Abstract

In western Canada, there has been an increase in seismic activity linked to anthropogenic energy-related operations including conventional hydrocarbon production, wastewater fluid injection, and, more recently, hydraulic fracturing (HF). Statistical modeling and characterization of the space, time, and magnitude distributions of the seismicity clusters is vital for a better understanding of induced earthquake processes and development of forecasting models. In this work, a statistical analysis of the seismicity in the Western Canada Sedimentary Basin was performed across past and present time periods by utilizing a compiled earthquake catalogue for Alberta and eastern British Columbia. Specifically, the inter-event space-time distance distributions of earthquakes were studied using the nearest-neighbour distance (NND) method. Additionally, the frequency-magnitude statistics and aftershock parameters of several clusters were analyzed using the Gutenberg-Richter relation and the epidemic type aftershock sequence model. The results suggest that recent regional changes in the NND distributions, namely, a disproportionate increase in loosely and tightly clustered seismic activity over time, are unnatural and likely due to the rise in HF operations for the development of unconventional resources. It is concluded that both these loosely and tightly clustered earthquake subpopulations differ measurably from what may be the region's tectonic seismic activity. Additionally, HF treatments have a greater probability of triggering swarm-like sequences that sharply spike the seismicity rate and are characterized by larger Gutenberg-Richter b-values. In contrast, conventional production and wastewater disposal operations largely trigger loosely clustered activity with more typical magnitude-occurrence distributions.

8 **Key Points:**

9 - Parts of western Canada have seen an increase in clustered seismic activity coinciding
10   with the growing usage of hydraulic fracturing

11 - The regional seismicity can be subdivided into three main classes of inter-event distance
12   using the nearest-neighbour distance method

13 - Analysis of earthquake clusters occurring near different types of anthropogenic
14   operations reveal key differences in scaling and structure

15

16   **Abstract**

17   In western Canada, there has been an increase in seismic activity linked to anthropogenic energy-

18   related operations including conventional hydrocarbon production, wastewater fluid injection

19   and more recently hydraulic fracturing (HF). Statistical modeling and characterization of the

20   space, time and magnitude distributions of the seismicity clusters is vital for a better

21   understanding of induced earthquake processes and development of forecasting models. In this

22   work, a statistical analysis of the seismicity in the Western Canada Sedimentary Basin was

23   performed across past and present time periods by utilizing a compiled earthquake catalogue for

24   Alberta and eastern British Columbia. Specifically, the inter-event space-time distance

25   distributions of earthquakes were studied using the nearest-neighbour distance (NND) method.

26   Additionally, the frequency-magnitude statistics and aftershock parameters of several clusters

27   were analyzed using the Gutenberg-Richter relation and the epidemic type aftershock sequence

28   model. The obtained results suggest that recent regional changes in the NND distributions,

29   namely a disproportionate increase in loosely and tightly clustered seismic activity over time, are

30   unnatural and likely due to the rise in HF operations for the development of unconventional

31   resources. It is concluded that both these loosely and tightly clustered earthquake subpopulations

32   differ measurably from what may be the region's tectonic seismic activity. Additionally, HF

33   treatments have a greater probability of triggering swarm-like sequences that sharply spike the

34   seismicity rate and are characterized by steeper frequency-magnitude distributions. Conventional

35   production and wastewater disposal operations largely trigger loosely clustered activity with

36   more typical magnitude-occurrence rates.

37   **Plain Language Summary**

38   In western Canada, there has been an increase in earthquake activity linked to industrial activities

39   including fossil fuel extraction, wastewater disposal and more recently hydraulic fracturing.

40   Statistical modeling of earthquake phenomena is important for the understanding of the specific

41   mechanisms involved in triggering earthquakes. In this work, a statistical analysis of the

42   recorded earthquakes in the Western Canada Sedimentary Basin is performed. The results of this

43   study suggest that there are discrete statistical differences between the natural, tectonic

44   earthquakes and those triggered artificially by human activity. Additionally, hydraulic fracturing

45   operations appear capable of triggering swarm-like sequences that temporarily increase the

46   earthquake rate and tend to occur at small-to-moderate magnitudes. Conventional fuel production

47   and wastewater disposal operations largely trigger earthquakes that are loosely clustered together

48   in space and time across a broader magnitude range.

49   **1 Introduction**

50   1.1 Induced Seismicity

51   Human activities, such as hydrocarbon production, reservoir impoundment, mining and

52   geothermal energy extraction, can alter subsurface stress regimes through a variety of

53   mechanisms, including the withdrawal or injection of fluid, reservoir compaction, excess surface

54   loading, and ground subsidence (Grigoli et al., 2017; Doglioni, 2018; Keranen & Weingarten,

55   2018). In some cases, these stress perturbations result in earthquakes, particularly in areas

56   characterized by higher states of stress and/or preexisting, well-oriented faults. This phenomenon

57   is referred to as induced seismicity and is contributing to an increase in seismic hazard in certain

58   parts of the world (Segall et al., 1995; Lei et al., 2008; Atkinson, 2017; McClure et al., 2017;

59   Eaton et al., 2018; Brudzinski & Kozłowska, 2019).

60   In the central United States, for example, numerous earthquakes have been attributed to

61   wastewater disposal wells operating in close proximity (Ellsworth, 2013; Llenos & Michael,

62   2013; van der Elst et al., 2013; Keranen et al., 2014; Hornbach et al., 2016; Schoenball &

63   Ellsworth, 2017). These wells inject large quantities of excess flow-back fluid from associated

64   oil and gas production operations deep into underground reservoirs. This creates a pore pressure

65   front that travels outward and may interact with fault structures, particularly in the crystalline

66   basement where most of the associated seismic events occur (Horton, 2012; Ellsworth, 2013;

67   Keranen et al., 2014; McClure et al., 2017; Shah & Keller, 2017). In the year 2016 alone,

68   Oklahoma observed three earthquakes of moment magnitude (**M**) >5, including an **M**5.8 event in

69   Pawnee that was the largest event recorded in the state's history. All three events occurred within

70   10 km of wastewater disposal wells and had moment releases that scaled with the net volume of

71   near-field injection (McGarr & Barbour, 2017).

72   In parts of western Canada, there has been a notable rise in the seismic rate coinciding

73   with the implementation of unconventional extraction technology developed for the production

74   of oil and gas, known as hydraulic fracturing (HF) or "fracking" (B.C. Oil and Gas Commission,

75   2012, 2014; Schultz, Stern, Novakovic, et al., 2015; Atkinson et al., 2016; Bao & Eaton, 2016;

76   Deng et al., 2016; Ghofrani & Atkinson, 2016; Schultz et al., 2016, 2017, 2018; Wang et al.,

77   2016; Eaton et al., 2018; Zhang et al., 2019). During the HF process, fractures are created or

78   enhanced within a target formation holding desired hydrocarbons, typically tight (low

79   permeability) sedimentary layers, by the pumping of chemical slurry into segments of the rock

80   over several stages. It is increasingly common for wells to be drilled at a deviated or horizontal

81   angle as they approach a reservoir, in order to engage a larger portion of the source rock than

82   would have been reached vertically. These technological advancements have prompted a

83   dramatic growth in the number of possible fracture stages per wellbore as well as increased the

84   average total volume of high-pressure fluid injected (King, 2010) and its areal extent. Between

85   2010 and 2018, approximately 20,000 HF wells had been drilled horizontally within the Western

86   Canada Sedimentary Basin (WCSB) (Atkinson et al., 2020). The associated rise in induced

87   seismicity in western Canada appears highly clustered near some of these HF operations and

88   cannot be fully accounted for by the deployment of denser seismic monitoring networks and

89   more sensitive instruments (Schultz, Stern, Gu, et al., 2015; Atkinson et al., 2016; Cui &

90   Atkinson, 2016). Furthermore, recent studies have demonstrated that the hazard related to

91   induced seismicity, including HF, is potentially much greater than that of natural seismicity,

92   particularly in areas characterized by low to moderate tectonic activity (Atkinson, 2017; Lee et

93   al., 2019; Atkinson et al., 2020; Langenbruch et al., 2020).

94   1.2 Earthquake Clustering

95   Cases of induced seismicity commonly appear as earthquake clusters and can manifest as

96   both mainshock-aftershock burst sequences and as seismic swarms. For example, the large

97   wastewater disposal-induced events in Oklahoma triggered typical aftershock behavior,

98   temporarily increasing the seismic rate due to the transfer of stress and brittle failure of the crust

99   (Keranen et al., 2014; McGarr & Barbour, 2017). On the other hand, the HF-induced clustering

100   near Youngstown, Ohio, and injection-related events in central Arkansas near Guy and

101   Greenbrier displayed swarm-like characteristics, where the events were of similar magnitude and

102   could not be attributed to any dominant mainshock (Horton, 2012; Llenos & Michael, 2013;

103   Skoumal et al., 2015). Studies have shown that both natural and anthropogenic changes to the

104   subsurface fluid content can enhance or induce earthquake sequences via subsidence and/or

105   changes in Coulomb fault stress and pore pressure conditions, especially near critically oriented

106   structures (Segall, 1985; Langenbruch & Shapiro, 2010; Brodsky & Lajoie, 2013; Kumazawa &

107   Ogata, 2013; Keranen et al., 2014; Goebel et al., 2015; Schoenball et al., 2015; Bao & Eaton,

108   2016; Kettlety et al., 2019, 2020). The nature of clustering observed within a region may be

109   attributed to its rheological structure, in the framework of viscoelastic deformation (Ben-Zion &

110   Lyakhovsky, 2006). In this context, a medium with low levels of heat flow and/or less fluid

111   content correlate with higher viscosity and the conditions of brittle rheology, resulting in "burst-

112   like" cracking of the crust and subsequent aftershock clustering. The converse is attributed to

113   lower viscosity lithospheres of more brittle-ductile rheology (higher levels of heat and/or more

114   fluid content), where failure is more likely to result in swarms of inter-linked events related to

115   factors such as local fluid balance, destabilizing aseismic slip, and inter-event triggering

116   (Zaliapin & Ben-Zion, 2016; Scuderi et al., 2017; Martínez-Garzón et al., 2018).

117   Identification of earthquake clustering involves a separation of the independent

118   background rate from dependent event sequences (Gardner & Knopoff, 1974; Reasenberg, 1985;

119   Baiesi & Paczuski, 2004; Console et al., 2010; Ader & Avouac, 2013; Zaliapin & Ben-Zion,

120   2013a; Schaefer et al., 2017). Due to the innumerable factors involved in the tectonic process,

121   background seismicity may be approximated as random and modeled as a time-stationary, space-

122   inhomogeneous marked Poisson process. Within this framework, rates of seismicity are assumed

123   to vary in space but not in time and data points (seismic events) are marked by their magnitudes.

124   Clustering, on the other hand, cannot be represented by a Poisson model, as the earthquake rate

125   does not remain constant and depends in part on prior events. The separation of background and

126   clustered earthquake phenomena is an important and non-trivial task required not only in cluster

127   analysis but also in seismic hazard assessment, where catalogues are typically de-clustered in

128   order to delineate source zones and assess recurrence parameters. The practical distinction of

129   clustered and background seismicity should not restrict the consideration for potential interplay

130   between them, particularly when external factors, such as anthropogenic activity, are involved.

131   Induced seismicity has been observed to increase both the background rate and clustering

132   productivity within affected regions (Lombardi et al., 2010; Llenos & Michael, 2013; Schoenball

133   et al., 2015; Maghsoudi et al., 2016, 2018; Zaliapin & Ben-Zion, 2016; Vasylkivska & Huerta,

134   2017; Martínez-Garzón et al., 2018). It is plausible that a rise in the former subsequently affects

135   a rise in the latter.

136   For example, Llenos & Michael (2013) characterized both natural and fluid injection-
137   induced swarms in Arkansas, namely the natural 1980s Enola sequence and the wastewater
138   disposal-related 2010-2011 Greenbrier sequences, by applying the epidemic type aftershock
139   sequence (ETAS) model (Ogata, 1988, 1989; Zhuang et al., 2004). The ETAS model estimates
140   the time dependent seismic rate using the summation of a constant background term with a
141   parameterized Omori-type aftershock kernel. Llenos & Michael (2013) found that the Enola and
142   Greenbrier swarms could not be modeled using the same set of parameter values, with the
143   induced cluster resulting in both a higher background rate and elevated aftershock productivity
144   relative to the natural swarm. The authors proposed that variation in the absolute values of ETAS
145   parameters may be a way to distinguish between natural and human-induced seismicity within
146   the same region, particularly changes in the background rate parameter and magnitude-weighting
147   factor. A comparable investigation was performed over the geothermal sites of Salton Sea and
148   Brawley in southern California, and obtained similar results (Llenos & Michael, 2016).

149   Zaliapin & Ben-Zion (2013a, 2013b) analyzed multiple southern California earthquake
150   catalogues, which contain a large amount of both natural (tectonic and magmatic) and man-made
151   (geothermal energy production-related) seismicity, using the nearest-neighbour distance (NND)
152   method (described in detail in section 3). Briefly, the NND approach links events to their closest
153   ancestor, i.e. their "nearest neighbour", based on a space, time, and magnitude-dependent metric.
154   Events are separated into clusters (those that are strongly linked to their nearest neighbour) and
155   background seismicity (those that are only weakly linked), whereby variation in relative mixing
156   proportions between the two populations may be evaluated. Clusters may then be classified
157   further into mainshock-aftershock "burst-like" sequences or inter-event triggered "swarm-like"
158   sequences, using their distinguishable structural characteristics. Zaliapin & Ben-Zion (2013a,
159   2013b), along with Hicks (2011), found that a natural separation occurs between clustered and
160   background events for many regional catalogues, as well as for worldwide seismicity.
161   Furthermore, the authors found that events within the clustered mode largely exhibit
162   characteristics of either burst or swarm-like sequences. Their studies agreed well with the
163   viscoelastic damage model, where a higher degree of inter-event triggering and swarm-like
164   clustering was found within more ductile regions, such as geothermal settings or areas prone to
165   magmatic or dike intrusion (e.g. Sagiya et al., 2002; Morita et al., 2006; Farrell et al., 2009),
166   whereas more brittle rheology tended toward a higher proportion of burst-like sequences.

167   1.3 Study Area and Motivation

168   This study focuses on Alberta and eastern British Columbia, where seismicity has been

169   low historically, with the majority of tectonic events occurring along the foreland belt of the

170   Rocky Mountain range (Rogers & Horner, 1991). However, isolated incidents of induced

171   spatiotemporally clustered seismicity have been documented. Baranova et al. (1999) and Eaton

172   & Mahani (2015) linked the earthquake clustering near Rocky Mountain House, Alberta, to a

173   depletion of pore pressure and an accumulation of compaction-related stress beneath the nearby

174   Strachan gas extraction field between the 1970s and 1990s. In the 1980s and 1990s, fluid

175   injection for secondary oil recovery and wastewater disposal had most likely triggered

176   earthquake clustering northwest of Fort St. John, B.C. (Horner et al., 1994). More recently, HF

177   and wastewater injection has taken place within the Montney and Horn River Basin shale

178   formations; these operations are suspected to be contributing to the growth of seismic activity in

179   that area based on spatiotemporal links to well activity as well as identification of nearby

180   subsurface fault channels (B.C. Oil and Gas Commission, 2012, 2014). Further, several studies

181   have provided evidence relating the extended HF-related fluid injection within the Duvernay

182   formation to the recent seismicity west of Fox Creek, Alberta, via pore pressure increase and

183   poroelastic stress perturbation. These events began in December 2013 as a series of clusters near

184   Crooked Lake and continue to transpire intermittently to the present day (Schultz, Stern,

185   Novakovic, et al., 2015; Bao & Eaton, 2016; Wang et al., 2016; Schultz et al., 2017; Zhang et al.,

186   2019).

187   While many other studied regions tend to have a single dominant mechanism driving

188   most of the induced earthquake activity, such as large-scale wastewater disposal in the central

189   United States (Horton, 2012; Ellsworth, 2013; Llenos & Michael, 2013; van der Elst et al., 2013)

190   or the geothermal energy operations in southern California (Brodsky & Lajoie, 2013; Zaliapin &

191   Ben-Zion, 2013a), the WCSB is characterized by a multiplicity of local triggering mechanisms.

192   The low natural occurrence rate has allowed for a relatively straightforward identification of the

193   recent surge in unnatural seismicity (e.g. Atkinson et al., 2016), in comparison to the situation in

194   other regions (e.g. Schoenball et al., 2015). Moreover, the increased seismicity may be

195   particularly consequential in low-hazard regions where facilities were not designed for high

196   seismic levels (Atkinson et al., 2020). These factors offer significant motivation to analyze the

197   regional changes in earthquake space, time, and magnitude distributions statistically. It is also

198   worthwhile to compare the different clusters and their potential triggers, particularly past cases of

199   conventional production and disposal-related earthquakes versus the recent seismicity triggered

200   by hydraulic fracturing. In this paper, we aim to characterize the regional and clustered

201   earthquakes using data from the Composite Alberta Seismicity Catalogue (CASC, described in

202   section 2) via the application of the nearest-neighbour distance method. The objectives are

203   twofold. The first is to demonstrate fundamental differences in the regional seismicity

204   distributions over time and the second is to illuminate specific features of induced seismicity

205   clustering that could be expected or recognized when performing certain types of operations,

206   particularly hydraulic fracturing.

207   In the following sections, background information is provided on the regional earthquake

208   catalogue and on four particular areas of earthquake clustering suspected to have been triggered

209   by nearby human operations (section 2). The nearest-neighbour distance methodology is

210   described (section 3). Analysis of the regional catalogue over time is presented (section 4);

211   scaling relationships and statistical properties of the four clustering sites are discussed (section

212   5). A discussion and comparison with other, similar regional studies (section 6) is followed by a

213   brief summary (section 7).

214 **2 Data and Study Regions**
215   2.1 Earthquake Catalogue

216

217 *Figure 1: Map of **M**2+ seismic events documented by the Composite Alberta Seismicity Catalogue (CASC) from 1975-2018.*
218 *Marker size and colour indicate earthquake moment magnitude.*

219   The Composite Alberta Seismicity Catalogue (CASC), available online at

220 www.inducedseismicity.ca, contains seismic event records from the early 1900s through to the

221 present. The spatial boundaries of the region encompass a rectangular area spanning $[49° -$

222 $60°N]$ and $[110° - 125°W]$, including the entirety of Alberta and a portion of eastern British

223 Columbia (Figure 1). The CASC is compiled from several contributing agencies operating across

224 Alberta and eastern British Columbia, including the Geological Survey of Canada and

225 Earthquakes Canada (www.seismo.nrcan.gc.ca), the Alberta Geological Survey and the Regional

226 Alberta Observatory for Earthquake Studies (ags.aer.ca), the Canadian Rockies and Alberta

227 Network (ds.iris.edu), and the TransAlta/Nanometrics Network (www.nanometrics.ca). The

228 catalogue contains information concerning the date, time, estimated geographic location,

229   magnitude, magnitude scale, and moment magnitude conversion for each detected event

230   occurrence (for a detailed discussion on the compilation of the CASC, see Cui et al. (2015)). The

231   database is estimated to be complete to the moment magnitude $M \approx 3$ level from 1985 onward

232   (Adams & Halchuk, 2003; Cui & Atkinson, 2016). Seismic network coverage is generally

233   spatiotemporally inhomogeneous and so local completeness levels over a given time period may

234   be substantially lower than the regional completeness; this matter is explored in the cluster

235   analyses in section 5. Accurate depth estimations remain a difficult task for most networks and,

236   as a consequence, depths listed in this catalogue have large errors or are only specified as default

237   values. While hypocentral locations would be beneficial for statistical analyses in three

238   dimensions, they are not critical. The methods used in this study require relatively few input

239   requirements; only the magnitudes, epicentral locations and times of occurrence are used from

240   the database.

241   Some potential artifacts related to catalogue inconsistencies are important to note. First,

242   many of the seismic recordings within the CASC are nontectonic and instead a product of quarry

243   and mining blasts. These events are generally flagged by network personnel based on several

244   criteria, including event time (blasts occur during daylight hours), proximity to active mines and

245   quarries, and specific waveform characteristics (typically compressional first motions and high

246   frequency spectra) (Cui et al., 2015; Schultz, Stern, Gu, et al., 2015; Cui & Atkinson, 2016). In

247   this study, all flagged events were removed from the catalogue beforehand. However, recent

248   blast events (after 2014), southwest of Calgary, had not yet been flagged by the network at the

249   time of access (last accessed June 2020, www.inducedseismicity.ca) and were hence included in

250   the analyses. A second potential artifact is that the CASC is spatially limited to the Alberta

251   region and only a portion of northeastern B.C. This explains the lack of recorded events

252   surrounding the Vancouver area in Figure 1. Readers interested in documented seismicity west of

253   Alberta are referred to the National Earthquakes Database (database link).

254   2.2 Induced Earthquake Clusters

255   The Rocky Mountain House cluster (RMHC)

256   One of the first significant instances of induced seismicity within the WCSB occurred

257   approximately 25 km southwest of the town of Rocky Mountain House, Alberta. The area had

258 been historically quiescent before the onset of conventional gas production within the Duvernay

259 formation in the early 1970s (Rogers & Horner, 1991). It became active predominantly from

260 1975-1992, lagging production rates by several years and returning to apparent background

261 activity by the year 2000. Wetmiller (1986) found that the majority of events occurred roughly

262 within a 15 km radius and were concentrated close to the Strachan and Ricinus gas fields.

263 Baranova et al. (1999) proposed that the earthquakes were triggered due to long-term

264 compaction-related changes in the stress field caused by the extraction of fluid. We refer to this

265 collection of events between 1975-2000 as the RMHC (Figure S1).

266 The Montney clusters (MC1 & MC2)

267 Conventional oil and gas production has occurred within the Montney formation, which

268 stretches across northeastern British Columbia and northwestern Alberta, since the 1950s.

269 Associated wastewater disposal wells have been active from the 1960s and are suspected to have

270 triggered two distinct earthquake clusters (Horner et al., 1994; B.C. Oil and Gas Commission,

271 2014). The first began in 1984, north of the town Fort St. John, B.C., and the second began in

272 2003, west of Halfway Ranch, B.C. We collectively refer to these two clusters, occurring

273 predominantly between 1984-2009, as the MC1.

274 Since the mid-to-late 2000s, with the development of horizontal drilling and HF

275 technology, the Montney trend has attracted significant interest for its siltstone and shale gas

276 reserves. By 2018, thousands of natural gas wells were active in the area, operating along the

277 formation's northwestern margin as well as to the southeast near Dawson Creek, B.C. In

278 addition, more than 15 wastewater disposal wells have been drilled since 2005, bringing the

279 formation's total to over 100 (B.C. Oil and Gas Commission, 2014). Since then, substantial low-

280 to-moderate seismicity has been recorded in the area, due to the augmentation of the local

281 seismic network and possibly the increase in subsurface human activity. The distribution of

282 events occurring in the formation has changed over time, as the dominant triggering mechanism

283 shifted from wastewater injection to HF (B.C. Oil and Gas Commission, 2014; Atkinson et al.,

284 2016). We refer to the recently recorded seismicity in this area, from 2010 to 2018, as the MC2.

285 The Fox Creek Cluster (FCC)

286   Conventional production in central Alberta, primarily within the Duvernay, Swan Hills

287 and Leduc formations, has been occurring since the 1960s and resulted in minor associated

288 seismicity apart from the clustering near Rocky Mountain House. However, in December 2013,

289 earthquakes began occurring approximately 30-40 km west of the town of Fox Creek, Alberta,

290 where HF wells had recently been drilled in order to access the Duvernay's reservoirs of tight

291 shale. Several hundreds of these wells have been drilled since 2012, near the recent clustering,

292 and a large proportion were drilled horizontally or at a deviated angle. Seismic activity began as

293 a few distinct sequences near Crooked Lake, Alberta, and continues to form further clusters up to

294 the present day (Bao & Eaton, 2016; Clerc et al., 2016; Deng et al., 2016; Schultz et al., 2016,

295 2017, 2018; Wang et al., 2016; Eaton et al., 2018; Zhang et al., 2019). We refer to this group of

296 events, from 2013 to January 2020, as the FCC.

297   We focus our study on these four clusters, as their seismicity is sufficiently rich for

298 analysis. New clusters continue to emerge, such as those in the area near Red Deer, Alberta (e.g.

299 Schultz et al., 2020).

300 **3 The Nearest-Neighbour Distance Method**

301   The nearest-neighbour distance (NND) method is a statistical approach to earthquake

302 cluster identification and classification, first formulated by Baiesi & Paczuski (2004) and

303 expanded significantly by Zaliapin et al. (2008) and Zaliapin & Ben-Zion (2013a, 2013b, 2016).

304 Its purpose is to link together and characterize *event families* or *sequences* using a rescaled inter-

305 event distance metric termed the nearest-neighbour distance η, which is defined below as space,

306 time and magnitude dependent. This method is applied in sections 4 and 5 in order to describe

307 the regional and local inter-event distance distributions within the WCSB as well as to

308 statistically categorize the types of seismic clustering observed.

309   3.1 The Rescaled Inter-Event Distance Metric η

310   The inter-event distance values η_{ij} are defined based on the spatiotemporal distance

311 between each event pair within the catalogue as well as on the magnitude of the event that

312 occurred *first* (the potential *parent* event i). Specifically, each event j is assigned values η_{ij} based

313 on its relationship with all other events i as

$$\eta_{ij} = \begin{cases} t_{ij}(r_{ij})^{d_f}10^{-bm_i}, t_{ij} > 0 \\ \infty, \quad t_{ij} \leq 0 \end{cases}, \qquad [1]$$

314 where $t_{ij} = t_j - t_i$ is the time in days between event j and event i. Note that event j must

315 succeed event i in order for the quantity t_{ij} to be positive, otherwise $\eta_{ij} = \infty$.

316   The inter-event spatial distance r_{ij} is computed between epicenters using the Haversine

317 formula for great-circle distance (or arc length) in kilometers

$$r_{ij} = 2r_e \arcsin \sqrt{\sin^2\frac{(\varphi_i - \varphi_j)}{2} + \cos\varphi_i \cos\varphi_j \sin^2\frac{(\lambda_i - \lambda_j)}{2}}. \qquad [2]$$

318 In Equation [2], r_e is the Earth's radius estimated as 6378.14 km, and (φ_i, λ_i) and (φ_j, λ_j) are the

319 latitudinal and longitudinal coordinates of events i and j, respectively.

320   d_f is the fractal spatial dimension of earthquake epicenter distribution. In 2 dimensions,

321 for both local and worldwide epicentral distributions, d_f has been found to vary approximately

322 between 1.2 and 1.6 (Sadovsky et al., 1984; Kagan, 1991; Kosobokov & Mazhkenov, 2013). m_i

323 is the magnitude of the ith event and b is the Gutenberg-Richter b-value, which approximates the

324 exponential distribution of magnitude scaling according to

325

$$N (\geq M) = 10^{a-b(M-M_0)}; M \geq M_0, \qquad [3]$$

326 where $N (\geq M)$ is the number of detected events greater than or equal to magnitude M and a

327 reflects the rate of seismicity over the time period considered.

328

329

330

331

332   The scalar distance η_{ij} may be expressed in terms of its rescaled temporal and spatial

333   components by defining

$$T_{ij} = t_{ij} 10^{-\frac{bm_i}{2}} ;$$

[4]

$$R_{ij} = r_{ij}{}^{d_f} 10^{-\frac{bm_i}{2}} .$$

334   By this formulation, $\eta_{ij} = T_{ij} R_{ij}$. Once nearest-neighbour values η have been determined for

335   each event j, where $\eta_j = \min_{i \; i<j} \eta_{ij}$, the η distribution, the joint distribution of (T, R) as well as

336   their individual histograms can be plotted to observe possible modality in the temporal and/or

337   spatial distance between events. Hicks (2011) showed that a bimodal distribution in η,

338   interpreted as a distinction between background and clustered events, is an intrinsic property of

339   both worldwide and regional seismicity. The clustered mode is identified as the subpopulation of

340   events occurring at small η values (small inter-event distances); these events are considered to be

341   strongly linked to their nearest neighbours. The background mode is identified as the set of

342   events occurring at larger η values (larger inter-event distances); these events are considered to

343   be only weakly linked to their nearest neighbours.

344   3.2 Formal Analysis of Modality in the η Distribution

345   Although the subpopulations of clustered and background events may be apparent upon

346   visual inspection, it is useful to define them rigorously considering a Gaussian mixture model

347   (GMM), as detailed in Hicks (2011). A GMM is defined as a composition of normal density

348   functions, each with a mean, covariance and mixing proportion (or weight). The parameters for

349   these component functions are estimated using the 2-step expectation-maximization algorithm

350   (Hastie et al., 2009). The approach uses an initial guess for the set of parameters to then:

351   a) Calculate Bayesian probabilities for each data point as a possible member of each

352   mode. This is the expectation step.

353   b) Estimate the model parameters for each mode through their maximum likelihood

354   function, using the probabilities determined in the expectation step as weights. This is

355   the maximization step.

356   This process is iterated until it converges to the optimal estimation of the means, standard

357   deviations and weights. The number of modes in the distribution is determined using information

358   criteria. The model that minimizes the information criteria is considered the best fit. Two such

359   criteria were used in this study, the Akaike and Bayesian information criteria (Akaike, 1974;

360   Schwarz, 1978). The threshold value $\log_{10} \eta_{thresh}$, which separates the background mode from

361   the clustered mode, is chosen as the intersection point between the resulting component

362   densities.

363   3.3 Event-Family Classification

364   By removing all weak links from the NND distribution, the clustered mode may be

365   further discretized into hierarchical families based on the strong links between parents and

366   offspring events. The largest event in each family is classified as the mainshock; if there is more

367   than one largest-magnitude event then the first is considered the mainshock. Events in the

368   sequence that occur before the mainshock are called foreshocks and occur after are called

369   aftershocks. An aftershock's *generation,* or *order,* is determined by its hierarchical distance from

370   the mainshock. For example, an aftershock whose parent event is the mainshock is considered 1st

371   generation, while an aftershock whose parent event is a 1st generation aftershock is considered

372   2nd generation, and so on.

373   These families can be categorized as aftershock sequences, seismic swarms, a

374   combination of the two, or neither, based on statistical parameters introduced by Zaliapin & Ben-

375   Zion (2013b). These parameters quantify the structural characteristics of each event family and

376   can determine their structure type. The terminology of a rooted tree-graph is employed, which

377   considers the first event in a sequence as the *root* of the tree, the downward-directed edges

378   connecting events as *branches* and the end-nodes (earthquakes that have no further offspring) as

379   *leaves*. The size N is computed as the number of events in a sequence. The *leaf depth d* is

380   calculated by counting the number of branches connecting each leaf back to its root. The *average*

381   *leaf depth $\langle d \rangle$* of a particular tree provides an indication of its shape, with larger $\langle d \rangle$ potentially

382   indicating higher levels of event chaining and a deeper structure, and smaller $\langle d \rangle$ implying low

383   orders of event offspring and a shallower structure. Therefore, swarm sequences are expected to

384   have larger $\langle d \rangle$ values than bursts, even given a similar number of leaves. However, since $\langle d \rangle$

385   scales with the sequence size N, a normalized leaf depth δ, where $\delta = \frac{\langle d \rangle}{\sqrt{N}}$, is also calculated. The

386   *inverted branching number B_I* of a tree is computed as the number of parent events divided by

387   the total number of branches. A maximum B_I value of unity indicates a perfect path shape and

388   only a single leaf within the structure. Smaller values of B_I imply more offspring from fewer

389   parents, i.e. a more burst-like formation. The *magnitude differential* Δm is defined as the

390   difference between the designated mainshock and second-largest event in a sequence. Generally,

391   aftershock sequences tend to have larger Δm values than swarms, given a similar size *N*. In

392   addition, we compute the *spatial area A* (in km^2) and *time period t_D* (in days) covered by each

393   family. However, these parameters also scale with *N* and are included for observational purposes

394   only.

4 Regional Analysis of NND Distributions within the WCSB

396   In this section, we applied the nearest-neighbour distance (NND) method to the regional

397   Composite Alberta Seismicity Catalogue (CASC; detailed in section 2). The entire time period,

398   between 1975-2018, was analyzed, as were separated time windows, between 1975-2009 and

399   2010-2018. The separation between time frames was chosen to correspond with the rapid rise in

400   hydraulic fracturing implementation that occurred within the region after 2009 (e.g. Atkinson et

401   al., 2016, 2020)

402   Zaliapin & Ben-Zion (2013a, 2013b) showed that NND distributions are stable for cut-off

403   magnitudes below the regional completeness magnitude ($M_c \approx 3.0$ in this case); we therefore

404   applied a magnitude cut-off of $M_0 = 2.0$ to enrich sampling. Figures S5-8 show that the results

405   found here hold for cut-off magnitudes up to the regional completeness level. The same constant

406   values $d_f = 1.5$ and $b = 1.0$ were used for each subset of the regional data to illustrate the

407   fundamental differences observed over time without prior parameterization.

408   4.1 Entire Time Period (1975-2018)

409
Figure 2: *NND distribution of the regional WCSB catalogue (1975-2018) using $M_0 = 2.0$. a) Joint distribution of the temporal and spatial components (T,R). Bold white line indicates the threshold $\log_{10} \eta_{thresh}$ between tightly clustered and loosely clustered components. Thin white line indicates the threshold $\log_{10} \eta_{tect}$ between loosely clustered and deep-background components. Colour bar indicates frequency of inter-event distance occurrence. b) Normalized density of η values. Solid black line is $\log_{10} \eta_{thresh}$ and dashed black line is $\log_{10} \eta_{tect}$. Dashed red line is the normalized probability density function of the Gaussian mixture and black crosses are the component means.*

416   Figure 2 shows the 2-dimensional (*T,R*) distribution and the normalized density of

417   nearest-neighbour distances η for the entire study period. There are two prevailing modes within

418   the joint distribution (Figure 2a), which differ in size and shape. The clustered mode, to the

419   bottom-left of the plot beneath the bold white line, is oriented somewhat horizontally, while the

420   background mode, in between the two white lines, covers a broader range along the *T* and *R* axes

421   and is faintly oriented along the downward diagonal. This observation is consistent with most

422   findings in other studies, which showed the existence and distinct shaping of clustered and

423   background earthquake subpopulations in several tectonic and induced areas (Hicks, 2011;

424   Zaliapin & Ben-Zion, 2013a, 2016; Schoenball et al., 2015). Notably, in these cases the

425   background mode was reminiscent of a time-stationary, space-inhomogeneous marked Poisson

426   process, which forms a unimodal distribution concentrated along a downward diagonal at large T

427   and R, while the clustered mode typically occupies an ellipse at smaller T and R values than

428   would be expected from a Poisson process (Zaliapin & Ben-Zion, 2013a). The chief disparity

429   between different regions, including within the WCSB, lies in the relative intensities, or mixing

430   proportions, of each mode; these proportions tend to reflect the nature of seismicity occurring

431   (discussed further below). More difficult to see in Figure 2a is a third subpopulation, to the

432   upper-right above the thin white line, which is much less concentrated and sprawls along a

433   downward diagonal over large values of T and R. The one-dimensional η distribution (Figure 2b)

434   reflects this tri-modality clearly, with the third mode at large η perhaps more apparent.

435   The results of the Gaussian mixture model analyses indicate that the optimal mixture

436   estimation, i.e. a minimization of the information criteria, is a 3-component, instead of the

437   typically observed 2-component (clustered and background), distribution. This may be observed

438   in Figure 2b, where the dashed red line and black crosses represent the resulting probability

439   density function and 3 component means, respectively.

440   The intersection point between the two dominant modes occurs at $\log_{10}\eta_{thresh} = -4.2$,

441   shown by the bolded white line in Figure 2a, and solid black line in Figure 2b. Out of the 3531

442   total events analyzed, 29% were found in the clustered domain, which is henceforth referred to

443   as the *tightly clustered* mode. 56% were located in the middle mode, which is henceforth referred

444   to as the *loosely clustered* mode, and 15% were located in the third mode at large η, henceforth

445   referred to as the *deep background*. The intersection between the loosely clustered and deep

446   background modes occurs at $\log_{10}\eta_{tect} = -1.7$, shown by the thin white line in Figure 2a, and

447   dashed black line in Figure 2b. No definitive trends were apparent in the individual T or R

448   distributions (not shown), with the exception of an increasing proportion of small R distances

449   that tended to stack at the limits of network location resolution, giving the tightly clustered mode

450   its azimuthal shape. This agrees with another observation of Zaliapin & Ben-Zion (2013a), who

451   state that the modality in η cannot be fully explained by marginal trends present in either T or R

452   but is in fact dependent on the association between the two, as seen in the 2-dimensional joint

453   distribution.

454   4.1.1 Comparative Analysis of Mixture Components

455

Figure 3: *Joint (T,R) distributions of individual modes for the regional WCSB catalogue (1975-2018) using $M_0 = 2.0$. Colour bar indicates frequency of inter-event distance occurrence. Bold white line indicates the threshold $\log_{10} \eta_{thresh}$ between tightly clustered and loosely clustered components. Thin white line indicates the threshold $\log_{10} \eta_{tect}$ between loosely clustered and deep background components. a) Entire distribution. b) Tightly clustered mode. c) Loosely clustered mode. d) Deep background.*

460   Figure 3 plots the modal decomposition of the joint distribution, where each

461   subpopulation is plotted separately, removing the dependence on mixing proportion. As

462   mentioned above, if a distribution does not intensify along the bisecting diagonal (constant η)

463   and instead forms an elliptical cloud, then a trend may exist in the data as a deviation from

464   Poisson behavior. As expected, the tightly clustered subpopulation deviates substantially from

465   the diagonal and forms an ellipse within the sub-region $\{-5 < \log_{10} T < -3.5 \mid -1.5 <$

466    $\log_{10} R < -0.5\}$. The loosely clustered mode is faintly concentrated along the diagonal yet also

467   forms a cloud within the sub-region $\{-3.5 < \log_{10} T < -1 \mid -1.5 < \log_{10} R < 1\}$. By contrast,

468 the deep background is distributed very closely along the diagonal and stretches almost its
469 complete length, most clearly resembling a Poisson process.

470

Figure 4: *Spatial map of earthquakes for the regional WCSB catalogue (1975-2018) using $M_0 = 2.0$, represented in terms of*
their nearest-neighbour distance categorization. Blue markers are the deep background, orange markers are the loosely
clustered events and yellow markers are the tightly clustered events. Marker size indicates magnitude. Dashed boxes surround
areas of suspected induced clustering (see (Atkinson et al., 2016)).

475   A spatial map of the catalogued earthquakes is displayed in Figure 4. Blue markers
476 represent deep background events, while orange and yellow markers represent the loosely
477 clustered and tightly clustered events, respectively. Dashed boxes surround individual areas of
478 suspected induced activity. According to the NND method, both the blue and orange markers are
479 classified as the "background" portion of events. However, the two subpopulations are not
480 representative of the same type of seismicity. As a physical representation of the results in Figure
481 3, the blue markers are substantially more evenly distributed and seemingly reflective of the

482   natural tectonic background (the majority occur along the foreland belt of the Rocky Mountain

483   range), whereas an obvious spatial dependence on the distribution of orange and yellow markers

484   is indicative of clustering. The orange and yellow markers overwhelmingly dominate the dashed

485   boxes.

486   We also observe that the background events which occurred farther away from their own

487   potential parent were less likely to initiate a clustering sequence, with deep background events

488   substantially less likely to trigger future earthquakes than loosely clustered events. Out of 320

489   non-single event families, 281 (88%) began from the loosely clustered mode and 39 (12%) began

490   from the deep background. Out of the 35 identified *significant* sequences, which we arbitrarily

491   define as containing five or more events, 33 (94%) initiated from loosely clustered ancestors

492   while only 2 (6%) initiated from the deep background. This correlation holds for all family sizes;

493   as the number of events within a family *increases*, the likelihood of the family to originate from

494   the loosely clustered mode also *increases*. On the other hand, it is true that there is a larger

495   population of loosely clustered events, which could partially explain the disparity. However,

496   even relative to the mixing proportion of each mode, a non-single event family is twice as likely,

497   and a significant event family is nearly four times as likely to have originated from the loosely

498   clustered mode rather than in the deep background. This may be observed in Figure 4; overlap

499   occurs substantially between loosely clustered (orange) and tightly clustered (yellow) markers,

500   but rarely occurs between deep background (blue) and tightly clustered (yellow) markers.

501   Overall, the differences between the loosely clustered and deep background subpopulations

502   appear noteworthy and demonstrable.

503   4.2 Separated Time Periods: 1975-2009 and 2010-2018

504
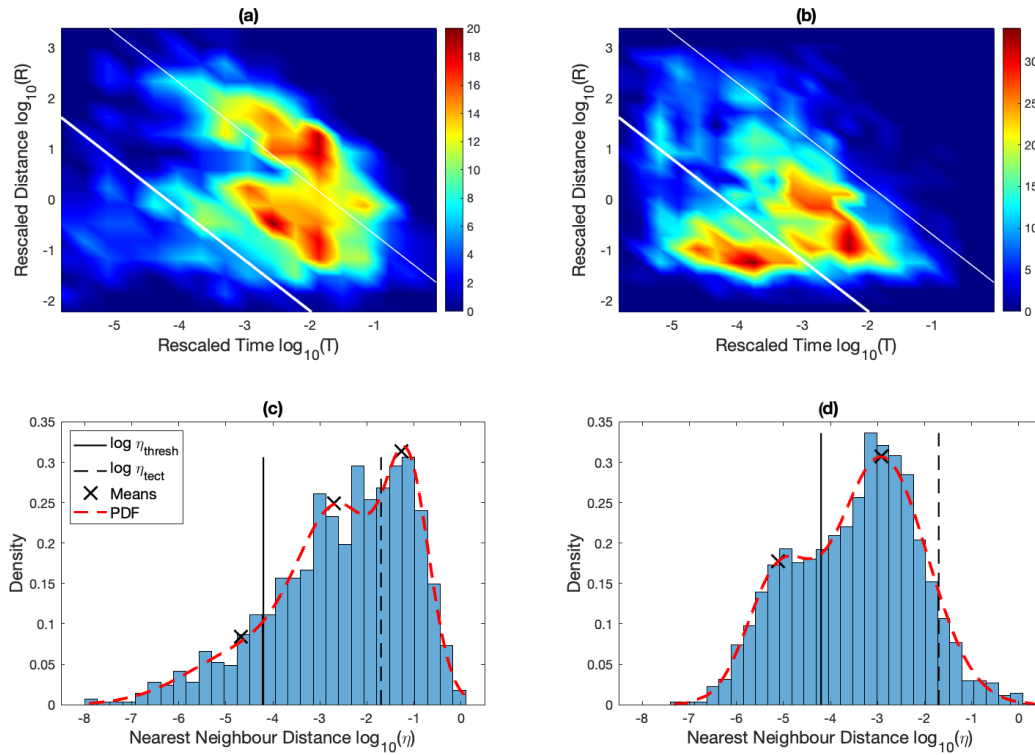

Figure 5: Comparison of NND distributions of the regional WCSB catalogue across time using $M_0 = 2.0$. (a,b) Joint

distributions of the temporal and spatial components (T,R). Bold white line indicates the threshold $\log_{10} \eta_{thresh}$ between tightly

clustered and loosely clustered components. Thin white line indicates the threshold $\log_{10} \eta_{tect}$ between loosely clustered and

deep background components. Colour bar indicates frequency of occurrence. (c,d) Normalized densities of η values. Solid black

line is $\log_{10} \eta_{thresh}$ and dashed black line is $\log_{10} \eta_{tect}$. Dashed red line is the normalized probability density function of the

Gaussian mixture and black crosses are the component means. (a, c) 1975-2009, both background modes are dominant. (b, d)

2010-2018, deep background shrinks while tightly clustered mode appears. The loosely clustered subpopulation is common to

both time frames.

513   Figure 5 presents the *(T,R)* and η distributions of the WCSB for separated time intervals.

514   From 1975-2009, the regional catalogue is characterized by natural activity and isolated cases of

515   induced clustering due to conventional oil and gas production and associated wastewater

516   disposal, primarily within the Duvernay and Montney formations (Wetmiller, 1986; Rogers &

517   Horner, 1991; Horner et al., 1994; Baranova et al., 1999; Schultz et al., 2014). The resulting

518   space-time inter-event distance distribution shows that both background modes are dominant,

519   containing 83% of all events analyzed, indicating mainly single events and loose clustering, but

520   little tight clustering (Figure 5a and Figure 5c). In contrast, the regional catalogue between 2010-

521   2018 is characterized by sparse natural activity, due to the shorter time-frame, and large amounts

522 of induced activity attributed to the sharp rise in the implementation of horizontally drilled HF

523 operations within the Duvernay, Montney, Cardium and Bakken formations, among others (B.C.

524 Oil and Gas Commission, 2012, 2014; Schultz, Mei, et al., 2015; Schultz, Stern, Novakovic, et

525 al., 2015; Atkinson et al., 2016; Bao & Eaton, 2016). The joint distribution changes strikingly;

526 the deep background subpopulation nearly disappears and a tightly clustered mode arises,

527 indicating both substantial loosely clustered and tightly clustered seismicity (Figure 5b and

528 Figure 5d). An important factor to consider is the variation in seismic monitoring capability over

529 time; many more stations were operational during the recent time period, which undoubtedly had

530 an effect on the distributions. We show below that the changes in mixing proportion across time

531 are vastly disproportionate and cannot be entirely attributed to improvement in network

532 detection.

533   The Gaussian mixture model analysis over the first time period detects the same three

534 modes identified over the entire time frame. Over the second period, it picks out only the tightly

535 clustered and loosely clustered components. This is understandable, as the deep background

536 shrinks and ultimately contains only 7.5% of the mixing proportion from 2010-2018. Overall,

537 there is a 27% drop in the relative number of deep background events and a 10% increase in the

538 proportion of loosely clustered events between the two time periods. There is a 17.5% increase in

539 the relative population of tightly clustered events. The changes in rate are disproportionate; while

540 the yearly detected **M**2+ deep background rate roughly doubles, the loosely and tightly clustered

541 rates increase tenfold and seventeen-fold, respectively. The disproportionality holds above the

542 estimated regional completeness level $M_c = 3.0$; for magnitudes above this threshold, the deep

543 background rate is almost doubled across the two time periods, while the loosely and tightly

544 clustered rates both increase nearly six-fold (Figure S8). We perform a two-sample Kolmogorov-

545 Smirnov test on the distributions of η values between the separated time periods, in order to test

546 the null hypothesis that the differences observed are within sampling errors and the two samples

547 are actually from the same continuous distribution. The test rejects the hypothesis at the 99%

548 confidence level.

549   These results suggest that the changes in the inter-event distance distribution across

550 Alberta and eastern B.C. over time are statistically significant and not naturally occurring. The

551 decreased mixing proportion of deep background events indicate that the majority of the recent

552 seismicity is not tectonic, while the increase in tightly clustered seismic activity correlates

553   temporally with the rise in horizontally drilled HF treatments within the region. Figure 4 shows

554   that clustering is highly spatially correlated with human activity as well, with smaller inter-event

555   distances (i.e. orange and yellow markers) transpiring chiefly near areas flagged as suspicious.

556   The statistical properties of several of these suspicious areas are explored in detail in the next

557   section.

558   **5 Analysis and Comparison of Isolated Seismic Clusters**

559   Here we examine four separate cases of seismic clustering within the Western Canada

560   Sedimentary Basin (WCSB): the Rocky Mountain House cluster (RMHC) – induced by

561   conventional natural gas extraction, the Montney clusters (MC1 and MC2) – triggered by

562   wastewater disposal and hydraulic fracturing, and the Fox Creek Cluster (FCC) – induced by

563   hydraulic fracturing (these clusters are described in more detail in section 2; see Figures S1-4 for

564   related event maps).

565   5.1 Frequency-Magnitude Statistics

566
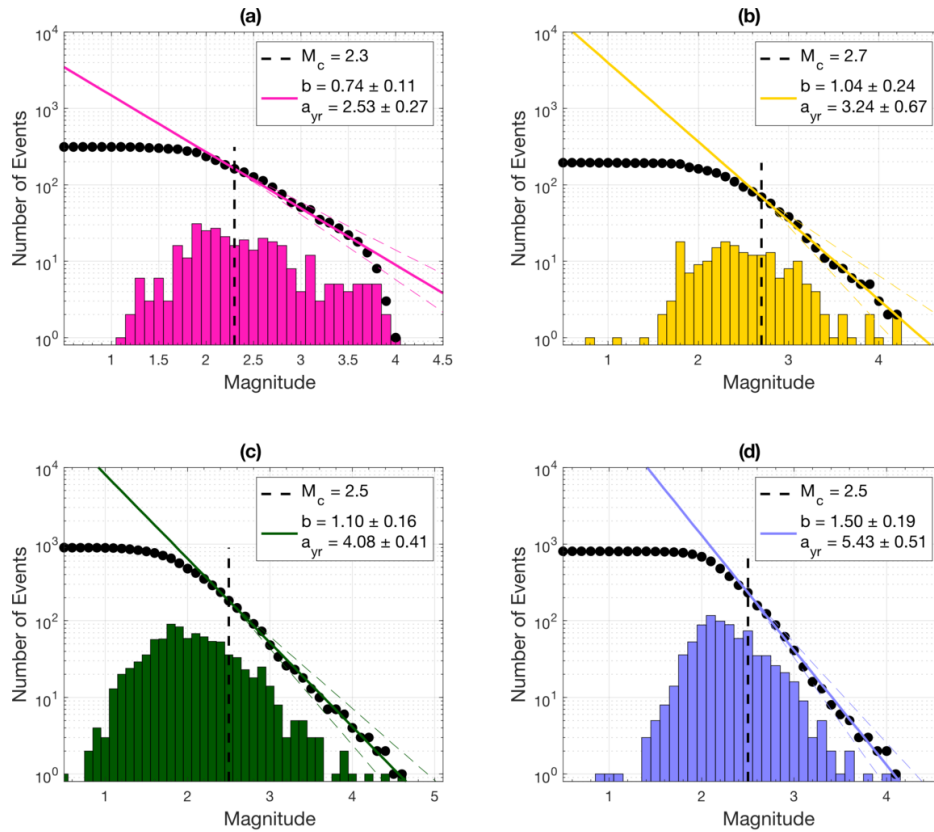

Figure 6: Frequency-magnitude distributions and estimated Gutenberg-Richter parameters for each investigated cluster. Coloured histograms represent the non-cumulative magnitude distributions and black dots represent the cumulative magnitude distributions. Dashed black lines indicate the determined magnitude of completeness. Coloured lines represent the modeled GR relations. a) Rocky Mountain House cluster. b) Montney cluster 1. c) Montney cluster 2. d) Fox Creek cluster.

We begin by assessing the frequency-magnitude distributions (FMDs) of each cluster and computing their Gutenberg-Richter scaling parameters (Figure 6). The FMD plots the cumulative and non-cumulative frequencies of earthquake magnitude occurrence in log-linear space. We use the maximum likelihood method to determine the *b*-values along with their 95% uncertainties (Aki, 1965; Utsu, 1966; Shi & Bolt, 1982). The local completeness level in each case was determined using a suite of catalogue-based methods, namely the method of maximum curvature, the goodness-of-fit test, and the method of *b*-value stability (Wiemer & Wyss, 2000; Cao & Gao, 2002).

The RMHC, which was induced by conventional gas extraction, is characterized by a very broad distribution of event magnitudes resulting in a very low *b*-value (Figure 6a, *b* =

581   0.74 ± 0.11). This contrasts with the Fox Creek cluster (FCC), induced by hydraulic fracturing,

582   whose FMD is very steep and contains many more small magnitude events and fewer large

583   magnitude events. As a consequence, it is described by a very high *b*-value (Figure 6d, $b =$

584   1.50 ± 0.19). Both the wastewater disposal and hydraulic fracturing-induced Montney clusters

585   (MC1 and MC2) have more typical magnitude distributions (Figure 6b, $b = 1.04 \pm 0.24$ and

586   Figure 6c, $b = 1.10 \pm 0.16$). The *a*-values are normalized to reflect the yearly-detected

587   seismicity rate. It is unsurprising that the more recent, densely populated clusters (MC2 and

588   FCC) have the highest yearly *a*-values, whereas the RMHC and MC1 both span longer periods of

589   time and are smaller overall, resulting in lower yearly *a*-values.

590   5.2 Nearest-Neighbour Distance Distributions

591
592   *Figure 7: Joint NND distributions of the temporal and spatial inter-event distances (T,R) for each investigated cluster. Bold*

593   *white line indicates the threshold $\log_{10} \eta_{thresh}$ between tightly and loosely clustered components. Thin white line indicates the*

594   *threshold $\log_{10} \eta_{tect}$ between the loosely clustered and deep background. Colour bar reflects inter-event distance occurrence*

595   *frequency. a) Rocky Mountain House cluster. b) Montney cluster 1. c) Montney cluster 2. d) Fox Creek cluster.*

596   Next, we use the *b*-values determined above to parameterize and plot the joint space-time

597 nearest-neighbour distance (NND) distributions for each cluster, which reflect the mixing

598 proportions of loosely and tightly clustered earthquakes (Figure 7). As an initial observation, the

599 modal locations of all four clusters provide confirmation of some of the regional interpretations

600 formed in section 4. In particular, we suggested that the regional clustering observed within the

601 WCSB occurred within a distinct subset of the multidimensional inter-event NND space, namely

602 within the $\log_{10} \eta \leq \log_{10} \eta_{tect}$ realm (i.e. within the loosely and tightly clustered domains). The

603 remaining earthquakes were evenly distributed and occurred largely within the $\log_{10} \eta >$

604 $\log_{10} \eta_{tect}$ realm (i.e. within the deep background domain). From Figure 7, it is indeed the case

605 that all of the investigated clusters occupy the $\log_{10} \eta \leq \log_{10} \eta_{tect}$ realm.

606   However, *within* the $\log_{10} \eta \leq \log_{10} \eta_{tect}$ realm, several distinctions between the clusters

607 regarding their mixing proportions can be made. The RMHC (Figure 7a) and MC1 (Figure 7b)

608 distributions are visually similar, containing dominant populations of loosely clustered events.

609 We can estimate the proportions of loosely clustered background events μ_{GMM}, based on a

610 bimodal Gaussian mixture model (disregarding the deep background), which is computed as a

611 fraction of the total seismicity within each cluster. This yields $\mu_{GMM} = 0.86$ for the RMHC and

612 $\mu_{GMM} = 0.74$ for the MC1. The majority of earthquakes in these clusters occur somewhat closely

613 together in space and time, but mainly as separate instances that rarely trigger future earthquakes.

614 This loosely clustered activity of single events may reflect the type of seismicity expected to

615 occur within the WCSB due to steady, long-term alterations to the subsurface stress field, such as

616 long-term gas extraction and wastewater disposal (Wetmiller, 1986; Horner et al., 1994;

617 Baranova et al., 1999; B.C. Oil and Gas Commission, 2014). Conversely, both the MC2 (Figure

618 7c) and FCC (Figure 7d) distributions contain distinct modes within the tightly clustered

619 $(\log_{10} \eta < \log_{10} \eta_{thresh})$ domain. The existence of these modes indicates that a significant

620 proportion of earthquakes are occurring very closely together and are possibly occurring in direct

621 response to a triggering mechanism (previous earthquakes and/or external forces). The

622 proportion of loosely clustered events in the MC2, estimated by the bimodal Gaussian mixture

623 model, reduces to $\mu_{GMM} = 0.41$. The FCC is further distinguishable from the other clusters by its

624 apparent lack of a loosely clustered subpopulation ($\mu_{GMM} = 0.09$). This is quite significant, as it

625 implies that either: (i) the small population of background events occurring in this area is capable

626 of triggering massive amounts of tightly clustered activity; or (ii) other, external triggering

627   factors are contributing to the unnatural levels of event sequencing. Based on the spatiotemporal

628   correlations between the increased rates of seismicity and the rise in horizontally drilled HF

629   operations made here and in other studies, it is logical to connect HF as one of the probable

630   causative mechanisms (discussed further below).
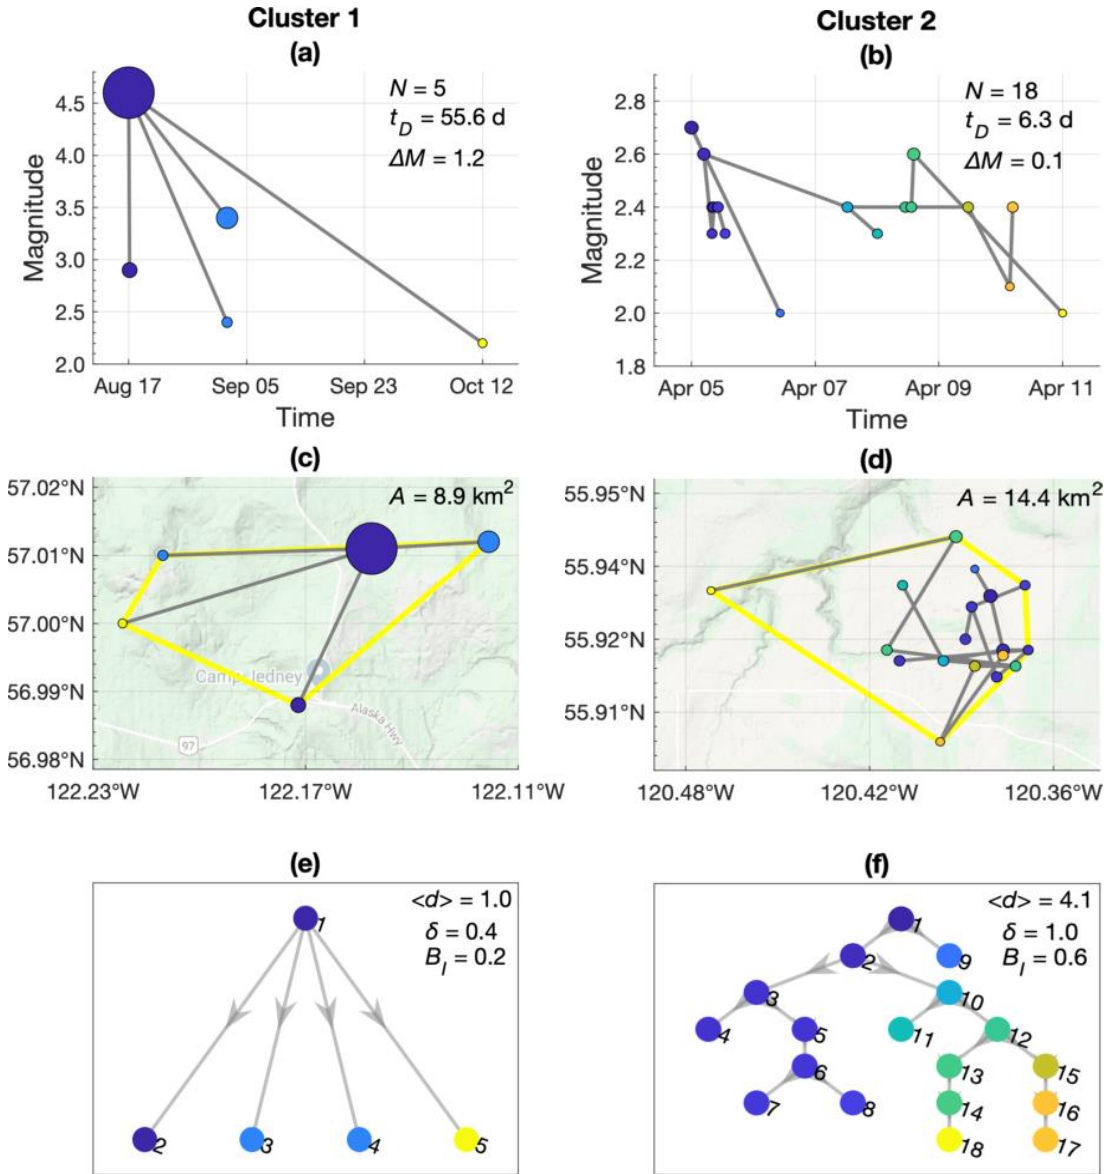

631   5.3 Event-Family Classification

632

633   *Figure 8: Characterizations of "burst" and "swarm" sequences found in the MC2. Circles represent earthquakes and are*

634   *coloured chronologically from darkest to lightest; grey lines represent the strong links connecting them. (a,b) Event family*

635   *magnitudes vs. times of occurrence.(c,d) Spatial maps of events; yellow border outlines the hull area occupied by the sequence.*

636   *(e,f) Topological trees, which branch downward in time.*

637   In this subsection, we discretize each of the RMHC, MC1, MC2, and FCC's tightly

638   clustered NND subpopulations into hierarchical families based on the strong links between

639   parents and offspring events. We then categorize these families as aftershock sequences, seismic

640   swarms, a combination of the two, or neither, based on statistical parameters outlined by Zaliapin

641   & Ben-Zion (2013b) (see section 3.3 for a detailed description of these parameters). We consider

642   only those families consisting of three or more events; event-pairs are discarded, as are the single

643   events that chiefly populate the background mode.

644   The RMHC and MC1 are each composed of six significant sequences across 26-year

645   periods; these sequences are small, with the largest containing five and eight events, respectively.

646   The MC2 is composed of ten families over a 9-year period, the largest containing 17 events,

647   while FCC is comprised of 16 sequences over a 6-year period, the largest containing 80 events.

648   Figure 8 shows examples of two families identified in the MC2, along with their associated

649   parameters, displayed as time-magnitude sequences, spatial maps and time-oriented, topological

650   trees. Cluster 1 is a typical aftershock sequence while Cluster 2 is a swarm. Intuitively, Cluster 1

651   is characterized by a *burst* or *spray-like* shape, involving a dominant mainshock causing several

652   lower magnitude, 1st generation offspring in multiple directions. Conversely, Cluster 2 displays a

653   *linear* or *path-like* shape where the events are chained together gradually, the mainshock is less

654   distinct and is succeeded by multiple generations of aftershocks.

655   **Table 1**: *Mean and median parameter values for all significant event families within each investigated cluster.*

Cluster	Number of Families		N	$\langle d \rangle$	δ	B_I	A (km^2)	t_D (days)	ΔM
RMHC	6	Mean	3.67	1.22	0.64	0.50	8.40	1.33	0.57
		Median	3.5	1	0.58	0.5	5.93	1.00	0.25
MC1	6	Mean	4.17	1.83	0.92	0.68	23.45	23.60	0.35
		Median	3.5	2	0.855	0.58	4.42	5.52	0.25
MC2	10	Mean	7.60	2.76	1.08	0.67	26.33	24.83	0.27
		Median	5.5	3	1.125	0.71	7.19	5.23	0.1
FCC	16	Mean	27.13	7.60	1.54	0.66	20.97	32.09	0.22
		Median	20.5	6.19	1.27	0.65	17.16	15.05	0.1

656 Table 1 presents the mean and median parameter values for all of the detected sequences

657 (see Figures S9-12 for the structural representations of all sequences, analogous to Figure 8). The

658 RMHC is almost entirely composed of small bursts; these sequences have a relatively large

659 mainshock and are followed by few (four or less) aftershocks. The mean and median values of

660 the magnitude differential Δm are large while the normalized leaf depth δ and inverted

661 branching number B_I are small, highlighting the spray-like nature of the sequences. The MC1 is

662 comprised of a mixture of small bursts and swarms. Its mean and median Δm are slightly smaller

663 and its topological parameters are larger than the RMHC's, indicating more swarm-like behavior

664 and possibly some level of inter-event triggering. The MC2 is more swarm-like than the MC1; it

665 consists of a large swarm, a large burst and smaller sequences. The mean and median topological

666 parameters are larger than both previous clusters while the magnitude differential is smaller. This

667 signifies that, apart from the large burst, the mainshocks are generally less distinct, the sequences

668 are graphically deeper and there are more parent events and fewer leaves. The mean Δm is

669 skewed somewhat by the large burst, which explains the disparity between it and the median

670 value. The FCC is overwhelmingly swarm-like; 13 of the 16 sequences are chain-like in time

671 (mean and median δ are large) and contain similarly sized events (mean and median Δm are

672 small). The B_I values are similar to the MC1 and MC2. The remaining 3 families in the FCC

673 consist of a large burst and two swarm-bursts (where there is a large mainshock but also many

674 generations of foreshocks and aftershocks chained together; see Figure S12, clusters 5 and 6). It

675 is important to note that while the average leaf depth $\langle d \rangle$ scales with the sequence size N, both δ

676 and B_I do not.

677 The spatial extents A and timeframes t_D are slightly more difficult to contextualize as

678 these parameters scale with N. The sequences within the RMHC are quite consistent; they all

679 cover small spatial areas and decay rapidly (within days). The MC1 suffered from occasional

680 improper location recording, where several events were placed in the same spot, resulting in

681 inaccurate area calculations. Its time periods are variable; the two largest families are bursts and

682 persist for over a month while the remaining smaller sequences degenerate within days. The

683 MC2 is consistent apart from a large burst, which covers a large area and persists for several

684 months. The remaining sequences are much more constrained spatiotemporally, including a large

685 swarm sequence, which explains the disparity between mean and median A and t_D values.

686 Finally, the FCC's swarm sequences are similar, with comparable A and t_D values. The largest

687   families cover spatial areas between 30-50 km^2 and span approximately a month's time, while

688   the smaller ones cover 10 km^2 or less and decay within two weeks. The lone identified burst

689   sequence in the FCC occupies a comparable area but spans over half a year's time (Figure S12,

690   cluster 4).

691   5.4 The Epidemic Type Aftershock Sequence Model

692   Finally, we use the point-process epidemic-type aftershock sequence (ETAS) model to

693   compare the rates of seismicity, aftershock parameters and model-fitting quality between the four

694   clusters. The ETAS model, developed by Ogata (1988, 1989), is a stochastic branching model

695   based on an extension of the Omori-Utsu law of aftershocks (Omori, 1894; Utsu, 1961). It aims

696   to represent the seismicity rate as the summation of a constant background term and a

697   parameterized aftershock kernel. The rate is modeled as a function of previous activity; at time t,

698   it is conditioned by all events M_i that satisfy $t_s \leq t_i < t$, where t_s is the start of a target window.

699   According to the model, each seismic event has the potential to trigger its own aftershock

700   sequence. Given the completeness magnitude M_c, the earthquake rate λ at time t is

$$\lambda(t|H_t) = \mu + \sum_{t_i < t} \frac{Ke^{\alpha(M_i - M_c)}}{\left(\frac{t - t_i}{c} + 1\right)^p}, \quad [8]$$

701   where H_t is the conditional earthquake occurrence history prior to time t within the target

702   window. μ represents the independent background rate, K is the aftershock productivity, p

703   controls the observed power law-based rate of aftershock decay, and c is the time offset between

704   the mainshock and start of decay. The parameter α governs the degree of aftershock cascading

705   for a given magnitude. Larger values of α imply a greater sensitivity to magnitude in the

706   generation of aftershocks, which has been observed for great earthquakes (Ogata, 1992; Omi et

707   al., 2014). Conversely, smaller α values reduce the significance of event magnitude on aftershock

708   triggering. This characteristic has been linked to swarm sequences where mainshocks are less

709   distinct (Mogi, 1963; Utsu, 1970; Ogata, 1988). Estimation of the set of parameters $\varphi =$

710    $\{\mu, K, \alpha, c, p\}$ may be obtained by maximizing the log-likelihood function for $\lambda(t)$ (see Ogata,

711   1989).

712   The quality of the ETAS model fit is generally evaluated based on a transformation of

713   occurrence times, where a new set of times τ is defined such that τ_i is the cumulative conditional

714   intensity function at time t_i. A plot of the cumulative ETAS model rate versus the transformed

715   time thus results in an increasing function with constant unit slope. If the model fits the data

716   well, then a plot of the observed cumulative event count versus the transformed time will match

717   the cumulative model with rate close to unity. We determine the model's quality-of-fit (*QOF*) to

718   each cluster by quantifying the deviations of the observed cumulative plot from the ideal

719   function in transformed time; the *QOF* value is computed as the normalized area present between

720   the two plots. The maximum area value is 0.5, corresponding to the worst possible fit to the

721   sequence; a value closer to 0 implies a better fit.

722
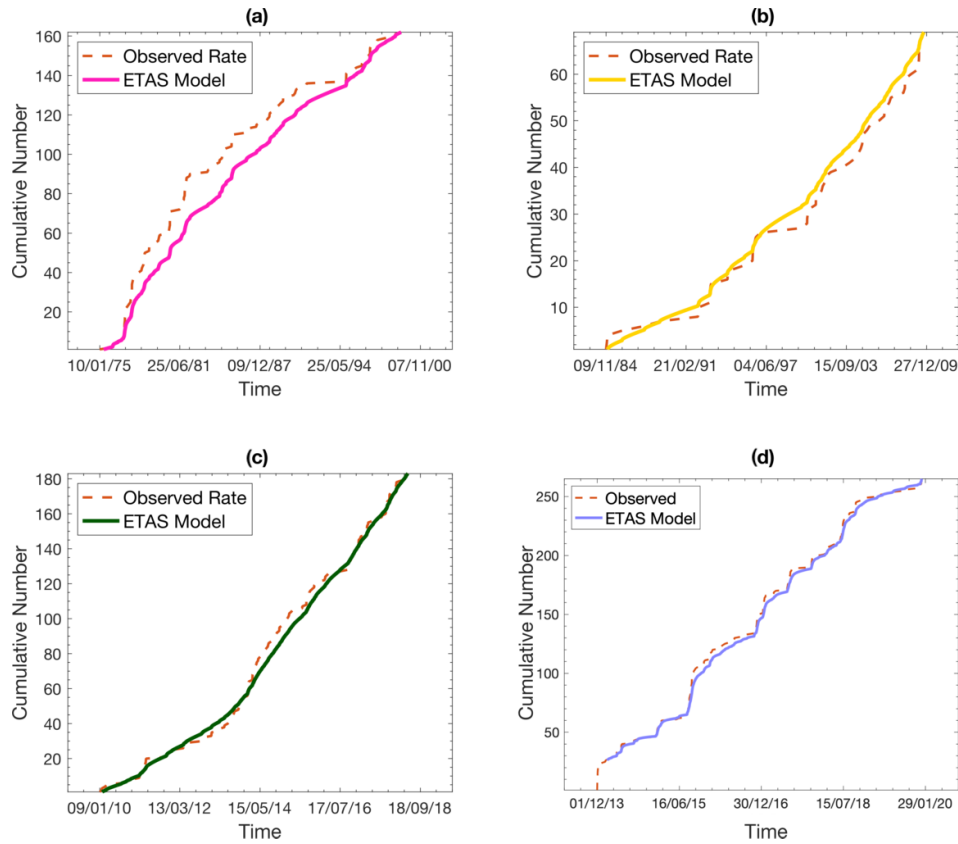

723   *Figure 9: ETAS Models in original time for each investigated cluster. Dashed orange lines are the observed cumulative rates of*

724   *seismicity. Solid coloured lines are the optimized models. Dates are given in dd/mm/yy format. a) Rocky Mountain House cluster.*

725   *b) Montney cluster 1. c) Montney cluster 2. d) Fox Creek cluster.*

726   Figure 9 presents the ETAS model and observed seismicity rates for each cluster, using

727   events above the magnitude of completeness thresholds determined in subsection 5.1. The

728   corresponding background and aftershock parameters are provided in Table 2. The model

729   successfully converged for the RMHC, MC1, and MC2 but failed to converge to realistic

730   parameter values for the FCC. We therefore constrained the background rate parameter μ to

731   nearly zero and reran the simulation, achieving convergence and an improved *QOF*. Justification

732   for this approach is provided below. The *QOF* varies for each cluster. The RMHC (Figure 9a) is

733   by far the worst fit; the model underpredicts the rate across the entire time frame. The MC1

734   (Figure 9b) fit is fair; this time, the model slightly overpredicts the rate. The MC2 (Figure 9c) is

735   fit well, while the FCC (**Figure 9**d, fixed μ) is fit very well. The type of seismicity within each

736   cluster, as illustrated by the NND model in the previous subsections, may provide some

737   explanation for the differing *QOF*s. The FCC is composed of large, distinct clustering sequences

738   that are easily distinguishable across time. The ETAS model appears to be correctly modeling

739   these individual spikes in the rate. Conversely, the RMHC is composed of a loosely clustered

740   type of seismicity that produces few clearly defined sequences and mainly manifests as elevated

741   background activity. Consequently, the ETAS model may have encountered difficulty in

742   replicating the gradually increasing rate with an absence of aftershock sequences. The steady

743   RMHC rate may be more suitably modeled by an increased background parameter μ without the

744   aftershock kernel. The improved *QOF* of the MC2 over the MC1 could be further evidence that

745   the ETAS model requires defined sequences with which to optimize its fit, although the MC1

746   dataset is likely too small for a realistic comparison.

747   *Table 2: ETAS model parameters for each investigated cluster.*

Cluster	M_c	N	μ	K	c	p	α	QOF
RMHC	2.3	162	0.0047	0.26	0.24	1.06	0.76	0.072
MC1	2.7	69	0.0033	3.09	0.0019	0.81	0.84	0.042
MC2	2.5	183	0.016	1.0	0.022	0.84	0.39	0.020
FCC[*]	2.5	242	0.000002	0.42	0.62	1.25	0.47	0.017

[*] μ is held constant.

748   It is problematic to compare the parameter values between all the clusters, as the model

749   may not be accurately representing the rate in the cases of the RMHC and MC1. For the MC2

750   and FCC, the ETAS model seems able to accurately capture the swarm activity in addition to the

751   aftershock sequences for which it was intended. 21 out of the 26 event sequences identified

752   within the MC2 and FCC do not have distinct mainshocks but are instead composed of similarly

753   sized events. This appears to be reflected in the optimized ETAS α parameter, which governs the

754   dependence on magnitude in the generation of aftershocks. α is low for both clusters, indicating

755   that the model may be correctly identifying the persistent nature of the swarm sequences, which

756   continue to produce generations of offspring despite the lack of an obvious mainshock. The p

757   parameter, which controls the sequence decay rate, is low for the MC2 and high for the FCC.

758   This might again be attributable to the more gradual rate increase within the MC2 (Figure 9c)

759   compared to the sharp spikes due to the large, tightly constrained sequences observed within the

760   FCC (Figure 9d).

761   Finally, within the FCC, a better fit and a realistic convergence are achieved by

762   constraining the background rate μ. Generally, the ETAS μ parameter is optimized to represent

763   independent seismicity as a non-zero constant, which allows for the generation of the conditional

764   aftershock rate. Consequently, μ may relate to the nearest-neighbour loosely clustered

765   subpopulation, as they both represent the subset of background earthquakes occasionally

766   preceding clustered activity. While the three other investigated clusters contained high amounts

767   of loosely clustered activity, likely resulting from long-term stress perturbations caused by fluid

768   extraction and injection, the FCC is comprised of tightly clustered sequences and relatively few

769   background events. This suggests that external factors may be contributing directly to the

770   triggering of seismicity. The absence of the loosely clustered population was used as motivation

771   for the fixed $\mu \approx 0$ constraint. When μ was similarly fixed on a trial basis for the other clusters,

772   either the QOF was worse or the model did not converge. This does makes sense, as the

773   seismicity in those areas is largely made up of an elevated background with few significant

774   sequences, and so assuming an absence of background seismicity would be inaccurate. The

775   comparatively high-quality fit of the model to the FCC also provides some confirmation that the

776   ETAS model seems to perform better on a dataset containing separable, tightly connected

777   sequences. For seismic clusters resembling an elevated background rate, on the other hand, it

778   may not be able to predict what events are or are not part of an earthquake sequence.

6 Discussion

Many regional studies of anthropogenic seismicity have described an elevation in background seismicity during and immediately after potential earthquake-inducing processes such as geothermal energy production, wastewater disposal, hydraulic fracturing etc. (Lombardi et al., 2010; Llenos & Michael, 2013; Schoenball et al., 2015; Maghsoudi et al., 2016; Zaliapin & Ben-Zion, 2016; Schoenball & Ellsworth, 2017; Martínez-Garzón et al., 2018). In sections 4 and 5, we found evidence that an induced background subpopulation of earthquakes in the WCSB was elevated near areas of human activity, which could be separated from the tectonic rate in the nearest-neighbour distance (NND) distributions. This elevated background was more specifically a collection of earthquakes that was loosely clustered in certain areas over limited time frames; its inter-event space-time distances were measurably lower than the regional Poisson-like background but larger than typical clustering activity. This is likely to have been the case in other regions as well. For example, Zaliapin & Ben-Zion (2016) used the NND method to examine seismicity within selected regions across the state of California; these regions were either (i) dominated by induced activity related to geothermal operations, (ii) a mixture of tectonic and induced earthquakes, or (iii) characterized entirely by tectonic events. In every instance, the anthropogenic seismicity contained a background mode that was situated much closer to the clustered mode than the natural activity. The separation threshold value between subpopulations was smallest for type (i) areas and largest for areas of type (iii); this difference spanned several orders of magnitude. Similar observations were made by Schoenball et al. (2015), who assessed the seismicity surrounding and within the Coso geothermal field in southern California. The induced seismicity again contained a background element positioned closer to the clustered mode compared to the surrounding earthquakes, which were attributed to tectonic and magmatic sources. Interestingly, the background mode held a dominant mixing proportion during the coproduction intervals and also extended further downward along the diagonal towards larger T and smaller R, suggesting that a large proportion of the induced activity was acting as an elevated Poisson process of independent events. Vasylkivska & Huerta (2017) studied the rapidly increasing earthquake rate in Oklahoma associated with large-scale wastewater injection. During the pre-injection time interval, only a single component was present in the two-dimensional NND distribution, located far in the upper right section of the space. This mode largely dissipated during the co-injection intervals and was replaced by clustered and

810   background components located closer to the center. As discussed in these studies, induced

811   seismicity tends to increase earthquake rates locally and across limited time spans. This is

812   reflected quite clearly in the joint NND distributions, where populations of the elevated induced

813   background manifest more centrally and closer to the clustered population. This effect is starkly

814   evident in regions governed by a low natural seismicity rate like the WCSB and Oklahoma,

815   where the tectonic and induced background components can be separated by inspection, but is

816   also discernable in naturally active areas such as California.

817   We also observed a tightly clustered earthquake subpopulation in the NND distributions,

818   which occurred at very small inter-event distance values and appeared highly correlated with the

819   loosely clustered background. We found that tightly clustered event sequences were nearly four

820   times as likely to be strongly linked to a loosely clustered event compared to a natural

821   background event. Both groups of earthquakes made up the entirety of discernable induced

822   clustering in the region and both grew disparately in relative proportion over recent times,

823   coinciding with the growing use of hydraulic fracturing technology. However, we discovered

824   that different triggering mechanisms produced differences in the mixing proportions of these

825   earthquake groups, with hydraulic fracturing operations resulting in much larger proportions of

826   tightly clustered earthquakes than conventional hydrocarbon production and wastewater disposal.

827   Based on the results in section 5, several further insights may be gathered regarding the induced

828   seismic clustering within the WCSB. First, wherever fluid injection was suspected as the

829   seismogenic mechanism, either through wastewater disposal or HF (i.e. the MC1, MC2 and

830   FCC), the clustering appeared more swarm-like and reminiscent of ductile failure. The lone case

831   of fluid extraction-related seismicity, the RMHC, resulted in an elevated background rate and

832   occasional burst-like sequencing, more suggestive of brittle failure. Second, HF operations

833   seemed to trigger greater swarm-like behavior than wastewater injection. Results of the NND

834   and ETAS model applications indicated that the MC2 and FCC contained higher levels of swarm

835   seismicity than did the MC1. This may have been a consequence of the differences in injection

836   volume and rate between cases, as well as the horizontal orientation of many new HF wells,

837   which allows fluid and stress perturbations to be forced through a much larger volume of rock in

838   the short term (King, 2010; Smith & Montgomery, 2015). There is also a possibility that HF-

839   induced swarms can occur predominantly at lower magnitude levels, as evidenced by the

840   elevated Gutenberg-Richter b-value within the FCC. Third, HF is capable of, albeit less

841   frequently, triggering larger aftershock sequences, where the migrating fluid or stress

842   perturbation may be traveling into the crystalline basement and interacting with critically

843   stressed faults, similar to the triggering mechanism attributed to wastewater disposal. Fourth,

844   these aftershock sequences appear to result in connected earthquakes that span longer time

845   frames than do the swarms of comparable sequence size. The swarms within the MC2 and FCC

846   are almost all tightly constrained in space and time relative to their size, which may correlate

847   with the spatial and temporal extent of their associated stimulating HF operations. This also

848   suggests that the two types of clusters are caused by different mechanisms; the bursts by fluid

849   intermingling with critically oriented faults resulting in a large event, which *then* triggers

850   multiple offspring events in a conventional aftershock manner, versus the swarms where no

851   distinct mainshock is present, yet multiple offspring continue to transpire as the pumped fluid

852   repeatedly disturbs nearby faults (Schultz, Stern, Novakovic, et al., 2015; Bao & Eaton, 2016;

853   Eaton, 2018). A possible example of swarms being directly related to HF activity is the notable

854   resemblance between the identified swarms in the FCC and the largest sequence in the MC2 near

855   Dawson Creek, B.C. (Figure S12, clusters 1, 2, and 3, and Figure S11, cluster 1). They each

856   occurred within kilometers of active HF operations and are structurally similar; the Dawson

857   Creek swarm is a smaller-scale version of the FCC sequences (comparable events chained

858   together with a rapid decay time, relative to its size). It is possible that the likenesses in the

859   fundamental structuring of these clusters may be reflective of their shared triggering mechanism.

860   The disparities in their size and scope may be due to factors such as different pumping

861   rates/pressures/times or total volume of fluid injected, in addition to local geologic factors.

862   A critical issue with the models employed in this study are their dependence on

863   earthquake sampling statistics, which vary in representative accuracy and precision based on

864   sample size and variance. The associated uncertainties for the Gutenberg-Richter and ETAS

865   parameter estimates can be quantified, although the ETAS parameter errors computed in this

866   study were unstable and hence removed; this needs to be addressed in future work. The NND

867   calculations are less well constrained. Zaliapin & Ben-Zion (2015) examined the potential

868   artifacts of catalogue inconsistencies on the results of their cluster analyses within southern

869   California. They found that location errors and short-term incompleteness can lead to an

870   overestimation of background seismicity and a corresponding underestimation of clustered

871   earthquakes. This phenomenon appears independent of any particular cluster identification

872   technique, as long as it is based upon parent-offspring relationships. With respect to the long-

873   term regional completeness, Zaliapin & Ben-Zion (2013a) showed that NND distributions

874   remain stable (up to a certain magnitude cut-off, after which the distribution becomes unimodal

875   and contains only single events). In this study, we nevertheless introduce some bias by applying

876   a cut-off below the regional estimated completeness level to enrich sampling. The networks

877   contributing to the Composite Alberta Seismicity Catalogue have undergone numerous changes

878   and improvements across time, particularly near areas of suspected induced activity including

879   along the Duvernay and Montney formations (for details, we refer to Adams & Halchuk (2003)

880   and Cui & Atkinson (2016)). This implies that the differences observed in earthquake

881   distribution over time and between clusters may be partly the result of a changing M_c. However,

882   we point to the disparate changes in rate between the earthquake subpopulations found in section

883   4, which hold for cut-off magnitudes up to the regional estimated completeness (Figure S8), as

884   well as the suspicious spatial relationship between the clustered events and human operations as

885   evidence that the recent changes in earthquake distribution are significant, and not entirely due to

886   the enhancement of the regional network.

887   **7 Conclusions**

888   A statistical analysis of catalogued seismicity within the Western Canada Sedimentary

889   Basin (WCSB) was performed. We conducted a regional study in section 4, analyzing space-

890   time-magnitude inter-event nearest-neighbour distance (NND) distributions across Alberta and

891   eastern B.C. over time, beginning from the first observed instance of induced activity in 1975 up

892   to the nearly present hydraulic fracturing (HF) related activity in 2018. Analysis over the entire

893   time frame revealed the existence of a tri-modal inter-event distance distribution, where events

894   generally appeared to occur either: (i) very closely together in space and time (within the tightly

895   clustered mode); (ii) moderately close together (within the loosely clustered mode); or (iii) as a

896   stationary, space-inhomogeneous Poisson process (the deep background). Analysis over

897   separated time intervals demonstrated that a disproportionate increase in both the loosely and

898   tightly clustered earthquake components occurred between 1975-2009 and 2010-2018, where the

899   first interval predates the broad-scale implementation of HF technology. The first two modes of

900   inter-event distance distribution are believed to reflect HF operation, wastewater disposal and

901   conventional hydrocarbon production-related earthquakes. The third mode is inferred to

902 represent natural background seismicity, based on its uniform spatial distribution and large inter-
903 event distances (resembling a point process). The spatial distribution of the natural background
904 events contrasts with the localized loosely and tightly clustered subpopulations occurring at
905 smaller inter-event distance values. We posit that the majority of induced activity occurs within
906 these clustered modes, and that their increasing prevalence within the region is attributable to the
907 growing usage of HF technology.

908 In section 5, we investigated four cases of induced seismic clustering within the WCSB.
909 Frequency-magnitude statistics were assessed using the Gutenberg-Richter (GR) relation. Inter-
910 event space-time-magnitude distributions and individual clustering properties were evaluated
911 with the nearest-neighbour distance (NND) method and the epidemic type aftershock sequence
912 (ETAS) model. It was determined that the seismicity triggered by conventional gas extraction
913 near Rocky Mountain House (the RMHC) and the wastewater disposal-related earthquakes near
914 Fort St. John (the MC1) primarily manifested as discrete events, loosely clustered in space and
915 time, that occupied the middle mode of the inter-event NND distributions. These events were
916 characterized by low-to-moderate GR *b*-values and poorer fits to the ETAS model. The few
917 tightly clustered event sequences that did occur were small and decayed rapidly. The more recent
918 clustering along the Montney formation (the MC2) also occupied the loosely clustered domain
919 but contained an additional mode within the tightly clustered domain. These earthquakes were
920 characterized by a slight increase in *b*-value from the previous period and were better fit by the
921 ETAS model, with a reduced magnitude-sensitivity parameter. We identified more event
922 sequences over this period, which were larger and more swarm-like. Finally, near Fox Creek (the
923 FCC), substantial HF-related activity occurred almost entirely within the tightly clustered
924 domain, in stark contrast with the previous clusters. These earthquakes formed a very steep
925 frequency-magnitude distribution with a high *b*-value and fit the ETAS model exceptionally
926 well, particularly when the background rate parameter was constrained to nearly zero, with a low
927 magnitude sensitivity comparable to the MC2. The many detected event sequences were large,
928 distinctly separable and overwhelmingly swarm-like.

Introduction

This supporting information provides additional context to both the regional (section 4) and the cluster (section 5) analyses in the main paper. In particular, Figures S1-4 show the event maps for each cluster discussed in section 2 and analyzed in section 5. Figure 5 shows the estimated completeness level of the Composite Alberta Seismicity Catalogue between 2010-2018. Figures S6-9 present the additional tests detailed in section 4, namely the nearest-neighbour distance (NND) analyses for randomized catalogues, sensitivity tests for variations in the Gutenberg-Richter b-value and fractal dimension (d_f), and the likelihood-ratio test to assess the validity of a three-component Gaussian mixture model. Figures S10-13 give the regional NND analyses results at higher cutoff magnitudes, which confirm the existence of three earthquake subpopulations and a transformation in earthquake distribution between 1975-2009 and 2010-2018 (analogous to Figures 2 and 5). Finally, Figures S14-17 give the structural representations and statistical parameters of the event families identified in section 5.3 (analogous to Figure 8).
Figure S1. Map of the Rocky Mountain House cluster (RMHC) study area between 1975-2000. Dashed circle represents a 20 km radius from the coordinates [115.24°W, 52.17°N]. Markers are seismic events. White markers are the data points used for analysis.
Figure S2. Map of the Montney cluster 1 (MC1) study area between 1984-2009. Dashed circle represents a 75 km radius from the coordinates [121.6°W, 56.5°N]. Markers are seismic events. White markers are the data points used for analysis.
Figure S3. Map of the Montney cluster 2 (MC2) study area between 2010 and 2018. Dashed circle represents a 150 km radius from the coordinates [121.6°W, 56.5°N]. Markers are seismic events. White markers are the data points used for analysis.
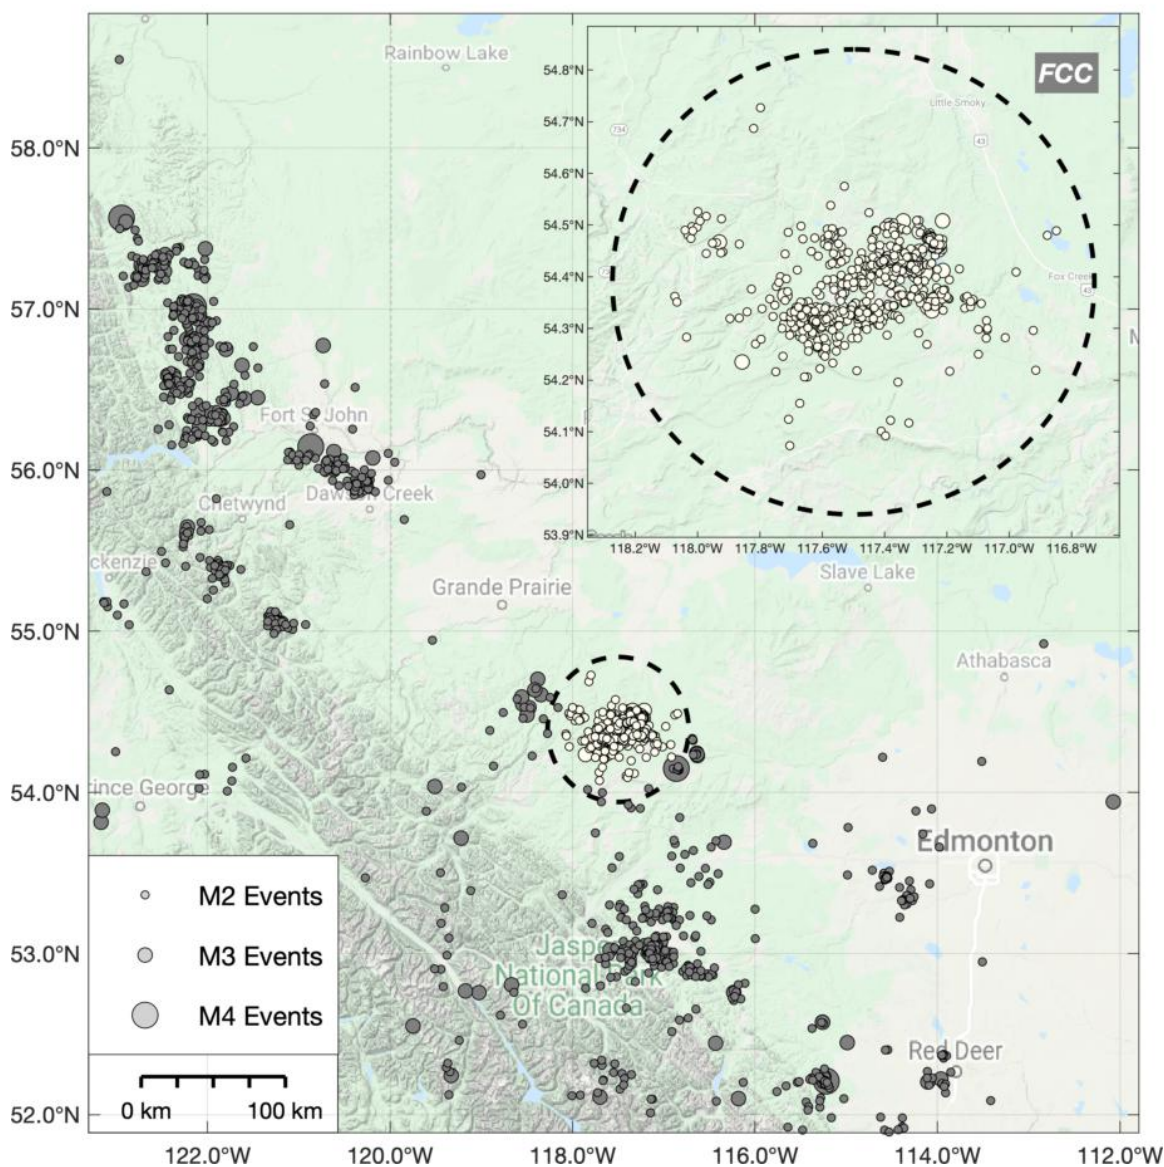

Figure S4. Map of the Fox Creek cluster (FCC) study area between 2013 and January 2020. Dashed circle represents a 45 km radius from the coordinates [117.4°W, 54.4°N]. Markers are seismic events. White markers are the data points used for analysis.
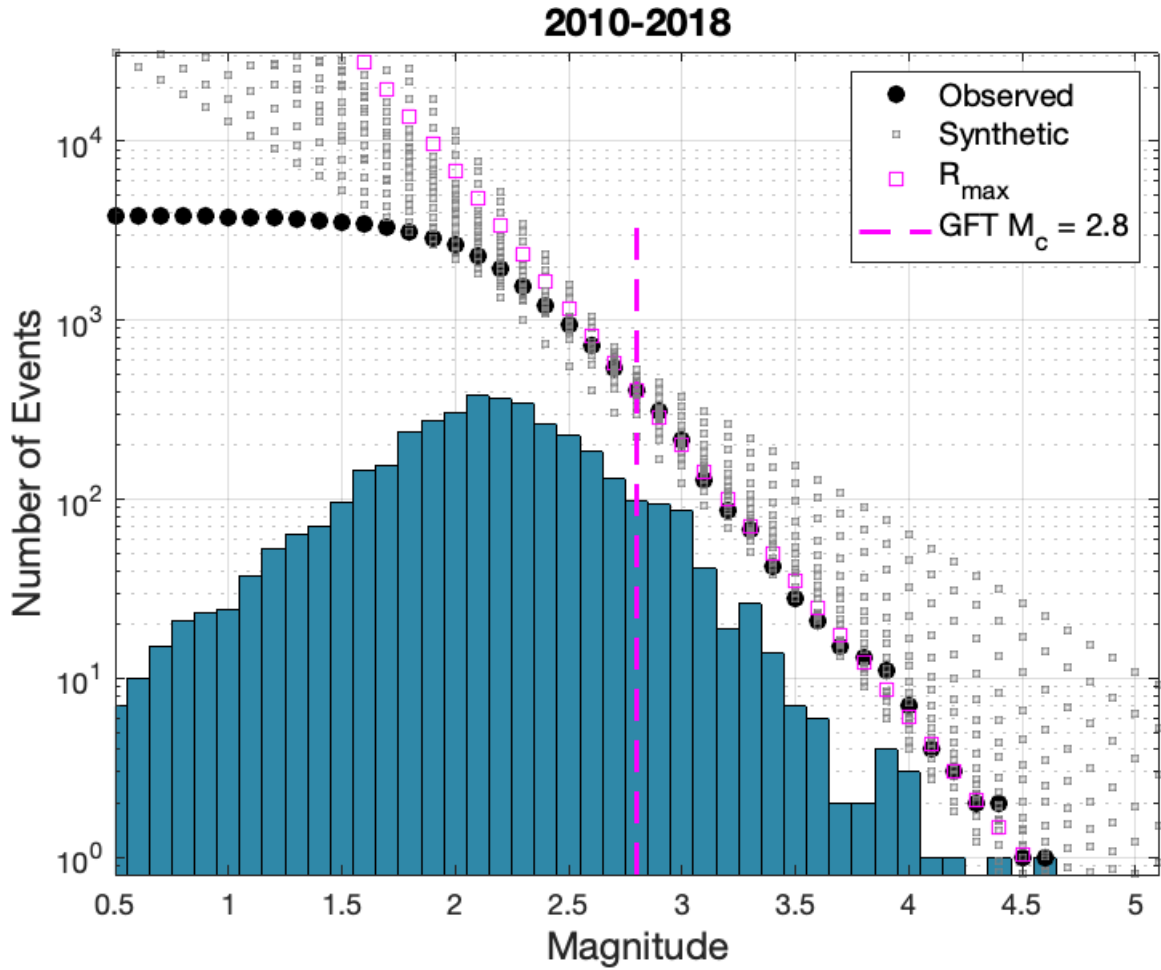

Figure S5. Estimated completeness of the Composite Alberta Seismicity Catalogue, between 2010-2018, using the goodness-of-fit test (GFT) of Wiemer & Wyss (2000). Squares represent synthetic distributions drawn from the (exponential) Gutenberg-Richter relation, for a range of *b*-values. Pink squares represent the synthetic distribution that maximizes the goodness-of-fit (*R*), i.e. that minimizes the residual between it and the cumulative frequency-magnitude distribution. Grey squares represent the rejected synthetic distributions. Vertical dashed pink line indicates the corresponding completeness threshold.
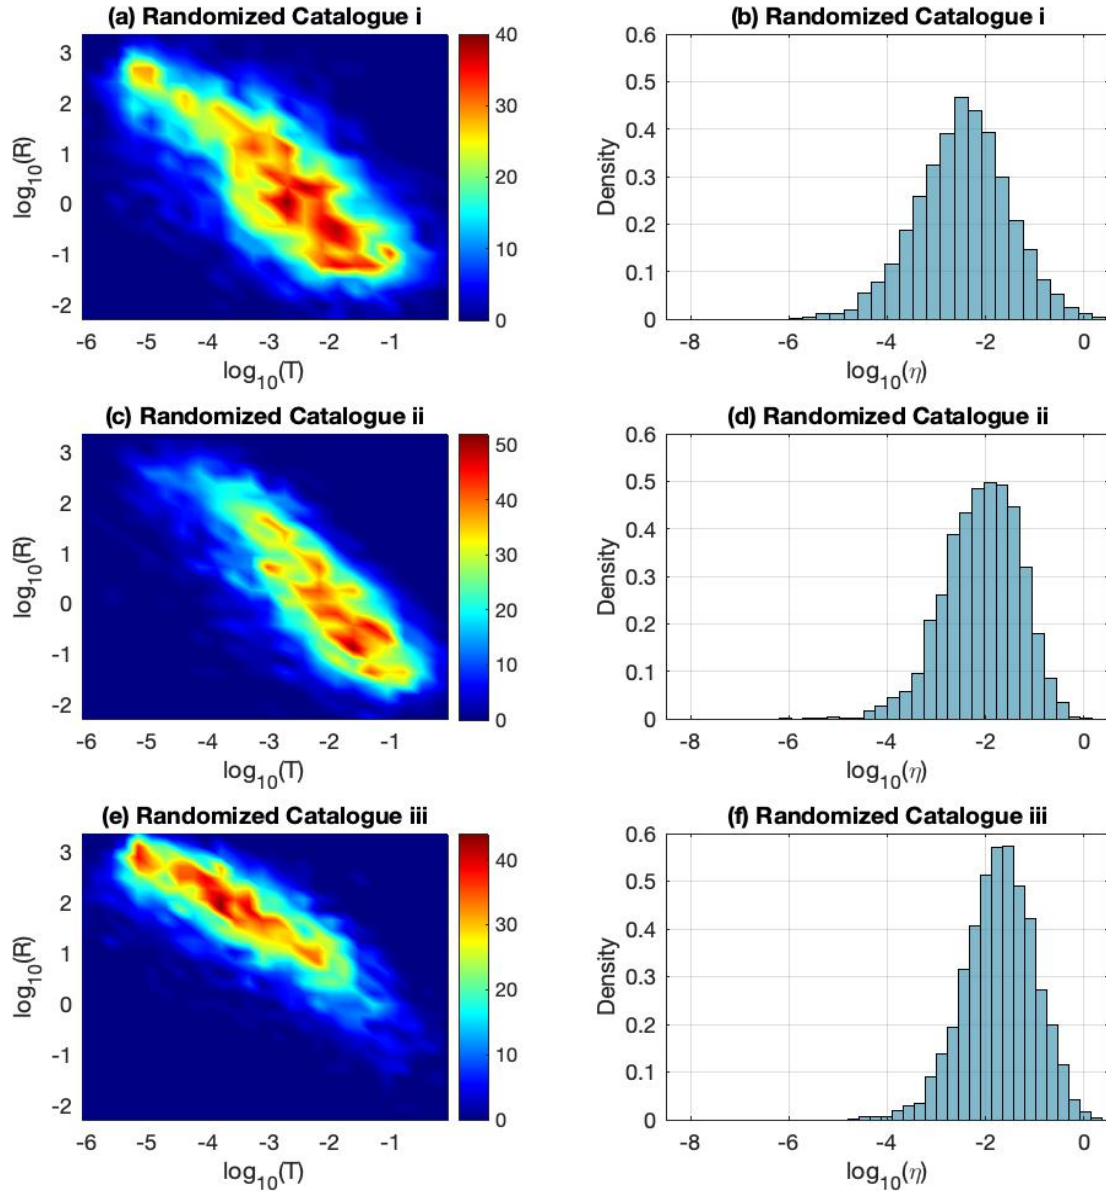

Figure S6. Nearest-neighbour distance distributions of three randomized versions of the Composite Alberta Seismicity Catalogue (CASC). (a, b) Event times and event locations are shuffled. (c, d) Event times are uniformly distributed within the temporal limits of the CASC and event locations are shuffled. (e, f) Original event times are kept and event locations are uniformly distributed within the latitudinal and longitudinal limits of the CASC.
Figure S7. One-dimensional η distributions, analogous to Figure 2b, using a range of fractal dimension (d_f) values. As d_f increases, the distribution spreads and trimodality becomes more apparent.
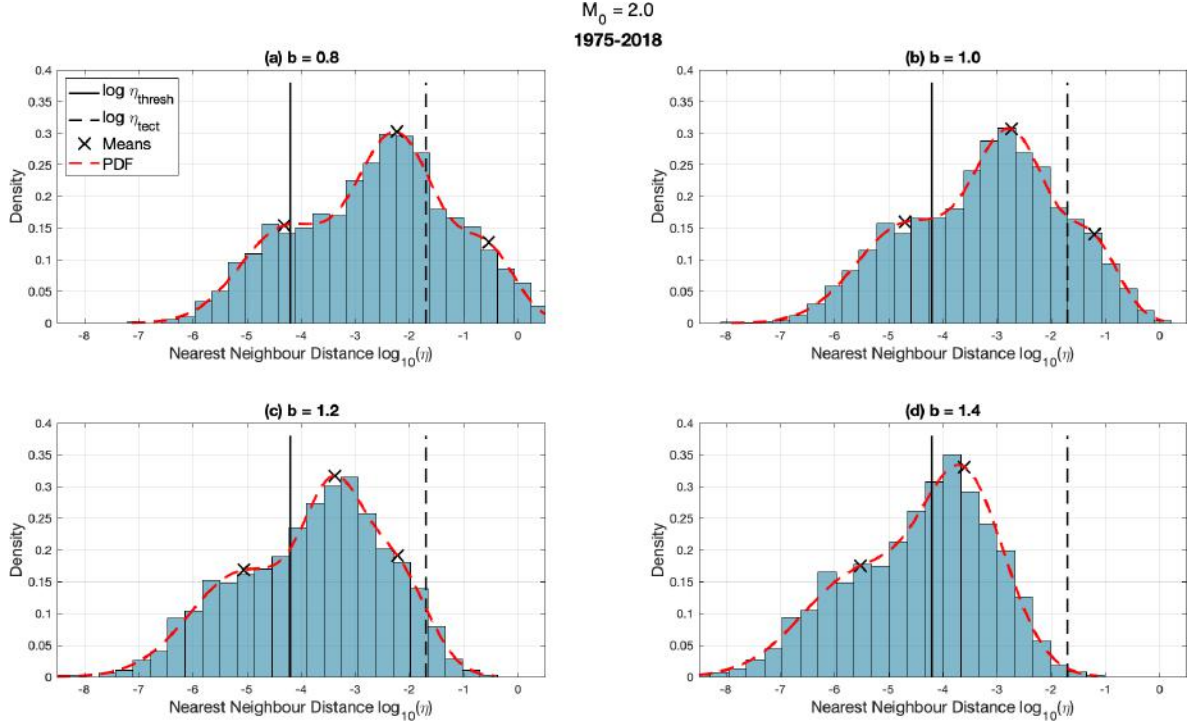

Figure S8. One-dimensional η distributions, analogous to Figure 2b, using a range of Gutenberg-Richter b-values. As b increases, the distribution gets squeezed and shifts leftward, obscuring the distinctive background mode at large η.
Figure S9. Gaussian mixture models, with 1, 2, and 3 components, for the regional distribution of inter-event distances η. AIC and BIC are their respective Akaike and Bayesian information criteria. The lowest AIC and BIC values correspond to the best fitting model; here they are minimized for a three-component mixture.

$$M_0 = 2.5$$

a) 1975 - 2018
b) 1975 - 2018

Figure S10. Nearest-neighbor distance distribution of the regional CASC dataset from 1975-2018, using a cutoff magnitude of M_0 = 2.5 (analogous to Figure 2). Percentages in subplot (b) reflect the modal mixing proportions. Trimodality remains distinguishable at M_0 = 2.5.
Figure S11. Nearest-neighbor distance distribution of the regional WCSB catalogue from 1975-2018, using a cutoff magnitude of M_0 = 3.0 (analogous to Figure 2). Percentages in subplot (b) reflect the modal mixing proportions. Trimodality remains distinguishable at M_0 = 3.0.
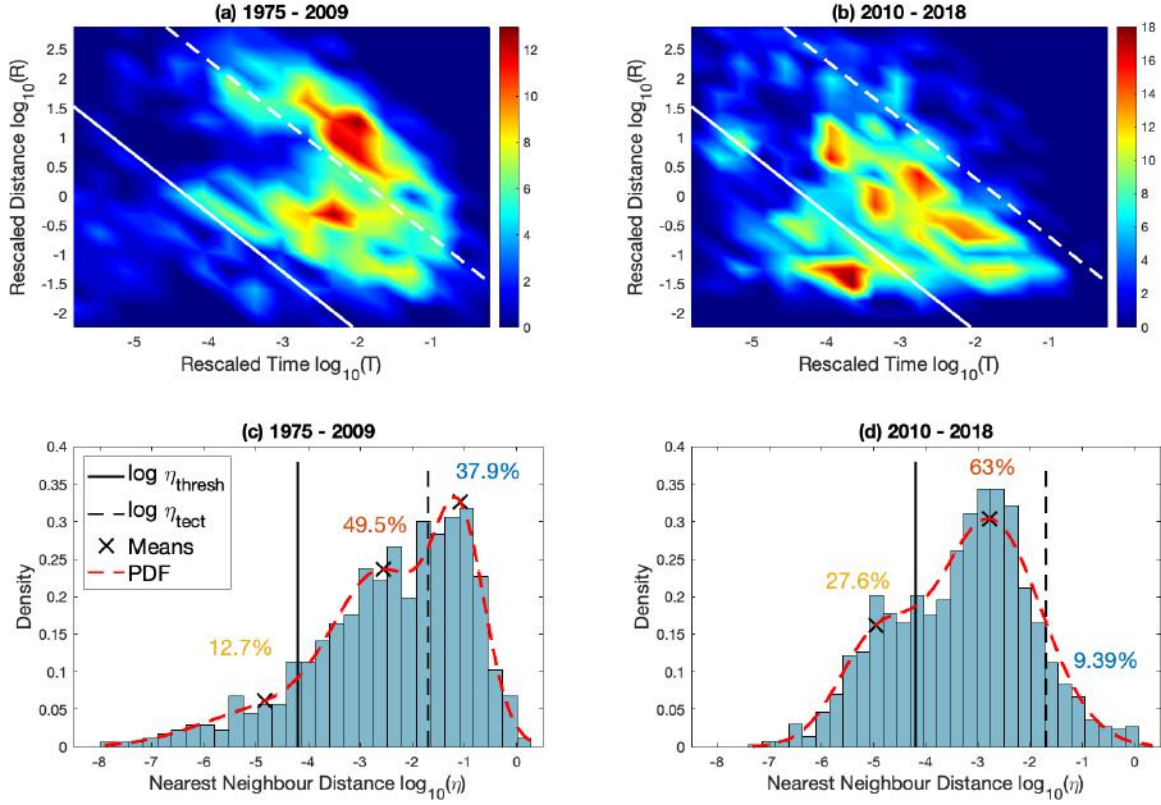

Figure S12. Comparison of nearest-neighbor distance distributions of the regional WCSB catalogue across time using a cutoff magnitude of M_0 = 2.5 (analogous to Figure 5). (a, c) 1975-2009. (b, d) 2010-2018. Percentages in subplots (c, d) reflect the modal mixing proportions.
Figure S13. Comparison of nearest-neighbor distance distributions of the regional WCSB catalogue across time using a cutoff magnitude of M_0 = 3.0 (analogous to Figure 5) (a, c) 1975-2009. (b, d) 2010-2018. Percentages in subplots (c, d) reflect the modal mixing proportions.
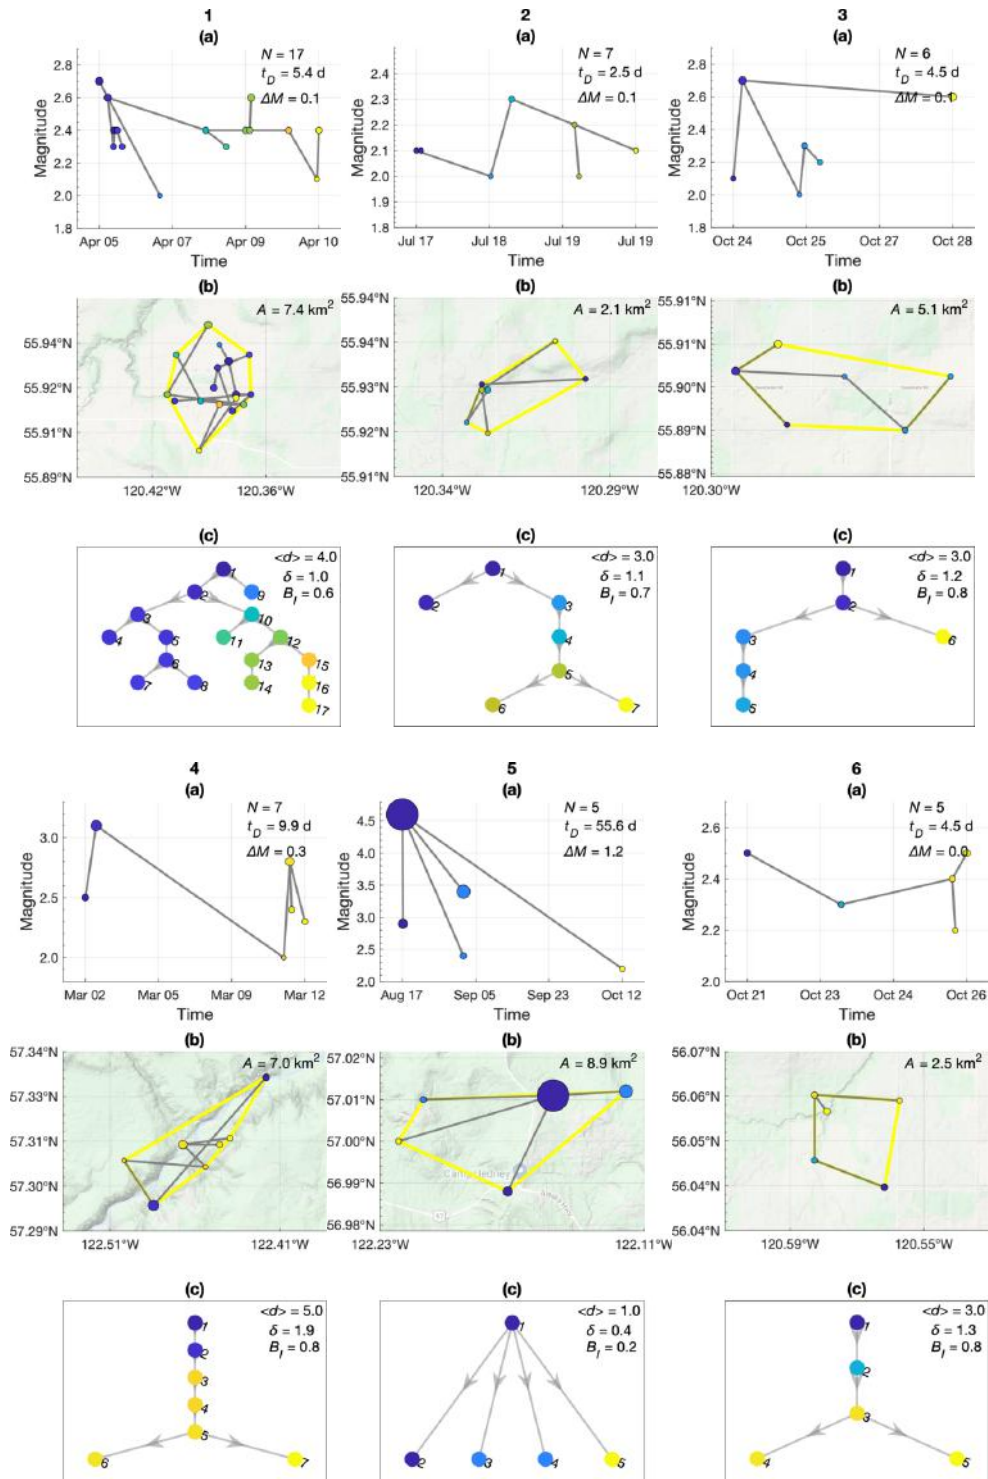

Figure S14. Event family structures in the Rocky Mountain House cluster (RMHC). a) Moment magnitude vs. time in days. b) Spatial map; yellow border outlines the hull area occupied by the sequence. c) Directed tree graph in dimensionless space. Data points are coloured chronologically from darkest to lightest.
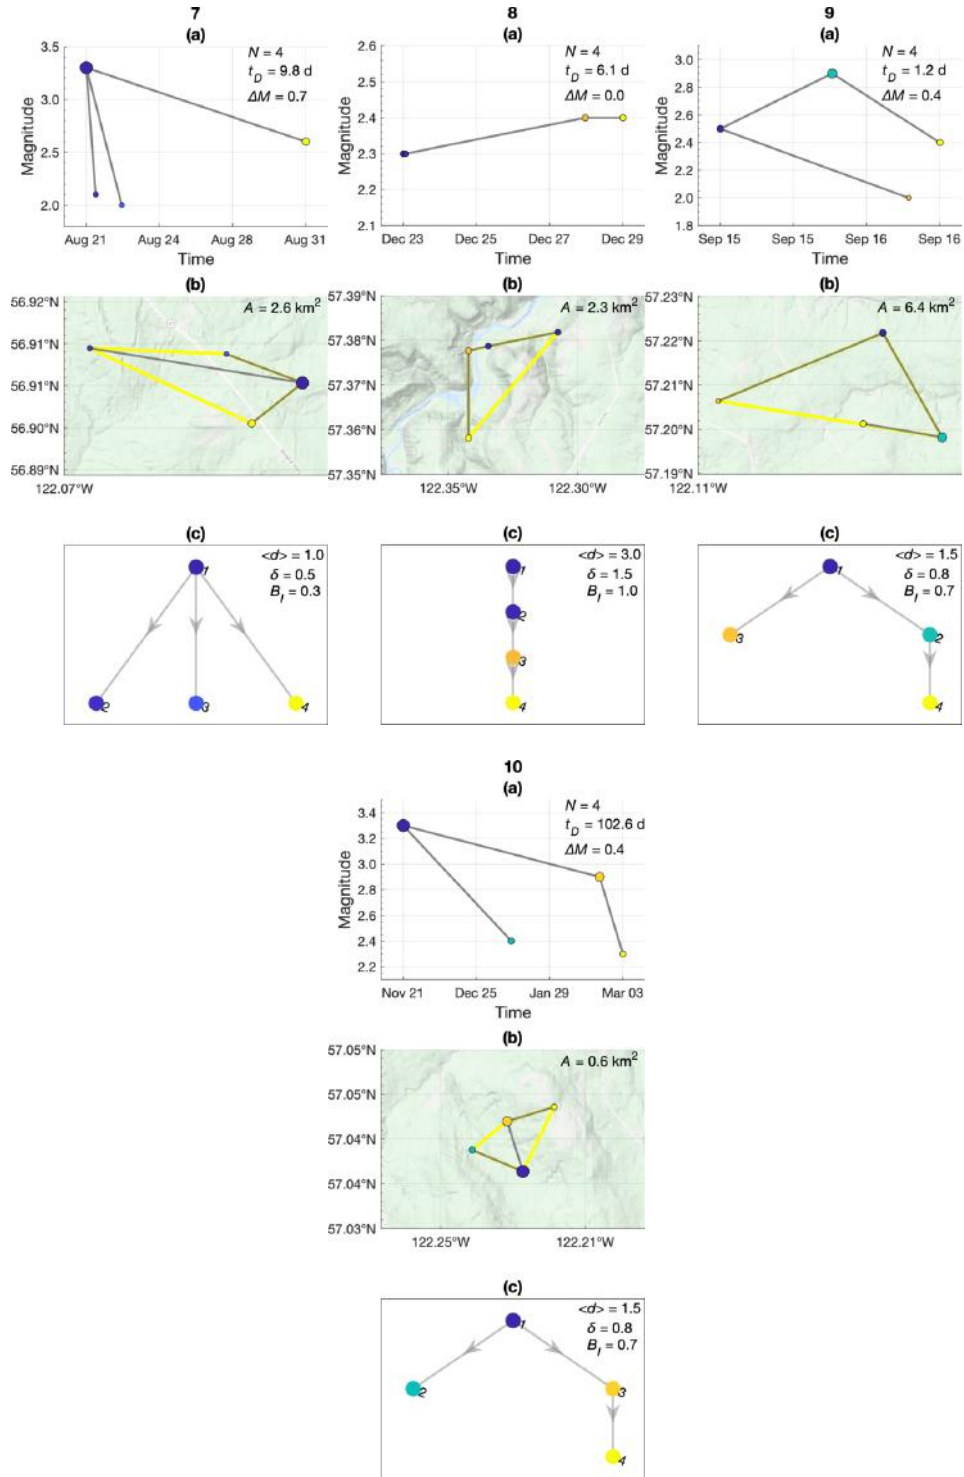

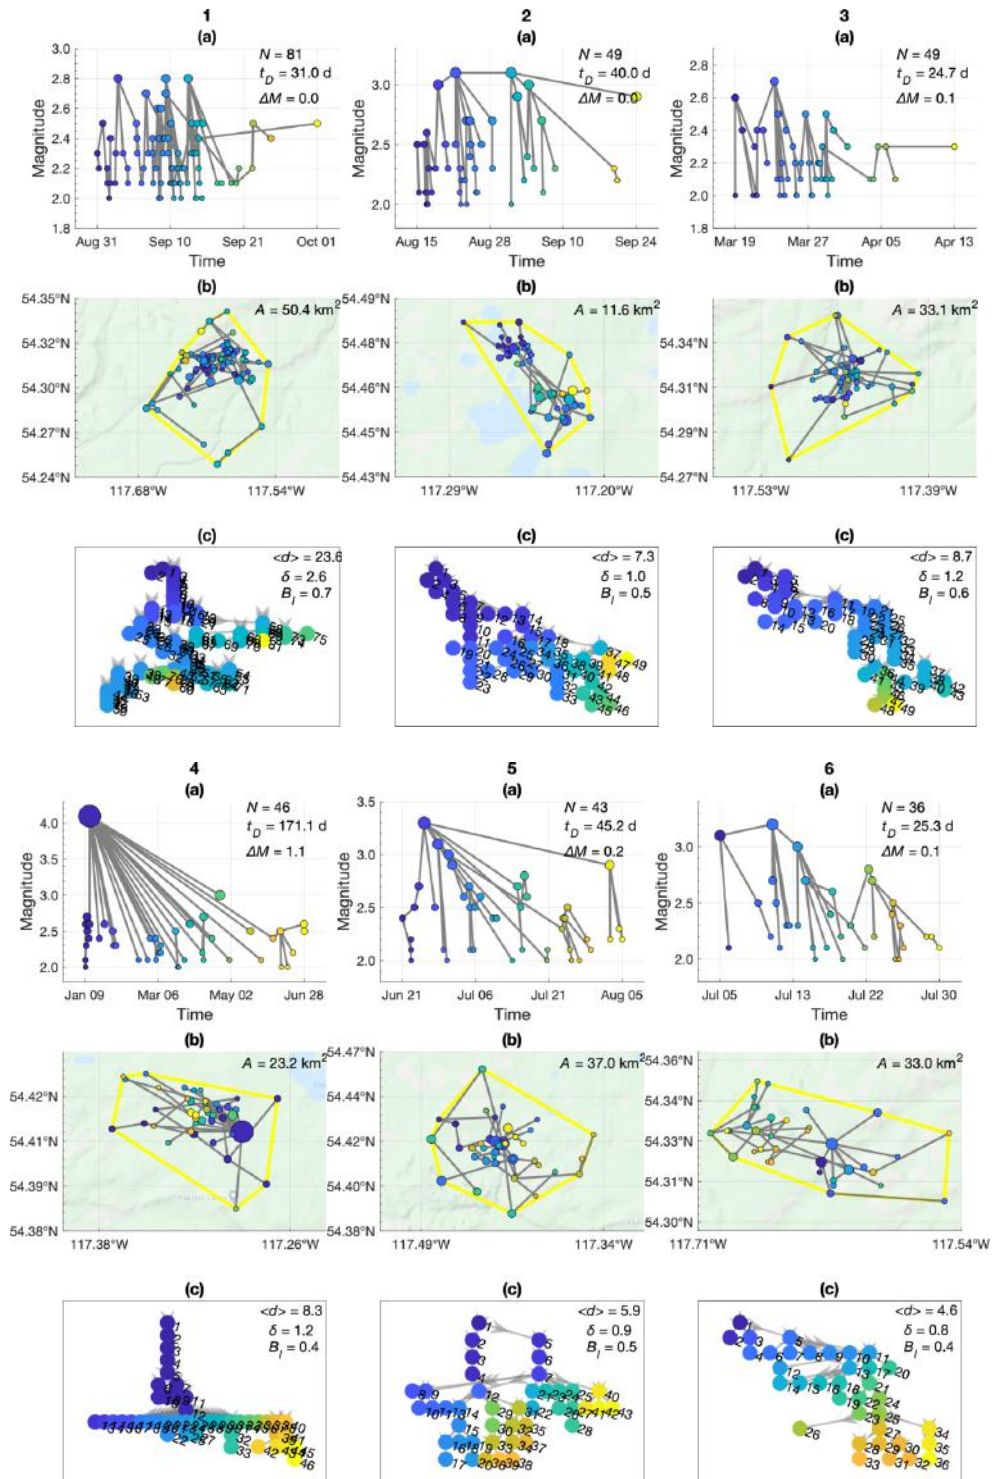

14
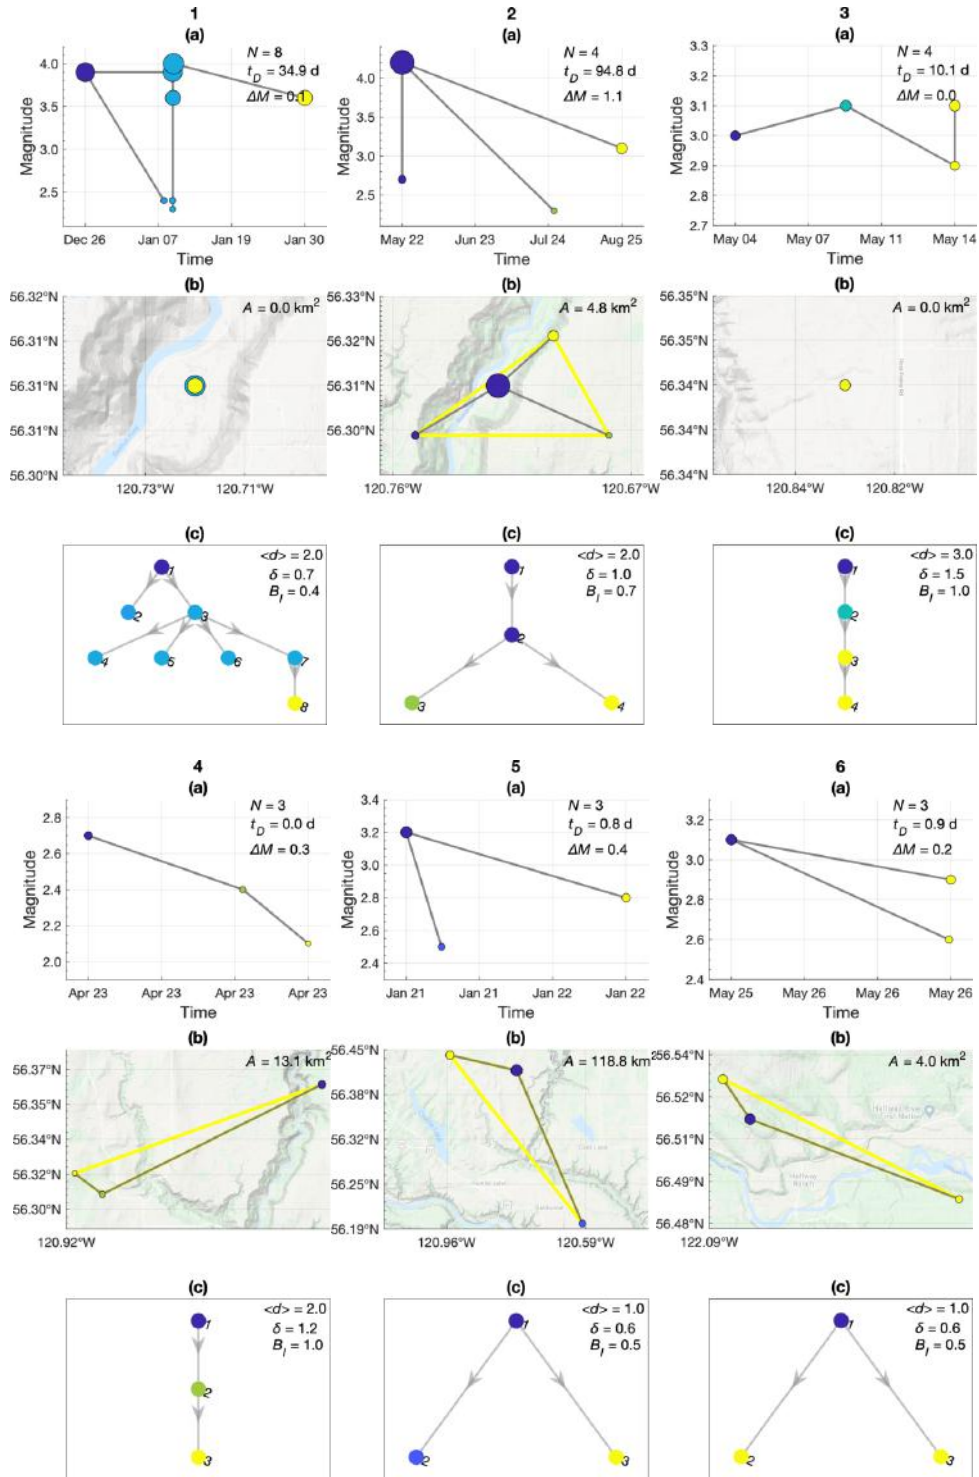

Figure S15. Event family structures in the Montney cluster 1 (MC1). a) Moment magnitude vs. time in days. b) Spatial map; yellow border outlines the hull area occupied by the sequence. c) Directed tree graph in dimensionless space. Data points are coloured chronologically from darkest to lightest.

Figure S16. Event family structures in the Montney cluster 2 (MC2). a) Moment magnitude vs. time in days. b) Spatial map; yellow border outlines the hull area occupied by the sequence. c) Directed tree graph in dimensionless space. Data points are coloured chronologically from darkest to lightest.
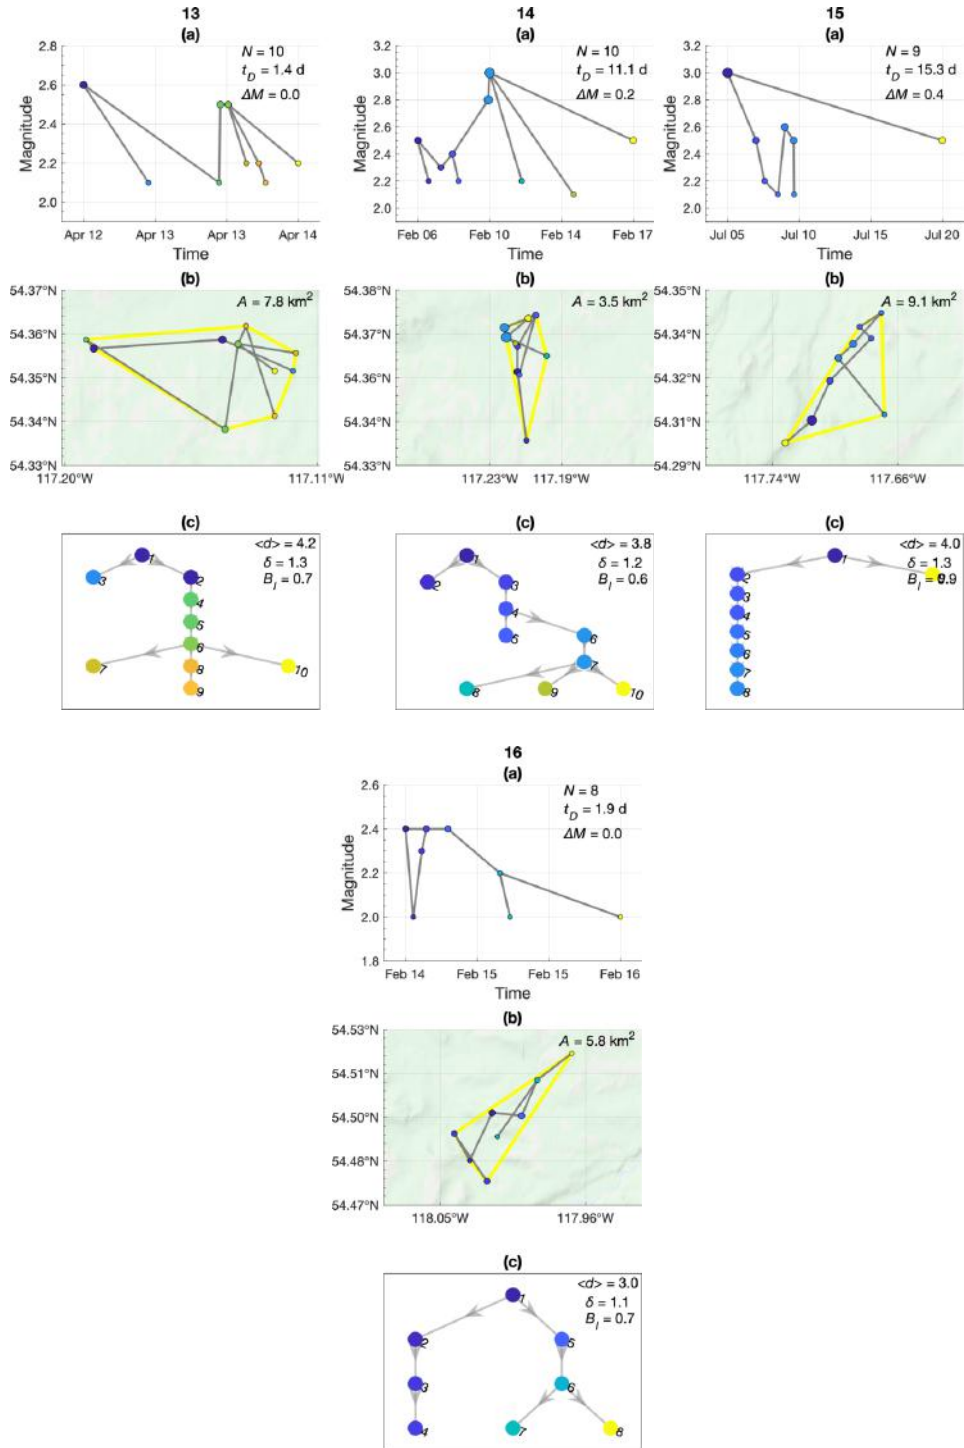

Figure S17. Event family structures in the Fox Creek cluster (FCC). a) Moment magnitude vs. time in days. b) Spatial map; yellow border outlines the hull area occupied by the sequence. c) Directed tree graph in dimensionless space. Data points are coloured chronologically from darkest to lightest.
