	117 m, 2 holes	1809 - 2008	16 per hole	NOAA (glass)	NOAA
SPO15	100 m, 1 hole	1929 - 2015	8	UCI (glass)	UCI and NOAA
MD03	67 m, 1 hole	1679 - 2003	14	NOAA (glass)	NOAA
