Abstract

Land skin temperature (LST) is one of the most important factors in the land-atmosphere interaction process. Raw measured LSTs may contain biases due to instrument replacement, changes in recording procedures, and other nonclimatic factors. This study attempts to reduce the above biases in raw daily measurements and achieves a homogenized daily LST dataset over China using 2360 stations from 1960 to 2017. The high-quality land surface air temperature (LSAT) dataset is used to correct the LST warming biases in cold months in regions north of 40° N due to the replacement of observation instruments around 2004. Subsequently, the Multiple Analysis of Series for Homogenization (MASH) method is adopted to detect and then adjust the daily observed LST records. In total, 3.68×10^3 significant breakpoints in 1.65×10^6 monthly records are detected. A large number of these significant breakpoints are located over large parts of the Sichuan Basin and southern China. After MASH procedure, LSTs at more than 80% of the breakpoints are adjusted within $+/- 0.5 \,^{\circ}$ C, and 10% of the breakpoints are adjusted over 1.5 $\,^{\circ}$ C. Compared to the raw LST dataset over the whole domain, the homogenization significantly reduces the mean LST magnitude and its interannual variability as well as its linear trend at most stations. Finally, we preliminarily analyze the homogenized LST and find that the annual mean LST averaged across China shows a significant warming trend (0.22 $\,^{\circ}$ C decadal⁻¹). The homogenized LST dataset can be further adopted for a variety of applications (e.g., model evaluation and extreme event characterization).

16 Abstract

Land skin temperature (LST) is one of the most important factors in the land-17 atmosphere interaction process. Raw measured LSTs may contain biases due to 18 instrument replacement, changes in recording procedures, and other nonclimatic 19 20 factors. This study attempts to reduce the above biases in raw daily measurements and achieves a homogenized daily LST dataset over China using 2360 stations from 1960 21 to 2017. The high-quality land surface air temperature (LSAT) dataset is used to correct 22 the LST warming biases in cold months in regions north of 40°N due to the replacement 23 24 of observation instruments around 2004. Subsequently, the Multiple Analysis of Series for Homogenization (MASH) method is adopted to detect and then adjust the daily 25 observed LST records. In total, 3.68×10^3 significant breakpoints in 1.65×10^6 monthly 26 records are detected. A large number of these significant breakpoints are located over 27 large parts of the Sichuan Basin and southern China. After MASH procedure, LSTs at 28 more than 80% of the breakpoints are adjusted within +/- 0.5 °C, and 10% of the 29 breakpoints are adjusted over 1.5 °C. Compared to the raw LST dataset over the whole 30 domain, the homogenization significantly reduces the mean LST magnitude and its 31 interannual variability as well as its linear trend at most stations. Finally, we 32 33 preliminarily analyze the homogenized LST and find that the annual mean LST averaged across China shows a significant warming trend (0.22 °C decadal⁻¹). The 34 homogenized LST dataset can be further adopted for a variety of applications (e.g., 35 36 model evaluation and extreme event characterization).

MASH method, variability

39 **1 Introduction**

Land skin temperature (LST) is a pivotal factor in the land-atmosphere interaction process. LST directly influences the sensible and latent heat fluxes from the land surface to the planetary boundary layer (Zeng et al., 2012; Zhou & Wen, 2016). Changes in LST and soil temperature can also be used as indicators of climate change (McMichael & Burke, 1998; Qian et al., 2011). Xue et al. (2018) found that soil
temperature has a relationship with subsequent downstream climate variables and can
be used as a predictor of extreme hydrological events. Furthermore, several researchers
have considered the difference between LST and land surface air temperature (LSAT)
as a teleconnection factor to predict changes in precipitation in downstream regions
(Xue et al., 2012; zhou & Huang, 2006). Therefore, through its local and teleconnection
effects, LST plays a significant role in modulating climate and climatic variability.

Long-term instrumental LST data have been collected and stored for many 51 52 decades in China. As one of the conventional observations, LST is liable to be influenced by changes in nonclimatic factors (e.g., station migration, equipment 53 replacement, and changes in the environment around the station location) (Li, 2016). 54 Of these factors, equipment replacement is always conducted at multiple stations 55 56 simultaneously (e.g., see Figure 1 of Xu et al., 2019). Ren et al. (2013) compared the soil temperature observed from both manual and automatic techniques at the same 57 stations during the same period in China and found that significant differences existed. 58 Furthermore, the sites of approximately 80% of observation stations have been 59 relocated at least once since 1950 due to the growth and expansion of cities (Cao et al., 60 2013). If we keep such inhomogeneities and directly analyze the raw data, which may 61 inaccurately describe actual climate variations, then we will potentially reach incorrect 62 conclusions, particularly in the representation of long-term trends and extremes 63 (Peterson et al., 2002; Xue et al., 2012). Therefore, it is necessary to homogenize the 64 raw observed LST before it can be used as the "ground truth" in various applications. 65

To homogenize the LST dataset, several methods have been developed and applied in different countries (e.g., Hu & Feng, 2003; Xu et al., 2019; Zhou et al., 2017). Hu and Feng (2003) applied a quality-control method to the in situ soil temperature in the United States and then reproduced a high-quality soil temperature dataset at multiple soil layers. Zhou et al. (2017) applied the RHtest software package to homogenize a monthly observed LST dataset from approximately 2200 stations from 1979 to 2003 in China and then used the homogenized LST to assess eight reanalysis

products. Xu et al. (2019) incorporated additional ancillary and metadata into a raw 73 LST dataset and then constructed a homogenized monthly LST dataset from 686 74 meteorological stations in China. Previous studies have mainly focused on 75 homogenizing LST datasets on a monthly time scale. The daily LST can describe 76 temporal variations at synoptic scales and is much needed in weather forecasts as well 77 as in modeling applications (Wu & Zhang, 2014; Xue et al., 2012). For instance, the 78 daily LST from atmospheric reanalysis products has been widely used in climate 79 research, but most of these projects underestimate the LST in China (e.g., Xu et al., 80 2019; Zhou & Wang, 2016; Zhou et al., 2017). Therefore, a publicly accessible 81 homogenized and high-quality in situ daily LST dataset in China is urgently needed. 82

Since the 1980s, various methods and techniques have been developed and used 83 to eliminate data inhomogeneities (Aguilar et al., 2003; Cao & Yan, 2012; Peterson et 84 85 al., 1998). However, there is no universal homogenization method for all climatic elements across different spatial and temporal scales. Each homogenizing method has 86 its advantages and limitations, and the choice and applicability of one method versus 87 another is often dictated by a few influencing factors, such as the station density, 88 availability of metadata, and type of variable (Peterson et al., 1998). Globally, two 89 methods are popularly used to homogenize in situ observations. One is the RHtest 90 method (Wang & Feng, 2013; Wang et al., 2010) and the other is the Multiple Analysis 91 of Series for Homogenization (MASH, Szentimrey, 1999, 2013, 2014). The RHtest 92 method applies a two-phase regression model to calculate linear trends of a target time 93 series, detect their statistically significant breakpoints, and finally, adjust them using 94 the quantile-matching adjustment method. The MASH method uses a point-to-point 95 comparison to detect breakpoints through an intercomparison of station observations 96 within the same climatic area. Then, the method homogenizes the breakpoints relied on 97 its neighbors (a detailed description is provided in section 2.2). Because the MASH 98 method is not very restricted by metadata, it is widely used to homogenize 99 100 meteorological variables. Li and Yan (2010) applied the MASH method to the daily air temperature of Beijing with additional reference information (with or without metadata) 101

and found that the MASH method could successfully detect the majority of inhomogeneities in the raw dataset. For a long-term historical station observation dataset, it is usually difficult to preserve and obtain metadata (Tao et al., 2004), and this is the case for the in situ measured LST dataset in China. Nevertheless, the MASH method allows users to perform data homogenization in the case of no metadata. As a result, we select the MASH method in the present work.

In this study, we aim to develop a high-quality LST dataset that can be used in future applications for long-term climatic and soil-related research. Using the MASH method, we examine and identify the inhomogeneities in the daily in situ collected LST from 2360 stations in the Chinese mainland. The manuscript is organized as follows. Section 2 describes the dataset and methods used in this study. Section 3 presents the detailed homogenization procedure. Section 4 demonstrates and discusses the changes in LST due to homogenization. The conclusions are presented in section 5.

115 **2 Data and Methods**

116

2.1 In situ observed LST

117 The raw daily LST dataset from meteorological stations in China was obtained from the National Meteorological Information Center of the China Meteorological 118 Administration (NMIC/CMA) from 1960 to 2017. Fundamental quality control (e.g., 119 120 screening for unreasonable extreme values) was performed on this dataset before it was released to the public (http://data.cma.cn/data). In China, a large number of 121 meteorological stations were established in the early 1950s, and the station density and 122 123 records were maintained with relatively high continuity and stability after 1960 (Cao et al., 2016; Shi et al., 2014). Currently, there exist more than 2400 national 124 meteorological stations in mainland China. LST is one of the factors regularly measured 125 126 and collected every day at the meteorological stations. Before 2000, LST was recorded and stored manually four times a day (at 02:00, 08:00, 14:00, and 20:00 Beijing time) 127 with a surface and bent stem earth mercurial thermometer. After 2000, the observation 128 system was updated gradually to employ a platinum resistance temperature sensor, 129

which is an automatic instrument and is more effective than mercurial thermometers.
After the update, the observation frequency became hourly (twenty-four times a day,
Ren et al., 2013). The renewal period is concentrated during 2000-2007 across mainland
China, and the observation system north of 40°N was updated in 2004 (see Figure 1 of
Xu et al., 2019). The arithmetic average of the observations collected at multiple times
within a day is regarded as the daily LST in the data collection.

136 In the present work, daily LST measurements from up to 2360 meteorological stations are used. The majority of stations are located in relatively low altitudinal 137 regions, which are usually densely populated (Figure 1a). For example, there is an 138 obviously higher density of stations in the Yellow and Yangtze River Basins, Southeast 139 China and the Central China Plain than in other regions. The station distribution is 140 relatively sparse in high altitudinal and sparsely populated areas, such as the Northwest 141 China and Qinghai-Tibet Plateau regions. In addition, the number of effective stations 142 (i.e., stations with measurements) was 1476 in 1960, after which it increased generally 143 144 over time (stable during 1980-2010). In 2017 the number of effective stations increased to 2628 (Figure 1b). 145

146

Figure 1. (a) Location of the meteorological stations (dots) and the division of the nine subregions (black curves). The black dots (a total of 197 dots) denote the specific stations described in Section 3.1; (b) the number of the daily nonmissing stations in

each year. The top (bottom) of the whisker plot represents the 90th (10th) percentile of
the station number, the top (bottom) of the box represents the 75th (25th) percentile,
and the middle line represents the 50th percentile. The straight line indicates the final
2360 stations used in the current study. (Additional information for the stations is
shown in **Table 1.**)

155

2.2 Multiple Analysis of Series for Homogenization (MASH)

The MASH method was developed by Szentimrey (1999, 2014) and is based on 156 the hypothesis test method to detect possible breakpoints at a given significance level. 157 Through comparisons of measurements at different stations within the same climate 158 region, the MASH method does not require prior assumptions of a homogeneous time 159 series. This method has been widely applied to detect and adjust the inhomogeneity of 160 161 raw meteorological observations at ground stations (e.g., Li et al., 2018, 2020). Guijarro et al. (2017) tested nine commonly used homogenization methods (including the RHtest 162 and MASH methods) and compared their homogenized performances in terms of the 163 root mean square errors and trends of air temperature time series. They found that the 164 MASH method produced more reliable results than other methods (Guijarro et al., 165 2017). 166

To homogenize daily records, the MASH method must first homogenize the corresponding monthly data. Therefore, the daily LST at each station is first aggregated to monthly values, and then, the breakpoints of the monthly LST are detected and adjusted. Finally, the MASH method is again applied to homogenize the daily LST with the incorporation of the homogenized monthly values. Detailed information of the MASH method, including the mathematics it uses and its technique, is provided in its online manual

(https://www.met.hu/en/omsz/rendezvenyek/homogenization_and_interpolation/softw
are/). The latest version of MASH, v3.03, is used in this study. According to the
description in the MASH manual, two different models can be selected and used. One
is the additive model, which requires that the targeted dataset has a normal distribution

(e.g., temperature). The other is the multiplicative model and can be used for quasi
lognormally distributed data series (e.g., precipitation). In this study, we choose the
additive model and define a Monte Carlo threshold of 0.05 as the significance level.

In the default MASH procedure, the monthly/annual value is set as missing if 181 any missing day/month exists within that month/year. Following this criterion, many 182 LST stations would be discarded, which would lead to the loss of a great deal of useful 183 184 data because most stations only have a few days missing in a specific month. Furthermore, the loss of useful data is not the intention of data homogenization. Here, 185 we use a lenient threshold condition for the missing value judgment to retain as many 186 useful observation stations as possible. At each station, the monthly LST is set as a 187 missing value when the daily LST is available for less than 9 days of the current month. 188 Meanwhile, the annual LST is set as a missing value when more than 3 continuous 189 monthly values are missing. Finally, we remove stations with available annual values 190 totaling less than 30 years of the full 58 years. Eventually, 2360 stations remained and 191 192 were homogenized by the MASH method (shown as the straight solid line in Figure 1b). According to the principle of MASH as well as the spatial variability of LST, we 193 perform MASH in each individual climate region. Based on the natural conditions for 194 agricultural production and also in consideration of climate characteristics, we divide 195 the mainland China areas into nine subregions (Figure 1a): Huang-Huai-Hai Plain 196 (HHH), Loess Plateau (LP), Middle-lower Yangtze Plain (YZ), Northeast China Plain 197 (NE), Northern arid and semiarid region (NA), Qinghai Tibet Plateau (TP), Sichuan 198 Basin and surrounding regions (SC), South China (SE), and Yunnan-Guizhou Plateau 199 (YG). The shapefile of each subregion is available from the Institute of Geographical 200 Sciences Sciences 201 and Resources. Chinese Academy of (http://www.resdc.cn/data.aspx?DATAID=275), and the number of effective stations 202 in each subregion is shown in Table 1. 203

Table 1. Number of stations in each subregion

Huang-Huai-Hai Plain	HHH	414
Loess Plateau	LP	202
Middle-lower Yangtze	YZ	488
Plain		
Northeast China Plain	NE	183
Northern arid and	NA	328
semiarid region		
Qinghai Tibet Plateau	TP	90

surrounding regions		
South China	SE	164
Yunnan-Guizhou	YG	291
Plateau		
Mainland China	China	2360

In addition, other statistical methods, including linear regression and standard deviation, are used to comparatively analyze the raw and homogenized LST dataset. Two-tailed Student's test is used to test the significance of these statistics.

3 Inhomogeneity in the raw climate time series

209 3.1 Prelimina

3.1 Preliminary adjustment of LSTs in northern China

As mentioned in the introduction section, automatic instruments for LST 210 211 measurements began to replace manual ones in 2004 in northern China (mainly north of 40°N, including Xinjiang Province and NE and NA subregions, shown as blue dots 212 in Figure 1a), which resulted in LSTs increasing abruptly in cold months since 2005. 213 214 To understand this result, we select one cold month (December) to analyze the time series of LST over northern China. Figure 2 shows the daily LST time series averaged 215 across 197 stations in northern China in December from 1960 to 2017. There is a 216 distinct jump in 2005, after which the magnitude of LST increases remarkably. The 217

mean value is -8.1 °C for 2005-2017, which is 8 °C higher than that for 1960-2005 (-218 16.1 °C). This phenomenon is prevalent at all 197 stations. Xu et al. (2019) found a 219 220 similar problem in the same regions (the NE and NA subregions) when they compared the differences of LST measurements from manual and automatic instruments during 221 parallel observation periods. The warm shift phenomenon is principally caused by the 222 223 change of the observation system from a manual to an automatic one around 2004. In winter, when the ground surface is covered by snow, the automatic instrument sensor 224 225 measures the temperature at the soil surface under snow, whereas the manual instrument measures the snow surface. Because snow provides strong insulation of heat, it can 226 absorb both longwave radiation from the ground surface transmitted upward and 227 shortwave radiation from the atmosphere transmitted downward. Therefore, the 228 measured LST from the automatic instrument would change much more slowly under 229 230 snow and cannot represent real LST change features (Liu et al., 2008; Ren et al., 2013). When the manual sensor was buried in snow, it was removed to measure the snow 231 surface temperature instead of the soil surface temperature (Administration, 2003). 232

233

Figure 2. Time series of the raw daily LST averaged across 197 stations (the black dots in Figure 1a) in December for the period of 1960-2017. The red solid line is a reference line to separate the years before and after 2005; the two blue dotted lines are the mean LSTs derived from the raw daily dataset during 1960-2005 and 2005-2017. The green solid curve represents the daily LST time series after LSAT adjustments (Section 3.1), and the red dotted line is the mean LST during 2005-2017. The corresponding mean LST values averaged for different periods are also indicated.

More specifically, we take a station (ID 50862, 46.98°E, 128.05°N) at the NE 241 subregion as an illustrative example. Figure 3 shows the abrupt warming shift in cold 242 months (from October to the following April) since 2005. A similar phenomenon 243 appears at all 197 stations (black dots in Figure 1a) in the NE and NA subregions. In 244 the MASH procedure, possible breakpoints are determined by comparing the values at 245 246 the candidate station with those at the nine nearest reference stations. If those surrounding reference stations show similarly abrupt changes or shifts as the candidate 247 station, then the MASH method cannot detect them (Li, 2016). Due to how MASH 248 works, it will fail to deal with the above problematic phenomenon (compared to the 249 250 blue and orange lines in Figure 3b). Thus, before applying the MASH method, we perform a preprocessing procedure for the LSTs from these 197 stations. 251

Figure 3. Case station (ID 50862, 46.98°E, 128.05°N) for the raw and calculated LST, and the homogenized results (unit: °C). (a) Raw daily LST plotted against the calculated daily LST in each month during 1960-2004, where the black solid line is the reference (x=y) line; (b) raw (blue) and MASH homogenized (orange) daily LST, and (c) raw and calculated (green line) LST during 2003-2007. The calculated daily LST is the LST adjusted by the LSAT (described in section 3.1).

252

There is a very close relationship between the LSAT and LST, and their differences determine surface heat fluxes (Zeng et al., 2012). The observed LSATs have undergone a strict quality control process and do not show such remarkable warming shifts. Therefore, the LSAT is used as a reference to correct the LST warming bias at

each station. Simplistically and practically, it is assumed that the characteristics of the 263 changes in LSATs are consistent with those in LSTs at the same station. This 264 assumption is reasonable because both LSAT and LST show similar variabilities. The 265 following procedure is used to adjust the LST via the LSAT. First, we construct a 266 regression equation between the LST (dependent variable) and LSAT (independent 267 268 variable) for each cold month (from October to the following April) at each of the 197 stations from 1960 to 2004. Second, the regression coefficient and the raw daily LSAT 269 in the current month are used to compute the corresponding daily LST from 2005 to 270 2017. The computed LSTs are regarded as the "calculated LSTs" at the 197 stations. 271 To verify the reasonableness and applicability of the above hypothetical relationship, 272 we compare the raw and calculated LSTs in Figure 3a. All the dots spread around the 273 reference y-x line, and the monthly absolute mean differences between the calculated 274 and raw LSTs are generally less than 1 °C. In cold months, the absolute differences are 275 less than 0.5 °C, except in April (October), when there is a relatively large error in the 276 mean differences of approximately -2 °C (2 °C). However, the standard deviation of the 277 278 raw LST during 1960-2005 in April (October) is 3 °C (6 °C) and is higher than the mean difference. Therefore, it still can be concluded that the calculated LSTs are consistent 279 with the raw LSTs during the whole period. Similar results are also shown at other 280 stations. After the above process, the distinct warm shift of the LST in cold months is 281 removed (Figure 3c). The calculated daily LST across all 197 stations averaged in 282 December from 2005 to 2017 (green line in Figure 2) also shows consistency with the 283 raw daily LST from 1960 to 2005, and the mean value for 2005-2017 (-15.9 °C) is close 284 to that for 1961-2005 (-16.1 °C). The above calculated LSTs at 197 stations for 2005-285 2017 are added to the raw dataset and replace the values at the same time and station. 286

287

3.2 Breakpoint detection by MASH

After the above preliminary adjustments, we apply the MASH method at all 289 2360 stations in China. The first step of MASH is to detect the temporal breakpoints of 290 the LST time series at each station. The breakpoint (also called the change-point) is 291 where the time series displays significant differences before and after that point. The

time series show a distinct leap at the breakpoint. To help understand this process, we 292 take one station (ID 57710 in the YG subregion) as an illustrative example (Figure 4). 293 The LST at the candidate station (the red dot in Figure 4a) is first compared with the 294 values from the nine closest stations (the blue dots in Figure 4a). Compared with the 295 other nine reference time series (Figure 4b), a breakpoint appears in 1970 in the 296 candidate time series, of which the mean LST during 1960-1970 is 21.1 °C, 3 °C higher 297 than that during 1970-2017 (18.1 °C). The variability of the homogenized time series 298 299 (the blue line in Figure 4c) is akin to the nine neighbor reference time series. The time series has a warming trend (0.09 °C decadal⁻¹), showing the opposite tendency 300 compared to the raw time series (-0.26 °C decadal⁻¹). 301

302

Figure 4. Annual LST series at station ID 57710 (27.85°E, 106.37°N, a candidate station) in the YG subregion (unit: °C). (a) Distribution of stations, including the candidate station (red dot), the nine nearest reference stations (green dots), and other stations (black dots) in the YG subregion; (b) the raw annual LST anomalies of the candidate station (red curve) and the nine reference stations (black curves); (c) annual LST from the raw (red curve) and homogenized time series at the candidate station.

Manuscript submitted to Earth and Space Science

309

Figure 5. Number of breakpoints for the monthly LST records at the effective stations during 1960-2017. (a) Spatial distributions at all stations and (b) accumulation in each month and in each year across all stations.

Repeating the above procedure for all the stations in each of the nine subregions, 313 we identify the breakpoints at all 2360 stations from the monthly LST time series for 314 the period of 1960-2017. Note that only breakpoints with an absolute value higher than 315 0.5 °C are treated as significant breakpoints, and there are a total of 3.68×10³ significant 316 breakpoints counted in Figure 5. The figure clearly shows that the monthly LSTs at the 317 majority of stations contain 5-25 significant breakpoints (Figure 5). Of all 2360 stations, 318 35 stations contain over 40 significant breakpoints, of which most are located in the SC 319 and SE subregions (the red dots in Figure 5a), while 21 stations scattered across China 320 321 contain no significant breakpoints (the dark blue dots in Figure 5a). The breakpoints are relatively concentrated in the SE, HHH, and SC subregions, where there are at least 322 20 significant breakpoints identified in most stations. Having aggregated the numbers 323 of significant breakpoints at all stations (Figure 5b), nearly 500 significant breakpoints 324 occur each year on average. However, the number of significant breakpoints shows 325 distinct interannual variations and evidently increases over time, in particular, since 326 2000. In 2003, when the replacement of the LST measurement instruments occurred at 327

many stations throughout China, more than 1200 breakpoints are identified, and this 328 number reaches the maximum value. For the monthly LST time series, the number of 329 breakpoints in cold months (January to April, and November to December) is higher 330 than in warm months (May to September) in every year. Previous documents and 331 reports have also mentioned that the LST measurement instruments in in situ 332 observation systems have been gradually changed from manual to automatic ones since 333 2000 (Liu et al., 2008; Xu et al., 2019). Furthermore, it is well known that urbanization 334 has developed rapidly during recent decades in China. The fact that some stations 335 suffered from changes in the surrounding environment may also induce abrupt changes 336 in the LST records, which is another reasons for the increase of the number of 337 338 breakpoints.

339

3.3 Frequency distribution of biases in MASH

To explore the LST biases identified in the MASH procedure, we count the 340 number of breakpoints with an absolute bias over 0.5 °C (hereafter called a significant 341 adjustment) at all stations in each subregion and throughout China (Figure 6). There are 342 approximate 1.6×10^6 monthly records, of which 3.28×10^5 records (approximately 20%) 343 of total records) show significant adjustments in MASH. In each subregion, the 344 345 majority of significant adjustments vary between 0.5 and 1.5 °C and between -0.5 and -1.5 °C (2.95×10⁵ or 90% of all significant adjustments), within which two peaks are 346 found around 0.5 °C to 1.0 °C and -0.5 °C to -1.0 °C. Except for the TP subregion, 347 stations in other subregions show that the number of breakpoints with positive 348 adjustments is greater than the number with negative ones. Moreover, absolute biases 349 less than 0.5 °C (hereafter called a minor adjustment) are also counted in Figure 7. We 350 find that the minor adjustments account for 80% of the total adjustments in most 351 subregions and in all of China, which is in accordance with the above results (records 352 353 with significant adjustments account for approximately 20% of the total records). The 354 YZ (NE) subregion in the cold season shows the highest (lowest) percentage of minor adjustments, above 90% (below 80%). The percentage of minor adjustments in the SE 355 subregion from June to December is less than 60%. Approximately 80% of the total 356

records in the HHH subregion have experienced minor adjustments. We also display
the frequency distribution of daily adjusted records (figures not shown), and it exhibits
similar characteristics compared to the monthly results (Figure 6).

360

Figure 6. Frequency distribution of the significant breakpoints of LST in the nine subregions and mainland China. Biases at these breakpoints are adjusted with MASH.

363

364 Figure 7. Percentage of records with adjusted LST biases between -0.5 °C and 0.5 °C

in different months over the nine subregions and the Chinese mainland.

366 4 Characteristics of raw and homogenized LSTs during 1960-2017

To comprehensively understand the effects of inhomogeneities on the LST, we first compute three statistical metrics (mean, standard deviation, and linear trend) from both homogenized and raw LST at all stations, and we then compare their differences. To illustrate the results in different seasons, we use the statistical metrics in January and July of multiple years to represent the results in summer and winter, respectively (Figure 8).

Figure 8. Spatial distribution of the differences of the monthly means ((a), (b)) and standard deviations ((c), (d)) between the homogenized and raw LSTs in January ((a), (c)) and July ((b), (d)). The filled dot and the '+' symbol indicate the mean LST differences passing or not passing the significance test (P=0.05), respectively. The histogram plot in the lower left corner shows the frequency distribution of significant differences (unit: $^{\circ}$ C).

373

In winter, there are 81 (279) stations with significant positive (negative)
 differences between the homogenized and raw monthly mean LSTs (Figure 8a). Among

these stations, 163 (58% of 279) stations with significant negative differences are 382 located north of 40°N, while some are in the SE subregion. In summer, significant 383 differences between stations are intense in the YG, SC, SE, and NA subregions. Three 384 hundred twenty-five stations have significant LST differences, of which 117 (208) 385 stations have significant positive (negative) differences (Figure 8b). In both winter and 386 summer, the significant negative differences mainly vary between -2 °C and -1 °C, while 387 the significant positive differences are within 1 °C (histogram plots in Figures. 8a and 388 389 8b).

We use the standard deviation to represent the interannual variability, and its 390 difference between homogenized and raw data can be regarded as the changes of the 391 392 interannual variability of LST. In winter, the interannual variability of the homogenized monthly LST is much smaller than that of the raw values (Figure 8c). All 197 stations 393 north of 40°N (Figure 1a) show negative differences. Stations with negative differences 394 are also prevalent in the TP subregion. In summer (Figure 8d), the interannual 395 396 variability of the homogenized mean exhibits a remarkable difference from that of the raw mean at 102 stations, of which 100 stations display negative differences, which 397 indicates that our homogenization process reduces the interannual variability 398 remarkably at most stations whether in winter or in summer. 399

400 To explore the changes in the long-term tendency of LST due to the MASH process, we also computed the linear trend for the homogenized and raw LSTs at all 401 2360 stations in winter and summer during 1960-2017. In winter (Figures 9a and 9b), 402 144 stations (6% of all 2360 stations) have negative linear trends in the raw dataset, of 403 which only the trends at three stations are significant (p=0.05). Most stations show 404 positive trends (94% of all 2360 stations), of which the LST trend at 57% of stations is 405 significant (p=0.05). Stations with significant positive LST trends are concentrated in 406 407 the NA, NE, LP, HHH, and TP subregions, and stations with negative trends are mainly 408 located in the YG and YZ subregions. After homogenization, the number of stations with negative trends decreases from 144 to 45, and the LST trends at all these stations 409 are not significant. The percentage of stations with significant positive LST trends 410

(57%) does not change, but the distribution differs greatly. Compared to the linear trend 411 of raw LSTs, stations with significant positive trends are reduced north of 40°N (the 412 NE subregion and Xinjiang Province) but increase in the SE and TP subregions. In 413 summer (Figures 9c and 9d), stations with negative trends increase and occupy almost 414 the entire southern part of the Yellow River Basin. There are in total 648 stations with 415 negative trends, and 12% of these are significant for the raw LSTs. This number 416 increases to 659, while only 2% of them are significant for the homogenized LSTs, 417 indicating that the homogenization process reduces the LST trends overall in mainland 418 419 China.

Figure 9. Distribution of linear trends of the monthly homogenized ((b) and (d)) and
raw ((a) and (c)) LST in January ((a) and (b)) and July ((c) and (d)). The filled dot ('+')
indicates stations with trends passing (not passing) the significance test (P=0.05).

420

Finally, we perform a preliminary analysis of the homogenized LST dataset in terms of its temporal and spatial variations. Figure 10 displays the distribution of the annual mean homogenized LST and its time series averaged in China. Notably, the annual mean LST has negative values at very few stations in the NE subregion, while most stations have positive values. Moreover, for the entire period of 1960-2017, the

- 429 annual mean LST shows a significantly warming trend of approximately 0.22 °C
- 430 decadal⁻¹, which is consistent with previous studies (Xu et al., 2019; Zhou et al., 2017).
- 431 The trend of the annual mean LSAT shows a similar magnitude ($0.21 \text{ }^{\circ}\text{C} \text{ decadal}^{-1}$), and
- the annual mean LST is generally 2 °C higher than the annual mean LSAT.

433

Figure 10. (a) Distribution of the multiyear mean homogenized LST and (b) its time
series and the linear trend averaged over all stations in China (LST/LSAT with the solid
line/dotted line) for the period of 1960-2017 (unit: °C).

437 **5 Summary and discussion**

Long-term station observed datasets are the fundamental basis of climate research. A homogenized long-term LST record will greatly help us to thoroughly understand land-atmosphere interaction processes. This study is devoted to developing a homogenized long-term LST dataset from 2360 stations in the Chinese mainland for the period of 1960-2017 based on the NMIC/CMA in situ measured LST at meteorological stations. The main results are summarized as follows:

444 Due to the replacement of instruments from manual to automatic ones around 445 2004 north of 40°N, the time series of the LSTs at 197 stations display remarkable warming shifts during cold months. This warming bias fails to be homogenized by the MASH
method. Therefore, the raw LST records at the above stations are first adjusted using
the high-quality LSAT under the assumption of the same monthly variability of both
the LST and LSAT at the same station.

Then, the MASH method is applied to homogenize the LST dataset in China. 450 During the period of 1960-2017, 5-25 significant breakpoints are detected in the LST 451 452 monthly time series at most stations. Stations in southern China and most parts of the Sichuan Basin exhibited more intensive breakpoints than those in other subregions. The 453 number of breakpoints has increased since 2000. Notably, in 2004, breakpoints are 454 detected at more than 1200 stations. For most breakpoints, the absolute adjusted biases 455 due to MASH are between 0.5 °C and 1.5 °C, with peaks around 0.5 °C and -0.5 °C. 456 Moreover, comparing the difference between the homogenized and raw LSTs, the 457 MASH process generally reduces the magnitude, interannual variability, and linear 458 trends of LST. The interannual variabilities and linear trends of the homogenized LSTs 459 460 are also reduced at the majority of stations, especially in the regions north of 40°N in winter. 461

It should be noted that there are some limitations of the new homogenized LST 462 463 dataset north of 40°N. We preliminarily adjusted warm shifts of LSTs in cold seasons from 2005 onwards by briefly using a linear relationship between LST and LSAT, but 464 many other factors can also directly affect changes in LST, including precipitation 465 frequency, solar radiation, vegetation, and so on (Zhou et al., 2017). In a recently 466 published article, Du et al. (2020) corrected LSTs through LSATs while considering 467 the influences of snow depth and solar radiation. They found that the stable linear 468 relationship between LST and LSAT is sensitive to the snow depth and solar radiation 469 to some extent. Therefore, the above data uncertainty should be considered when this 470 471 dataset is applied in research.

In summary, we provide a 58-year (1960-2017) homogenized daily LST dataset
with abundant stations (2360) in China. The current paper only presents the

homogenization process of the LST dataset and its preliminary analysis, but our work extends beyond this. We apply the MASH method on soil temperature at nine soil depths (0 cm, 5 cm, 10 cm, 15 cm, 20 cm, 40 cm, 80 cm, 160 cm and 320 cm). The results for other soil depths are similar to those for LST, so we do not present them in this paper. The long-term homogenized LST and soil temperature in different soil depths contain a relatively dense number of stations and can have a variety of applications, such as for model evaluation and climate and soil related research.
