#### Abstract

In this study, we investigated the chemical composition and hygroscopicity of water-soluble fraction in PM<sub>2.5</sub> collected from a rural site of Guanzhong Basin, a highly polluted region in northwest China. Hygroscopic growth factors, g(RH), of watersoluble matter(WSM) were measured by hygroscopic tandem differential mobility analyzer(H-TDMA) with an initial dry particle diameter of 100 nm. The g(90)<sub>WSM</sub> and  $\varkappa_{WSM}$  was in the range of 1.08~1.49(1.35{plus minus}0.10) and 0.04~0.29(0.19{plus minus}0.06) in summer, 1.24~1.45(1.36{plus minus}0.07) and 0.12~0.26(0.20{plus minus}0.04) in winter, respectively. We found that increased nitrate concentration at night in summer suppressed 60-70% of the deliquescent point, and increased g(RH) at elevated relative humidity, compared to daytime. Secondary inorganic ions were the main components in heavy haze day, and greatly contributed to the hygroscopicity of particles. In contrast, more potassium compound and WSOM existed during Chinese Spring Festival event but exhibited no deliquescence point in the process of hygroscopic growth with the elevated RH. The g(90)<sub>WSOM</sub> and  $\varkappa_{WSOM}$ , obtained using ZSR model, were in the range of 1.06~1.52(1.25{plus minus}0.14) and 0.024~0.32(0.13{plus minus}0.09) in summer, 1.06~1.58(1.38{plus minus}0.15) and 0.02~0.38(0.22{plus minus}0.10) in winter, respectively. The mean g(90)<sub>WSOM</sub> and levoglucosan, confirming that the aerosol's hygroscopicity were highly influenced by biomass burning in winter. Briefly, it is revealed that the aerosol in rural regions of Guanzhong Basin is mainly influenced by biomass burning based on the hygroscopicity in winter and summer.

#### Key points: 33

- Inorganic matters promote the hygroscopicity of particulate matter in summer, 34 35 while the contribution from organics increases in winter.
- The concentration of sulphate, nitrate, ammonium is higher on heavily polluted 36 days, and the organic matter is high in non-polluting days. 37
- 38

The rural site of Guanzhong Basin is affected highly by biomass combustion.

39

#### Abstract: 40

41 In this study, we investigated the chemical composition and hygroscopicity of watersoluble fraction in PM2.5 collected from a rural site of Guanzhong Basin, a highly 42 polluted region in northwest China. Hygroscopic growth factors, g(RH), of water-43 soluble matter(WSM) were measured by hygroscopic tandem differential mobility 44 45 analyzer(H-TDMA) with an initial dry particle diameter of 100 nm. The g(90)<sub>WSM</sub> and  $\kappa_{WSM}$  was in the range of 1.08~1.49(1.35±0.10) and 0.04~0.29(0.19±0.06) in summer, 46  $1.24 \sim 1.45(1.36 \pm 0.07)$  and  $0.12 \sim 0.26(0.20 \pm 0.05)$  in winter, respectively. We found that 47 increased nitrate concentration at night in summer suppressed 60-70% of the 48 49 deliquescent point, and increased g(RH) at elevated relative humidity, compared to daytime. Secondary inorganic ions were the main components in heavy haze day, and 50 greatly contributed to the hygroscopicity of particles. In contrast, more potassium 51 compound and WSOM existed during Chinese Spring Festival event but exhibited no 52 deliquescence point in the process of hygroscopic growth with the elevated RH. The 53  $g(90)_{WSOM}$  and  $\kappa_{WSOM}$ , obtained using ZSR model, were in the range of 54  $1.06 \sim 1.52(1.25 \pm 0.14)$  and  $0.02 \sim 0.32(0.13 \pm 0.09)$  in summer,  $1.06 \sim 1.58(1.38 \pm 0.15)$  and 55  $0.02 \sim 0.38(0.22 \pm 0.10)$  in winter, respectively. The mean g(90)<sub>WSOM</sub> was in the range of 56 57 that of biomass burning aerosols, and a good correlation (R=0.71) was found between g(90)<sub>WSOM</sub> and levoglucosan, confirming that the aerosol's hygroscopicity were highly 58 influenced by biomass burning in winter. Briefly, it is revealed that the aerosol in rural 59 regions of Guanzhong Basin is mainly influenced by biomass burning based on the 60

- 61 hygroscopicity in winter and summer.
- 62

### 63 Plain Language Summary:

This manuscript reports the chemical compositions and hygroscopic properties of 64 water-soluble fraction in PM2.5 collected from a rural site of Guanzhong Basin, a 65 highly polluted region in northwest China. We found that inorganic components 66 (ammonium and sulphate, etc) are the main substances that promote the hygroscopic 67 properties of particulate matter in summer, while in winter, the contribution from 68 organic matters increases. The SNA concentration is higher on heavily polluted days, 69 70 and the content of organic matter is high in non-polluting days. The  $g(90)_{WSM}$  values measured by H-TDMA and the retrieved  $\kappa_{WSM}$  was in the range of  $1.08 \sim 1.49(1.35 \pm 0.10)$ 71 72 and 0.04~0.29(0.19±0.06) in summer, 1.24~1.45(1.36±0.07) and 0.12~0.26(0.20±0.04) 73 in winter, respectively, which is particularly similar to the hygroscopicity parameters of particulate matter produced by biomass burning. We further infer that this region area 74 75 is affected by biomass combustion due to the fact that the hygroscopicity parameters of WSOM, calculated by E-AIM and ZSR model, is almost equal to the value of the 76 biomass combustion indicator. 77 78

79

#### 80 1 Introduction

81 Air quality problems caused by atmospheric particulate matter (PM) is a major concern globally. Research on atmospheric PM has increased over the past decades 82 because of its impact on human health (Brook et al., 2010; Fernández-Camacho et al., 83 2016; Karagulian et al., 2015; Petrowski et al., 2019), ecosystems and climate change 84 (He et al., 2019; IPCC, 2001; Paraskevopoulou et al., 2015; Zhao et al., 2017). 85 Hygroscopicity, which describes water uptake ability by particles in response to 86 elevated relative humidity(RH) (Alonso-Blanco et al., 2019; Gasparini et al., 2004), is 87 an important thermal dynamic property of atmospheric particles. Due to water 88 89 ab/adsorption, the particles extinction index will change, the mass and volume will 90 increase and can provide media for heterogeneous chemical reactions(X G Liu et al., 2010; Y Liu et al., 2016b; Y Wu et al., 2017a). The hygroscopicity of particles largely 91 depends on chemical composition, including some water-soluble inorganic matters 92 (WSIM) such as SO<sub>4</sub><sup>2-</sup>, NO<sub>3</sub><sup>-</sup>, and NH<sub>4</sub><sup>+</sup>(Junji et al., 2009) and organic matters (WSOM) 93 (J C Zhang et al., 2011a). Another concern is that because the fine PM<sub>2.5</sub> aerosol 94 particles in the atmosphere contain a variety of components, some of which are highly 95 96 hygroscopic, the haze events caused by them have become a common weather phenomenon in heavily polluted areas(Ma et al., 2012). 97

High PM<sub>2.5</sub> levels can be caused by direct emissions or by the formation of 98 99 secondary aerosols; the latter are produced from gaseous precursors, especially sulfur dioxide (SO<sub>2</sub>), nitrogen oxides (NO<sub>x</sub>), ammonia (NH<sub>3</sub>), and volatile organic compounds 100 101 (VOCs), which mainly form the components of sulfate, nitrate, ammonium and organic carbon in the particles(Bi et al., 2007; Chan and Yao, 2008; T J Wang et al., 2012). A 102 lot of previous studies had revealed that chemical composition of PM2.5 in China varies 103 significantly in different season, which in general has highest concentration in winter 104 105 and lowest in summer (Z Liu et al., 2014b; S Wang et al., 2015; L Yao and Lu, 2014). For example, Shen et al. indicated that spring samples were highlighted by abundance 106 of Ca2<sup>+</sup>, while the secondary aerosol species (NO3<sup>-</sup>, SO4<sup>2-</sup>, and NH4<sup>+</sup>) and OC dominated 107

in summer, autumn, and winter samples from 2006 to 2007 at Xi'an, China.(Shen et al., 108 2014) Moreover, a pronounced seasonal variation was observed with relatively lower 109 water content in the colder season, indicating that the inorganic salts were mainly 110 crystalline in winter, whereas they were probably dissolved during the rest of the 111 year(Hueglin et al., 2005). These seasonal variations are related to meteorological 112 conditions, emissions and chemical transformations (Z Liu et al., 2014b; S Wang et al., 113 2015; L Yao and Lu, 2014), and in turn affect the hygroscopic growth factor in each 114 115 season.

Guanzhong Basin is one of the most heavily polluted regions in the world with an 116 annual concentration of PM<sub>2.5</sub> on the ground surface more than 80  $\mu$ g·m<sup>-3</sup> during 117 2001-2006(van Donkelaar et al., 2010). Compared to other regions in China such as 118 North China Plain, Yangtze River Delta (YRD), Pearl River Delta (PRD) and Sichuan 119 Basin, air quality in Guanzhong Basin is highly affected by the dust-related emissions 120 from the Loess Plateau in the northwest direction, and the relatively stagnant 121 122 meteorological condition due to the basin topography(Jianjun Li et al., 2011). Not only the air pollution in Guanzhong urban areas such as Xi'an and Weinan City is serious, 123 but also the situation in the surrounding rural areas is very serious, which may be related 124 to the way of obtaining heat energy(Jin et al., 2018), such as biomass burning. Although 125 126 some studies have paid attention over the past decades to PM<sub>2.5</sub> chemical composition and hygroscopicity in East and North China(X-C Chen et al., 2017; Johannesson et al., 127 2007; J Wang et al., 2013; Yu et al., 2018), few studies were conducted in Guanzhong 128 Basin, especially for its rural areas. 129

In this experiment, summertime and wintertime  $PM_{2.5}$  samples were collected in a rural area of Guanzhong Basin. Some chemical compositions and optical properties of the  $PM_{2.5}$  samples were reported elsewhere(Jianjun Li et al., 2020). Here, the hygroscopic growth factor of water-soluble matter in winter and summer under high relative humidity (90%) was determined to investigate the seasonal variation of hygroscopic properties of  $PM_{2.5}$  in the rural region. We also combined the contribution of WSIM and WSOM to analyze the influences of chemical compositions and source 137 emissions on the hygroscopicity of PM<sub>2.5</sub> in the different seasons.

138

## 139 2 Methodology

140 2.1 Sample collection

The sampling was performed at at a rural background site, Lin Village (109 ° 32 'E, 141 34 ° 44' N, 354 m a.m.s.l), Weinan city, in the hinterland of the Guanzhong Basin. No 142 obvious point sources of atmospheric pollution were found nearby the sampling site. 143 Detailed information of the sampling campaign was described by Li et al. (Jianjun Li 144 145 et al., 2020). Briefly, daytime (08:00 - 20:00) and nighttime (20:00 - 08:00 next morning) PM<sub>2.5</sub> samples were collected on pre-combusted (450°C for 6 h) quartz filters 146 (Whatman QM/A) using a high volume air sampler (TISCH, TE6070DV-BL, 1.13 147 m<sup>3</sup>·min<sup>-1</sup>) during Aug. 3-23, 2016 (summer) and Jan. 20 – Feb. 1, 2017 (winter). Field 148 blank samples were also collected at the beginning, middle and end of sampling period 149 by mounting blank filters onto the sampler for about 15 min without pumping any air. 150 Before and after sampling, the sample filters were wrapped in aluminum foil and kept 151 in the refrigerator at -5 °C to prevent the decomposition and volatilization of substances. 152

- 153
- 2.2 Hygroscopicity of water-soluble matter
- 154 2.2.1 Hygroscopicity Measurement

A square of  $\sim 2.6 \text{ cm}^2$  of the sampling filter was cut (corresponding to 813.6 m<sup>3</sup> 155 sampling air) and extracted with ultrapure water under ultrasonication for 1 hour (15 156 157 min each, repeated four times). The dissolved solution was filtered through a PTFE syringe membrane filter (millex-GP, 0.22 µm in pore size, Millipore) to remove water-158 insoluble suspensions. The water-extract in 30 ml was then placed in the atomizer to 159 generate suspended aerosol particles (S K Boreddy et al., 2016). The generated aerosol 160 particles pass through a Nafion dryer (MD-070-12,  $\frac{1}{4}''$ ,  $14\pm\frac{1}{4}''$ ) and a silica gel 161 diffusion dryer (self-made, I.D.100mm, length 650mm) to remove water and leave 162 crystalline substances (RH<5%), which are then charged positive and negative ions by 163 a corona-discharge electrode operated at a high AC voltage by the neutralizer (<sup>85</sup>Kr, TSI, 164

2mCi, Model 3077). After that, the charged polydisperse aerosol particles flow 165 (0.3L/min) went through the first differential mobility analyzer (DMA1, TSI model 166 3081) with the aerosol to sheath flow ratio as 1:10 to select dry particles with the 167 diameter of 100 nm. The monodisperse100 nm aerosol particles are then introduced 168 into the RH conditioner, where RH is controlled between 10%~93%, transferred to 169 humidified DMA2 for measuring the diameter of particles at defaulted RH. 170 Condensation particle counter (CPC, TSI model 3010) is used to count the humidified 171 172 aerosol particles. All H-TDMA experiments were performed at room temperature of 298 K and atmospheric pressure of 1 atm(S K Boreddy and Kawamura, 2016; S K 173 Boreddy et al., 2016; Michihiro Mochida and Kawamura, 2004b). The system was 174 calibrated every two hours with pure ammonium sulfate particles at 90 % RH to ensure 175 the accuracy of system(H J Liu et al., 2014a). 176

#### 177 2.2.2 Hygroscopicity growth factor calculation

Aerosol hygroscopicity is described by the hygroscopic growth factor, g(RH), which is the ratio of the particle diameter at elevated RH relative to that of the initial dry particles (S K Boreddy and Kawamura, 2016; Suresh Kumar Reddy et al., 2014; Swietlicki et al., 2017) and is given by the following equation:

182 
$$g(RH) = \frac{D_p(RH)}{D_{dry}}$$
(1)

where  $D_{dry}$  is the initial dry particle diameter at RH <5% and  $D_p(RH)$  is the diameter at 183 184 an elevated RH. In this study, the hygroscopic growth factor of the water-extract components at RH of 90, i.e. g(90)<sub>WSM</sub>, was measured for all PM<sub>2.5</sub> samples. Moreover, 185 a total of 8 samples in typical whether were selected to investigate the hygroscopic 186 behaviors at whole RH range of 10%, 20%, 30%, ..., 90%, 93%. Investigation of the 187 hygroscopic growth of particles was reduced to analyzing their size distribution spectra 188 measured before and after particle humidification and fitted with a lognormal Gaussian 189 190 curve.

191 2.2.3 Kappa and ZSR calculation

192 According to the Köhler theory, the hygroscopicity parameter,  $\kappa$ , introduced by

Petters and Kreidenweiss(Petters and Kreidenweis, 2007), could be used to describe the
hygroscopicity of the aerosol particles based on the H-TDMA measured data(Suresh
Kumar Reddy et al., 2014; Swietlicki et al., 2017; Z J Wu et al., 2015; Ye et al., 2013).

196  $\kappa$  is defined according to:

$$\kappa = \frac{\left(g\left(RH\right)^3 - 1\right)\left(1 - a_w\right)}{a_w} \tag{2}$$

198 where g(RH) is the measured growth factor using an HTDMA and  $a_w$  is the water 199 activity

$$a_{w} = \frac{RH}{100} \left( \exp\left(\frac{A}{g(RH)D_{0}}\right) \right)^{-1}$$
(3)

(5)

201 with

200

202

$$A = \frac{4\sigma_{s/a}M_{w}}{\rho_{w}RT}$$
(4)

where  $\sigma_{s/a}$  is the surface tension of the solution-air interface,  $M_w$  is the molar mass of water,  $\rho_w$  is the density of water, R is the universal gas constant, T is the temperature in Kelvin, and  $D_0$  is the droplet diameter.

Assuming there is no interaction between different components of WSM, GF of internally mixed particles can be reproduced based on the ZSR relation as followed (Luo et al., 2020):

 $g_{mixed} = \left[\sum_{i} (\varepsilon_i g_i)\right]^{1/3}$ 

210 where  $g_i$  is the hygroscopic growth factor of species i and  $\varepsilon_i$  is its volume fraction in the 211 mixed WSM.

#### 212 2.3 Chemical Analysis

A punch of the filter sample (~ $8.6 \text{ cm}^2$ ) was extracted with Milli-Q water (18.2M $\Omega$ ), and filtered through a PTFE syringe filter. Then the water-extract was analyzed for water-soluble inorganic ions (SO<sub>4</sub><sup>2-</sup>, NO<sub>3</sub><sup>-</sup>, NH<sub>4</sub><sup>+</sup>, Cl<sup>-</sup>, Ca<sup>2+</sup>, K<sup>+</sup>, Na<sup>+</sup> and Mg<sup>2+</sup>) using a Metrohm Ion Chromatography (Metrohm 940, Switzerland) and WSOC using a Shimadzu TOC analyzer (TOC-L CPH, Japan). After every 10 samples are tested, one sample is randomly selected for repeated test. Concentrations of individual molecules, including levoglusosan, galactosan, and mannosan, were measured using GC/EI-MS
(Agilent 7890A-5975C, USA) calibrated by authentic standards. The details for the
sample extraction procedures and chemical measurements were provided in previous
publications (J. Li et al., 2014; Jianjun Li et al., 2020; Steven et al., 2016; T Zhang et
al., 2011b).

224 3 Result and discussion

225 3.1 Chemical composition of WSM

Previous studies indicated that the water-extract of atmospheric aerosol is mostly 226 composed of water-soluble inorganic ions, metals, and organic matters (WSOM). 227 228 However, water-soluble metals were not discussed in this study because their contribution to hygroscopic can be neglected compared with inorganic ions and OM 229 in the extract of atmospheric fine particulate (Swietlicki et al., 2017; H. Xu et al., 2019). 230 What's more, the concentration of WSOM could be calculated by multiplying the 231 232 concentration of WSOC by a factor of 2.1(Aggarwal et al., 2007; S K Boreddy et al., 2016; Jung et al., 2011). Figure 1 summarizes the temporal variation of mass 233 concentration of PM<sub>2.5</sub> and each water-soluble matter in both summer and winter. The 234 average mass concentration of PM<sub>2.5</sub> in winter is about three times higher than that in 235 236 summer (Figure 1a and Table 1), mainly attributed to enhanced emissions from residential activities for house heating and relatively stable meteorological conditions 237 in winter(Sun et al., 2019; X Zhang et al., 2019). The wintertime PM<sub>2.5</sub> concentration 238 (185.5µg m<sup>-3</sup>) in this study is comparable to that in Nanliu Village (191.0 µg m<sup>-3</sup>), 239 another small village about 110 km away from the Lin Village, in the winter of 2016 240 (Hongmei Xu et al., 2018), suggesting that PM<sub>2.5</sub> pollution is regional rather than local 241 in the Guanzhong Basin area. 242

244 Figure 1 PM<sub>2.5</sub> concentration and concentration and proportion of water-soluble substances during 245 the two sampling campaigns.

246 ----

243

247	The total amount of WSM, i.e. the sum of WSOM and water-soluble inorganic ions,
248	accounts for 66.93% and 67.16% of $PM_{2.5}$ concentration in summer and winter,
249	respectively. Inorganic ions predominate the WSM concentration in both seasons,
250	accounting for more than 50% of WSM. However, the contribution of WSOM to WSM
251	increases by 1.4 times from 27.04±8.18% in summer to 41.18±10.64 % in winter (Table
252	1). In summer, the high temperature and solar radiation are favorable for atmospheric

photochemistry activity, and thus can enhance the formation of secondary pollutants 253 (Calvo et al., 2008). Thus, the contribution of the sum of  $NO_3^-$ ,  $SO_4^{2-}$ , and  $NH_4^+$  to WSM 254 is always higher than 50% in summer (Figure 1). Sulfate is the most abundant 255 composition, accounting for about half of WSM, followed by decreasing in order of 256 WSOM, NH<sub>4</sub><sup>+</sup>, and NO<sub>3</sub><sup>-</sup>. In winter, however, WSOM becomes the most abundant 257 composition, accounting for more than one third of WSM in both daytime and nighttime. 258 The contribution of  $SO_4^{2-}$ ,  $NO_3^{-}$ , and  $NH_4^{+}$  increased continuously during the haze 259 period(Ge et al., 2019; G Wang et al., 2018a; G Wang et al., 2016a; Xie et al., 2020) 260 (January 23<sup>rd</sup> to 26<sup>th</sup>, 2017), because the high RH and stable meteorological condition 261 are favorable for their secondary formation. This result agrees well with most previous 262 studies in China (An et al., 2017; S Y Chen et al., 2015; X Wang et al., 2018b; Xiang et 263 al., 2016; Yue et al., 2015). However, it is worth noticing that the content of Cl<sup>-</sup> in the 264 particles is relatively stable, regardless of whether it is haze weather, which may 265 indicate that primary emission changes litter during winter. 266

Figure 2 Comparison of water-soluble matters between daytime and nighttime in both seasons.

Figure 2 shows the proportion of day and night components during summer and winter sampling. In summer, the contribution of  $NO_3^-$  (12.66%) in nighttime increases by around 3 times compared with that in daytime (4.35%), which is related to the enhancing gas-to-particle partitioning at lower temperature in nighttime. The proportion of WSOM at nighttime (21.30%) is lower than that in daytime (29.99%), because more secondary OM are formed in daytime. In winter, however, the proportion of water-soluble matters in the samples collected in the daytime and at nighttime has almost no change, which is different from that in summer. And it could also indirectly be explained by the static and stable environmental conditions between day and night in winter.

#### 279 3.2 Variation of g(90)WSM in association of chemical compositions

Figure 3 shows the temporal variation of  $g(90)_{WSM}$  and  $\kappa_{WSM}$  in both seasons. 280 Although the average values of  $g(90)_{WSM}$  in summer (1.35±0.10) and winter (1.36±0.07) 281 282 are comparable, daily g(90)<sub>WSM</sub> presents an obvious variation in both seasons 283 (1.08~1.49 in summer and 1.24~1.45 in winter). The results indicate that the hygroscopic properties of PM<sub>2.5</sub> in the region are highly affected by biomass burning. 284 The hygroscopic growth factor also showed a distinct diurnal pattern with higher value 285 286 at night in summer, while in winter the value of day and night was almost the same, which should be attributed by the different by the proportion of different components 287 in WSM. 288

Figure 3 The temporal variation of  $g(90)_{WSM}$  and  $\kappa_{WSM}$  in both seasons: (a) for summer, (b) for winter.

The correlation coefficient (R) is 0.71 in summer and 0.50 in winter between g(90)<sub>WSM</sub> and PM<sub>2.5</sub>, indicating that the particles in summer environment contain more substances that are more hygroscopic (e.g.,  $SO_4^{2-}$ ) than that in winter, as shown in Figure 4(a)(Steven et al., 2016). The linear correlation between g(90)<sub>WSM</sub> and major

ionic components in different seasons are shown in Figure 4. In summer,  $g(90\%)_{WSM}$ 295 presents a strong correlation with sulfate (R=0.86, Figure 4(b) and ammonium (R=0.88, 296 Figure 4(d)), implying that secondary inorganic ions formed from precursors are 297 important for the growth factor of PM2.5 over Guanzhong Basin in summer. The nitrate 298  $(R^2=0.61, Figure 4(c))$  shows a weaker correlation with  $g(90\%)_{WSM}$ , indicating their 299 weak contribution due to the relatively low abundance. Organic matters seems have 300 neglectable effect to the g(90%)<sub>WSM</sub> in summer (R<0.1; p>0.1). The correlations of 301 302  $g(90\%)_{WSM}$  with inorganic ions are much weaker in winter, e.g., the coefficients (R) is 0.50 for sulfate, 0.49 for nitrate, and 0.50 for ammonium, respectively. These results 303 suggest that the role of inorganic ions playing on the hydroscopic property of WSM of 304 PM<sub>2.5</sub> decreased in winter. Whereas, the effect of water-soluble organic matter increased 305 slightly so that it also have a weak correlation with g(90%)<sub>WSM</sub> (R=0.45, p<0.01; Figure 306 4(e)) in winter. Moreover, the correlation coefficients (R) between biomass burning 307 tracers, i.e. levoglucosan, galactosan, mannosan, and hygroscopic growth factor of 308 WSM at 90% RH are 0.54 (Figure 4(f)), 0.49, 0.52 (not shown as figures), 309 310 respectively(S K R Boreddy et al., 2014; Jung et al., 2011; M. Mochida and Kawamura, 2004a). The correlation coefficient of biomass burning indicators is larger than that of 311 WSOM, revealing that the source of biomass burning has a significant contribution to 312 the hygroscopicity of aerosols, and is the major part of organic matter. 313

314

Figure 4 Scatter plots and Linear fit curve between  $g(90\%)_{WSM}$  versus mass concentration PM<sub>2.5</sub> and WSM mass concentration of different chemical species: (a) mass concentration PM<sub>2.5</sub> in summer,(b) SO<sub>4</sub><sup>2-</sup>, (c) NO<sub>3</sub><sup>-</sup>,(d) NH<sub>4</sub><sup>+</sup>, (e) WSOM, (f)levoglucosan in the PM<sub>2.5</sub> aerosols collected at Lin Village.

 $\kappa_{\text{WSM}}$  values derived from hygroscopic growth factor measured by H-TDMA in both 318 seasons are presented in Figure 3. The calculated kwsM ranges from 0.04~0.29 averaged 319 of 0.19±0.06 in summer and 0.12~0.26 with the average of 0.20±0.05 in winter, 320 respectively. The hygroscopic growth factor of the WSM in the environmental PM<sub>2.5</sub> 321 aerosol in this study are significantly lower than that of other regions, such as marine 322 sites and urban sites (Table 2). This related to the composition of aerosols in different 323 324 regions(Y Liu et al., 2016b). Marine aerosols contain a large amount of inorganic salts, 325 of which Na<sup>+</sup> and Cl<sup>-</sup> are the most abundant, showing very high hygroscopicity (2.1)(S K Boreddy and Kawamura, 2016; S K Boreddy et al., 2016). In addition, the 326

hygroscopicity parameters of water-soluble matter in urban environments aerosols are 327 higher than those of rural aerosols due to the influence of sulfate and nitrate discharged 328 by more human activities in urban areas (Y Liu et al., 2016b; Ye et al., 2013; J C Zhang 329 et al., 2011a). At rural and suburban sites, however, PM2.5 aerosols contain more water-330 soluble organic matters(Jin et al., 2018; Suresh Kumar Reddy et al., 2014) with lower 331 hygroscopicity than SNA and NaCl(Swietlicki et al., 2017). In this study, the samples 332 were collected at rural site, Lin village, with the proportion of water-soluble organic 333 334 matter in winter and summer was 27.04% and 41.18% respectively. Therefore, the measured hygroscopic growth factor with HTDMA is closer to the value of less 335 hygroscopicity, such as biomass burning aerosols, and the value of the retrieved 336 hygroscopicity parameter,  $\kappa$ , is smaller. 337

Hygroscopicity parameters,  $\kappa$ , is typically characterized in the range of  $0.1 < \kappa < 0.9$ 339 for atmospheric particular(Petters and Kreidenweis, 2007). What's more, biomass-340 burning aerosols was significantly lower than that of typical urban aerosols (Z J Wu et 341 342 al., 2015). Previous studies have focused on the biomass burning aerosols typically, which exhibit lower hygroscopic properties and are therefore classified as less-343 hygroscopic particles(Kreidenweis and Asa-Awuku, 2014). The κ values of biomass-344 burning aerosols are reported to be 0.05–0.1 in the African savannah (Kotchenruther 345 and Hobbs, 1998), 0.1 in Brazil (Magi and Hobbs, 2003), 0-0.04 for the almost 346 hydrophobic modes and 0.06–0.13 the less hygroscopic modes in Amazonia(Swietlicki 347 et al., 2017), and 0.11±0.07 (range: 0.04–0.24) in Tanzania(Suresh Kumar Reddy et al., 348 2014), respectively. An average  $\kappa$  of 0.08 for 100 nm particles for freshly emitted 349 350 particles from the burning of different hard and soft woods(Dusek et al., 2010b), biomass-burning secondary organic aerosols was 0.11(Engelhart et al., 2012), 351 352 environmental aerosol particles are about 0.1 in Beijing (Z Wu et al., 2017b)and  $0.16 \pm 0.006$  in Athens(Psichoudaki et al., 2018). However, a wider range of 353 hygroscopic parameters of biomass combustion aerosols has also been reported. For 354 examples, the  $\kappa$  values ranging from 0.01 to 0.55 for grass burning are reported by 355 Andreae and Rosenfeld (Andreae and Rosenfeld, 2008), DeMott et al. derived k values 356 in the range of 0.02–0.56 from H-TDMA data(Demott et al., 2009), and Maria et al. 357 358 calculated that it is in the range of 0-0.39 for fresh wood combustion particles. Interestingly, the mean of  $\kappa_{WSM}$  (~0.19 in summer and ~0.20 in winter) in this study is 359 comparable to that of biomass burning aerosols measured by Rose et al. with the 360 average  $\kappa$  value elevated to 0.20 during a strong local biomass burning event near the 361 mega-city Guangzhou, China (Rose et al., 2010). In addition, the  $\kappa$  value from crop 362 residues burning ranges from 0.20 to 0.35.(C Li et al., 2016). Therefore, it can be 363

364 concluded that  $PM_{2.5}$  in this area is greatly affected by biomass combustion emissions 365 according to the correlation between biomass burning indicators and  $g(90)_{WSM}$ , as well 366 as hygroscopicity parameters.

367 3.3 Hygroscopic Growth Curves of WSM

Aerosol particles, particularly the water-soluble matter have the ability to ab/desorb 368 water vapor during their interaction in the atmosphere, thus affecting their size, optical 369 370 properties, and aqueous phase reactions(X G Liu et al., 2010; Y Liu et al., 2016b). Therefore, it is of great significance to explore the hygroscopicity in the atmosphere. 371 372 To further investigate the hygroscopic growth of WSM in the PM<sub>2.5</sub> aerosols, four pairs of PM<sub>2.5</sub> samples in typical weather or event, that are summertime samples (day and 373 night on 3 August, 2016), wintertime severe haze event (day and night on 25 January, 374 2017), wintertime clean day (day and night on 29 January, 2017), and Chinese Spring 375 Festival event (night on 27 January, 2017 and day on January 28, 2017), were chosen 376 377 to analyze their hygroscopic growth at RH ranging from 10% to 93%.

378

Figure 5 Changes in hygroscopic growth factor of the WSM ( $g(RH)_{WSM}$ ) of aerosol particles nebulized from water extracts of samples, as a function of RH under hydration experiments. (a) for

typical summer weather, (b) for heavy haze day, (c) for the China New year Eve and the first day of
the new year, (d) for no-pollution day.

Figure 5 shows the changes in g(RH) of the WSM, as a function of RH under 383 384 hydration experiments. The hygroscopic growth curve of water-soluble substances in summer has no obvious deliquescence point in the daytime, however, a clear 385 deliquescent point appears between  $60\% \sim 70\%$  during the night (Figure 5(a)). When the 386 RH is in the range of 30%~60%, the gfs(RH)<sub>WSM</sub> in daytime are greater than those in 387 nighttime. However, the gfs(RH)<sub>WSM</sub> in daytime are less than that in nighttime when 388 389 RH are higher than 60%, which attributed to the distinct organic to inorganic ratios in WSM. As shown in Figure 6(a) and (b), inorganic salts dominated the water-soluble 390 matter in both summertime samples. When the relative concentration of nitrate 391 392 increases at night, the solution after ab/adsorbing water is more inclined to form the mixed aqueous solution of nitrate and sulfate(Schaap et al., 2004). Therefore, it could 393 be inferred that the deliquescent relative humidity (DRH) is in the range of 60%~70% 394 due to the abrupt increased growth factor. For solutions with more than two electrolytes, 395 396 the deliquescent relative humidity (DRH) of a salt in a multicomponent solution is always lower than its DRH in solution alone(Wexler and Seinfeld, 1991). In addition, 397 the internal mixing of organic and inorganic aerosol components usually leads to a 398 decrease of deliquescence and efflorescence RH(Mikhailov et al., 2009). Therefore, 399 400 when the concentration of nitrate increases from day to night with 3.76% to 15.15%, the deliquescence point of mixed electrolyte will be reduced to be closer to that of 401 NH<sub>4</sub>NO<sub>3</sub>. The first deliquescence point of the NH<sub>4</sub>NO<sub>3</sub>-(NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> system occurs at 402 RH=61.2~61.3%, and the second-stage hygroscopic growth occurs at RH=77~78% 403 404 when the system becomes a saturated solution droplet(Lee et al., 2001). On the other hand, nitrate during the night showed a substantial increase of about 12%, while the 405 406 sulfate concentration produced a decrease of about 10%. Thus, increased nitrate 407 concentration can reduce the deliquescent point of the mixed particles(Wexler and Seinfeld, 1991), which is consistent with the results during nighttime of summer in this 408 409 study. As shown in Figure 6(a) and (b), inorganic salts dominate the water-soluble substance in both summertime samples. WSOM also contributes substantially to WSM 410

in PM<sub>2.5</sub>, and its concentration is higher during the day-time than at night-time. Previous
studies indicated that the organic matters could affect the hygroscopicity of inorganic
salts by decreasing the deliquescence point of salt, changing the efflorescence point or
suppressing the crystallization of salts(Bouzidi et al., 2020; Q Liu et al., 2016a; Y Wang
et al., 2016b; Z Wang et al., 2018c).No obvious deliquescence point was found is mainly
because of the higher contribution of WSOM in the daytime(Dusek et al., 2010a; Z
Wang et al., 2018c).

In the three typical events of winter, the proportion of inorganic and organic 418 substances has greatly changed. In heavy haze day in winter, the particulate hygroscopic 419 deliquescence point obviously emerges between 50%~60% with the growth factor 420 421 increase from 1.05 at 50% RH to 1.17 at 60% RH in Figure 5(b). In terms of chemical 422 composition from Figure 6(c) and (d), it can be found that although the proportion of organic matter soluble in water during heavy haze weather is higher than that in summer, 423 the inorganic SNA (sulfate, nitrate, ammonium) is still the main component, which 424 425 greatly contributes to the hygroscopic properties of particles. In severe haze days, the concentration of nitrate is dominant, followed by sulfate, which is fundamentally 426 different from that in summer. When the relative humidity is below 50%, there is no 427 significant increase in the size of the particles, similar to the characteristics contained 428 429 in inorganic substances. But after that, the particles grow rapidly and become larger, and the growth factors of particulate matter during the day and nighttime are 430 comparable in each RH condition. This is consistent with the average day and night 431 comparison of the whole process in the previous analysis. During this period, the 432 content of components represented by day and night is almost the same, which also 433 indirectly explain the unfavorable atmospheric photochemistry and low wind speed in 434 the rural area in winter. However, no significant abrupt change in the hygroscopic 435 growth curve of particulate matter were found for clean day (Figure 5(d)) and Chinese 436 437 Spring Festival event (Figure 5(c)). More potassium matters were emitted from the 438 fireworks and firecrackers on Chinese Spring Festival event. For K<sub>2</sub>SO<sub>4</sub>, the DRH was reported to be 96%, while KNO<sub>3</sub> displayed continuous hygroscopic growth (Freney et 439

al., 2009; Tang et al., 2019). Thus, no deliquescence was observed in the samples during 440 the Spring Festival. And the emissions on the first day of the new year are more than 441 New Year's Eve. Unlike daytime, the concentration of nitrate is higher, which is due to 442 the intensification of nitrogen oxides to nitrate during the night. As the no-pollution day 443 is close to the Spring Festival, and the continuous firecracker emissions in rural areas, 444 the proportion of inorganic aerosol components such as potassium and sodium ions is 445 still high. Compared with that in summer typical day, the content of WSOM in 446 447 environmental particles in winter has been increased significantly. Especially, in clean day, WSOM accounts for about 60% of WSM (Figure 6(g) and (h)). Due to the large 448 proportion of organic matter, the hygroscopic growth factor of WSM with the increase 449 of relative humidity tends to be more consistent with that of organic matter without 450 451 deliquescence point. In addition, on no-pollution day, the proportion of sulfate in the inorganic component SNA is still the highest except for WSOM, similar to that in 452 453 summer.

454

456 3.4 Hygroscopic Growth of WSOM

Generally, the hygroscopic property of environmental particles is mainly controlled by the inorganic to organic ratios contained in them. The additional water, which cannot be explained by the WSIM, can be then attributed to the WSOM(Jung et al., 2011; Suresh Kumar Reddy et al., 2014). However, the measurement of hygroscopic characteristics of water-soluble organic substances is still insufficient in the currently applicable technology. There are several studies which have confirmed that the use of the ZSR mixing rule can achieve a better chemical composition and particle hygroscopicity closure(Almeida et al., 2019; Dusek et al., 2010a; Meyer et al., 2008). The g(RH)wsom can be calculated as follows:

466 
$$g(RH)_{WSOM} = \left[\frac{g(RH)^{3}_{WSM} - \left(\varepsilon_{WSIM} g(RH)_{WSIM}\right)^{3}}{\varepsilon_{WSOM}}\right]^{\frac{1}{3}}$$
(6)

where  $\varepsilon_{WSIM}$  and  $\varepsilon_{WSOM}$  represent the volume fractions of WSIM and WSOM in the 467 WSM, respectively. These two values are listed in Table 3. The g(RH)<sub>WSIM</sub> corresponds 468 to the growth factor of water-soluble inorganic substance, which are calculated by 469 model IV of E-AIM (S K Boreddy and Kawamura, 2016; Jung et al., 2011; Q Liu et al., 470 2016a; Suresh Kumar Reddy et al., 2014). K<sup>+</sup>, Ca<sup>2+</sup>, and Mg<sup>2+</sup> that are not included in 471 the model are converted into equivalent Na<sup>+</sup> based on charge conservation (Hennigan 472 et al., 2015). g(RH)<sub>WSIM</sub> can be calculated by the Zdanovskii–Stokes–Robinson (ZSR) 473 model according to the chemical compositions of the mixture, which is based on the 474 linear addition of water content of individual component in the mixture(Bouzidi et al., 475 2020; Jung et al., 2011; Z Wang et al., 2018c). The composition of organic matter causes 476 the density to change, and it is found that the density is mainly distributed near 1.4g/cm<sup>3</sup> 477 478 during measurement(Aggarwal et al., 2007; Dick et al., 2000; Jung et al., 2011)

482

The retrieved  $g(90\%)_{WSOM}$  and  $\kappa$  for all the samples during the study period is shown 485 in Figure 7. In summer, g(90%)<sub>WSOM</sub><1 in some samples, meaning that organic matter 486 487 does not contribute to the increase of the hygroscopic growth of particles. g(90%)<sub>WSOM</sub> ranges from 1.06~1.52 with an average of 1.25±0.14, excluding samples with 488  $g(90\%)_{WSOM} < 1$ . While in winter, the  $g(90\%)_{WSOM}$  of all samples is always greater than 489 1, in the range of 1.06~1.58 with an average of 1.38±0.15, indicating that organic 490 matters contributes to particle size growth. The corresponding  $\kappa$  values are in the range 491 492 of 0.02~0.32(0.13±0.09) for summer and 0.02~0.38(0.22±0.10) for winter, respectively. 493 The mean value of  $g(90\%)_{WSOM}$  is close to the hygroscopic growth factor of biomass

burning indicator, such as levoglucosan (1.29), mannosan (1.28), and galactosan (1.27) 494 (Mikhailov et al., 2009; Michihiro Mochida and Kawamura, 2004b), which adds 495 another evidence for the influence of biomass burning on aerosol particles in the region. 496 More importantly, the correlation between the hygroscopic growth factor of WSOM 497 and the levoglucosan is analyzed to be 0.53 in summer and 0.43 in winter (not shown 498 as figures). This means that levoglucosan contributes only a part to g(90%)<sub>WSOM</sub>. While 499 in winter heavy haze episode, the hygroscopic growth factor of organics shows a 500 501 downward trend, indicating that their contribution to particle hygroscopic property decreases. Therefore, it can be inferred that the relative contribution of inorganic 502 substances will increase. This is consistent with the results published in many literatures 503 suggesting that severe haze in winter is caused by an increase in inorganic substances(S 504 K Boreddy et al., 2016; Gysel et al., 2007). However, in non-pollution weather, the 505 hygroscopic growth factor of WSOM increases. When the effects of anthropogenic 506 activities such as severe haze events and New Year's Day were excluded, the correlation 507 parameters(R) of g(90)<sub>WSOM</sub> and levoglucosan in other weather conditions increased to 508 509 0.71 (not shown as figures). This further proves that the rural areas in Guanzhong Basin are affected by biomass burning. 510

#### 511 **4** Conclusion

In this study, we investigated the chemical components and hygroscopic properties 512 of water-soluble fraction in PM2.5 aerosols collected from a rural site, Lin village 513 514 located at Guanzhong Basin. Air pollution in winter over the Guanzhong Basin was a regional problem, not just a local area that needs to be urgently addressed. Inorganic 515 ions predominated the WSM concentration in both seasons, however, the contribution 516 of water-soluble organic matter (WSOM) to WSM increased by 1.4 times from summer 517 518 to winter. The g(90)<sub>WSM</sub> values measured by H-TDMA and the retrieved  $\kappa_{WSM}$  was in the range of 1.08~1.49 (1.35±0.10) and 0.04~0.29 (0.190±0.06) in summer, 1.24~1.45 519  $(1.36\pm0.07)$  and  $0.12\sim0.26$   $(0.144\pm0.04)$  in winter, respectively. g(90)<sub>WSM</sub> presented fair 520 521 correlations with levoglucosan, galactosan, and mannosan in winter, suggesting an influence of biomass burning on hygroscopic properties of PM<sub>2.5</sub> in the region. 522

Increased nitrate concentration at night in summer reduced the deliquescent point (60%-523 70%) of the particles, and enhanced the hygroscopic growth factor of the particles at 524 elevated relative humidity. For heavy haze day in winter, SNA are the main components, 525 which greatly contributes to the hygroscopic property of particles (deliquescence point 526 ranges from 50% to 60%). In contrast, more metal matters emitted on Chinese Spring 527 Festival event and WSOM in clean day causes no deliquescence point in the process of 528 hygroscopic growth with the elevated RH. The derived  $g(90)_{WSOM}$  and  $\kappa_{WSOM}$  was 529 calculated by ZSR model. The mean value of  $\kappa_{WSOM}$  in this study was significantly 530 lower than that of marine sites and urban sites. The mean  $g(90)_{WSOM}$  is in the range of 531 that of biomass burning aerosols. Moreover, it was found that the correlation between 532  $g(90)_{WSOM}$  and levoglucosan increased significantly (R=0.71) after eliminating heavy 533 haze and New Year's events, further confirming the impact of biomass burning in the 534 535 region.
