Abstract

The ocean's "biological pump" significantly modulates atmospheric carbon dioxide levels. However, the complexity and variability of processes involved introduces uncertainty in interpretation of transient observations and future climate projections. Much work has focused on "parametric uncertainty", particularly determining the exponent(s) of a power-law relationship of sinking particle flux with depth. Varying this relationship's functional form introduces additional "structural uncertainty". We use an ocean biogeochemistry model substituting six alternative remineralization profiles fit to a reference power-law curve, to characterize structural uncertainty, which, in atmospheric pCO2 terms, is roughly 50% of the parametric uncertainty associated with varying the power-law exponent within its plausible global range, and similar to uncertainty associated with regional variation in power-law exponents. The substantial contribution of structural uncertainty to total uncertainty highlights the need to improve characterization of biological pump processes, and compare the performance of different profiles within Earth System Models to obtain better constrained climate projections.

[2]Ocean Biogeochemistry and Ecosystems, National Oceanography Centre, Southampton, SO14 3ZH, UK.

Key Points:

- Six alternative flux profiles fit to a Martin curve yield large differences in atmospheric carbon.
- Structural uncertainty comprises one third of total uncertainty in the ocean's biological pump.

Plain Language Summary

The ocean's "biological pump" regulates atmospheric carbon dioxide levels and climate by transferring organic carbon produced at the surface by phytoplankton to the ocean interior via "marine snow", where the organic carbon is consumed and respired by microbes. This surface to deep transport is usually described by a power-law relationship of sinking particle concentration with depth. Uncertainty in biological pump strength can be related to different variable values ("parametric" uncertainty) or the underlying equations ("structural" uncertainty) that describe organic matter export. We evaluate structural uncertainty using an ocean biogeochemistry model by systematically substituting six alternative remineralization profiles fit to a reference power-law curve. Structural uncertainty makes a substantial contribution, about one third in atmospheric pCO_2 terms, to total uncertainty of the biological pump, highlighting the importance of improving biological pump characterization from observations and its mechanistic inclusion in climate models.

Abstract

The ocean's "biological pump" significantly modulates atmospheric carbon dioxide levels. However, the complexity and variability of processes involved introduces uncertainty in interpretation of transient observations and future climate projections. Much work has focused on "parametric uncertainty", particularly determining the exponent(s) of a power-law relationship of sinking particle flux with depth. Varying this relationship's functional form introduces additional "structural uncertainty". We use an ocean biogeochemistry model substituting six alternative remineralization profiles fit to a reference power-law curve, to systematically characterize structural uncertainty, which, in atmospheric pCO$_2$ terms, is roughly 50% of parametric uncertainty associated with varying the power-law exponent within its plausible global range, and similar to uncertainty associated with regional variation in power-law exponents. The substantial contribution of structural uncertainty to total uncertainty highlights the need to improve characterization of biological pump processes, and compare the performance of different profiles within Earth System Models to obtain better constrained climate projections.

1 Introduction

Carbon and nutrients are consumed by phytoplankton in the surface ocean during primary production, leading to a downward flux of organic matter. This "marine snow" is transformed, respired, and degraded by heterotrophic organisms in deeper waters, ultimately releasing those constituents back into dissolved inorganic form. Oceanic overturning and turbulent mixing returns resource-rich deep waters back to the sunlit surface layer, sustaining global ocean productivity. The "biological pump" maintains this vertical gradient in nutrients through uptake, vertical transport, and remineralization of organic matter, storing carbon in the deep ocean that is isolated from the atmosphere on centennial and millennial timescales, lowering atmospheric CO$_2$ levels by hundreds of microatmospheres (Volk & Hoffert, 1985; Ito & Follows, 2005). The biological pump resists simple mechanistic characterization due to the complex suite of biological, chemical, and physical processes involved (Boyd et al., 2019), so the fate of exported organic carbon is typically described using a depth-dependent profile to evaluate the degradation of sinking particulate matter.

Various remineralization profiles can be derived from assumptions about particle degradability and sinking speed(s) (Suess, 1980; Martin et al., 1987; Middelburg, 1989;
Figure 1. Fraction of sinking particulate organic matter exported from the 50 m surface layer remaining at each depth for (a) the reference power-law (Eq. 1) with exponents 0.84 $\pm$ 0.14, and six alternative functions (Eq. S1–S6) fit to the reference power-law curve (b=0.84) by (b) statistically minimizing the relative error ("RFIT"), or (c) the absolute error ("AFIT"), and (d) matching the e-folding depth scale of 164 m ("EFD"). See Materials and Methods, Table S1 for fitting details, coefficients, and fit statistics. Inset plots show the attenuation rate of the export flux with depth $\left[\frac{1}{f} \frac{\partial f}{\partial z}, m^{-1} \right]$.

Banse, 1990; Armstrong et al., 2001; Lutz et al., 2002; Rothman & Forney, 2007; Kriest & Oschlies, 2008; Cael & Bisson, 2018). The ubiquitous "Martin Curve" (Martin et al., 1987) is a power-law profile (Eq. 1) that assumes slower-sinking and/or labile organic matter is preferentially depleted near the surface causing increasing sinking speed and/or remineralization timescale with depth (e.g. Kriest & Oschlies, 2011).

$$f_p(z) = C_p z^{-b}, \qquad (1)$$

where $f_p(z)$ is the fraction of the flux of particulate organic matter from a productive layer near the surface (Buesseler et al., 2020) sinking through the depth horizon z [m], C_p [m^b] is a scaling coefficient, and b is a nondimensional exponent controlling how f_p decreases with depth. Eq. 1 is often normalized to a reference depth z_o but this parameter is readily absorbed into C_p.

Considerable effort has been dedicated to determining value(s) for the exponent, b (e.g., Martin et al., 1987, 1993; Berelson, 2001; Primeau, 2006; Kwon & Primeau, 2006; Honjo et al., 2008; Henson et al., 2012; Kriest et al., 2012; Gloege et al., 2017; Wilson et al., 2019). Open ocean particulate flux observations from the North Pacific (Martin

73 et al., 1987) indicate a b value of 0.858. Further analyses of expanded sediment trap datasets

74 suggest a possible range of approximately 0.84 ± 0.14 for the global b value (Martin et

75 al., 1993; Berelson, 2001; Primeau, 2006; Honjo et al., 2008; Gloege et al., 2017), though

76 a much wider range has been observed when including regional variability in b and optically-

77 and geochemically-derived flux estimates (Henson et al., 2012; Guidi et al., 2015; Pavia

78 et al., 2019). This may result from differences in temperature (Matsumoto, 2007), mi-

79 crobial community composition (Boyd & Newton, 1999), particle composition (Armstrong

80 et al., 2001), oxygen concentration (Devol & Hartnett, 2001), particle aggregation (Gehlen

81 et al., 2006; Schwinger et al., 2016; Niemeyer et al., 2019), or mineral ballasting (Gehlen

82 et al., 2006; Pabortsava et al., 2017).

83 Uncertainty in the value of b translates to uncertainty in the biological pump's im-

84 pact on the ocean carbon sink, atmosphere-ocean carbon partitioning, and climate model

85 projections. Thus, constraining b for the modern ocean and how it may differ in the past,

86 or the future, is of much interest from a climate perspective. Varying a global value of

87 b between 0.50–1.4 altered atmospheric pCO_2 by 86–185 μatm after several thousand years

88 of equilibration, in an influential modeling study (Kwon et al., 2009): Higher values of

89 b result in enhanced particle remineralization at shallower depths. Shallow watermasses

90 are more frequently ventilated, allowing remineralized CO_2 to be released back into the

91 atmosphere on shorter timescales. Due to this depth-dependence, a small change of degra-

92 dation depth can appreciably change atmospheric pCO_2 (Yamanaka & Tajika, 1996; Kwon

93 et al., 2009). Varying b over the plausible range in global values between 0.70–0.98 pro-

94 duces a more modest change in atmospheric pCO_2, over the range of $(-16,+12)\mu$atm (Gloege

95 et al., 2017), while the modeled uncertainty in atmospheric pCO_2 associated with regional

96 variation in b is estimated between 5–15 μatm (Wilson et al., 2019).

97 Biogeochemical models are subject not only to parametric uncertainty (which value

98 for b and how b varies in space and time), but also structural uncertainty, i.e. which equa-

99 tion(s) to choose for the vertical flux of organic matter. The Martin Curve power-law

100 is an empirical fit to sediment trap data, but several other functional forms have also been

101 put forward (Suess, 1980; Middelburg, 1989; Banse, 1990; Armstrong et al., 2001; Lutz

102 et al., 2002; Dutkiewicz et al., 2005; Rothman & Forney, 2007; Marsay et al., 2015) that

103 fit sediment trap fluxes equivalently well and have equal if not better mechanistic jus-

104 tification (Cael & Bisson, 2018). Atmospheric pCO_2 and many other global biogeochem-

105 ical properties (Kwon & Primeau, 2006; Kriest et al., 2012; Aumont et al., 2017) will be

affected by this structural uncertainty, so it is critical to evaluate the impact of choosing one remineralization profile "shape" over another.

We assess the effect of remineralization profile shape on biological pump strength and evaluate a comprehensive estimate of structural uncertainty in terms of atmosphere-ocean carbon partitioning in a global ocean biogeochemistry model. We substitute the reference power-law curve for six plausible alternative remineralization profiles: exponential (Banse, 1990; Dutkiewicz et al., 2005; Marsay et al., 2015; Gloege et al., 2017), ballast (Armstrong et al., 2001; Gloege et al., 2017), double exponential (Lutz et al., 2002), stretched exponential (Middelburg, 1989; Cael & Bisson, 2018), rational (Suess, 1980), and upper incomplete gamma function of order zero (Rothman & Forney, 2007, we use the shorthand "gamma function" for "upper incomplete gamma function of order zero", although different orders are possible). Each form corresponds to a basic mechanistic description of particle fluxes (Cael & Bisson, 2018), that we tightly constrained to the reference profile by statistically minimizing export fraction misfits or by matching degradation depth scales (Kwon et al., 2009). See Supporting Information for derivations of these profiles.

These simulations indicate that structural uncertainty is an appreciable component, around one third, of total uncertainty for understanding the biological pump (with the remaining two thirds attributed to parametric uncertainty in b). Changing remineralization functional form alters atmospheric pCO_2 by $\sim$10-15 μatm depending on how structural uncertainty is quantified, equivalent to $\sim$0.08 uncertainty in a global value of the power-law exponent, b, and similar to the uncertainty resulting from regional variation of b.

Our results underscore the importance of characterizing basic mechanisms governing the biological pump. Furthermore, our results corroborate that depth-dependence of these mechanisms is particularly important (Gehlen et al., 2006; Kriest & Oschlies, 2008): not only is biological pump-driven carbon export and storage an important control on atmospheric pCO_2, we find that rapidly decreasing particle degradation in the upper ocean is equally important for a sufficient quantity of carbon to become isolated in the deep ocean. While a given flux curve may be chosen for historical reasons or mathematical convenience, its skill should be compared to those of other idealized flux profile parameterizations in Earth System Models used for projections of future climate.

2 Materials and Methods

2.1 Fitting the alternative remineralization curves.

We fit the alternative functions for export fluxes and remineralization (Fig. 1, Eq. S1–S6, see Supporting Information) to the reference power-law curve (Eq. 1) with the exponent b=0.84 using nonlinear regression on the model vertical grid to minimize the absolute curve mismatch ("ABS" simulations). Subsurface points were weighted equally (1.0), except for a heavily weighted top level (valued 1000, but the overall fit was largely insensitive to the choice of this value) to ensure all the profiles pass through the same value as the control profile, i.e. fraction of export from the productive surface layer is unity. We further matched the e-folding depth of remineralization to the reference ("EFD" simulations) by adding a second heavily weighted point to the reference power-law at $164\,\mathrm{m}$ depth ($z_0 e^{(1/b)}$), with an export fraction of e^{-1}. In a third set ("RFIT" simulations), the nonlinear regression is performed on the natural logarithm of the remineralization fraction in order to minimize the relative error of the reference profile match. Goodness of fit is evaluated by the Standard Error of Regression, $\mathcal{S}$, which is the sum of squared residuals, divided by statistical degrees of freedom (number of points minus number of parameters). Coefficients and $\mathcal{S}$ values for the eighteen curves are given in Table S1.

2.2 Numerical ocean biogeochemistry model.

Alternative remineralization profiles are substituted into global ocean simulations of a coarse resolution ($2.8°$, 15 vertical level) configuration of the Massachusetts Institute of Technology general circulation model, MITgcm (Marshall et al., 1997), coupled to an idealized marine biogeochemistry model that considers the coupled cycles of dissolved inorganic carbon, alkalinity, phosphate, dissolved organic phosphorus, oxygen, and dissolved iron (Dutkiewicz et al., 2006; Parekh et al., 2005, 2006).

Two-thirds of surface net community production (that depends on light, phosphate, and iron using Michaelis-Menten kinetics) is channelled into dissolved organic matter that is largely remineralized in the surface ocean with a timescale of $6\,\mathrm{months}$ (Yamanaka & Tajika, 1997), while one-third is exported to the ocean interior via sinking particulate organic matter subject to depth-dependent remineralization rates. Elemental biological transformations are related using fixed stoichiometric ratios $R_{C:N:P:Fe:O_2} = 117 : 16 : 1 : 4.68 \times 10^{-4} : -170$ (Anderson & Sarmiento, 1994) with a prescribed inorganic to

169 organic rain ratio of 7% (Yamanaka & Tajika, 1996). The total atmosphere-ocean car-

170 bon inventory is conserved as there is no riverine carbon input or sediment carbon burial,

171 which may impact the model's transient behavior and steady state (Roth et al., 2014).

172 Atmosphere-ocean exchange of CO_2 captures the magnitude and variation of observed

173 air-sea fluxes (Lauderdale et al., 2016).

174 Our model includes tracers to separate the *in situ* concentrations of carbon into:

175 (i) a component subducted from the surface layer and transported conservatively by ocean

176 circulation (the "preformed" carbon concentration, C_{pre}), and (ii) a component that in-

177 tegrates export and remineralization of sinking particles as a watermass transits the ocean

178 interior (the "biological" carbon concentration, C_{bio}), which encompasses both soft tis-

179 sue regeneration and carbonate dissolution, and connects more directly to the biolog-

180 ical pump (Volk & Hoffert, 1985; Ito & Follows, 2005). We integrate simulations for 10,000

181 years toward steady state in atmosphere-ocean carbon partitioning.

3 Results

3.1 Varying the exponent of the reference power-law curve.

184 Global power-law exponent, b, estimates range from 0.70 (Primeau, 2006) based

185 on sediment traps to ∼1.00 based on inverse models fit to tracer distributions (Kwon &

186 Primeau, 2006, 2008; Kwon et al., 2009; Kriest et al., 2012). These values match the global

187 b interquartile range of 0.70–0.98 in (Gloege et al., 2017). We integrate three simulations

188 with $b = 0.84 \pm 0.14$ (Fig. 1a) using the standard power-law parameterization (Eq. 1)

189 to produce a baseline estimate of biological pump parametric uncertainty. The reference

190 simulation has the exponent $b=0.84$.

191 Higher b values cause the fraction of sinking particulate matter to decrease faster

192 with depth, that is, attenuation $(1/f_p \cdot \partial f_p/\partial z)$ is higher in the upper ocean, whereas

193 lower exponents have less attenuation and a larger proportion of export reaching the deep

194 ocean (Figs. 1a and S2a–f). A negative feedback occurs near the surface in our simula-

195 tions. For example, when b is increased, higher rates of upper ocean attenuation cause

196 an increase in surface nutrient availability, and therefore more overall biological produc-

197 tion (see ΔB_C, Table S2). Local biological activity enhancement increases local rates of

198 particle export, evaluated by integrated fluxes through the deepest mixed layer depth

199 (ΔE_{mld}, Table S2). However, higher shallow export is compensated by greater upper ocean
Figure 2. Change in the integrated export flux rate [PgC y^{-1}] passing through the 1 km depth level against integrated biological carbon reservoir anomaly [PgC], both with respect to the power-law curve where b=0.84 (Martin et al., 1987). Three power-law simulations (b=0.84±0.14) are indicated by the blue symbols (diamond, cross, and pentagon), circle, square, and triangle symbols indicate that profile coefficients (Eq. S1–S6) were derived by minimizing the relative fit error ("RFIT"), minimizing the absolute fit error ("AFIT"), and fixing the e-folding depth of remineralization ("EFD") to the reference power-law curve. Values are given in Tables S2 and S3.

remineralization, due to larger exponent value, resulting instead in reduced export flux anomalies through 1 km depth (ΔE_{1km}, Table S2), and vice versa when b is decreased (e.g. global experiments in Kwon et al., 2009; Kriest & Oschlies, 2011). The global ocean reservoir of biological carbon changes proportionally with ΔE_{1km} (Figs. 2, blue symbols, S2g–l, and ΔC_{bio}, Table S2) and inversely-proportional to ΔE_{mld} (Fig. S3a).

3.2 Impact of alternative remineralization curve shape.

Generally speaking, the six alternative remineralization profiles (Eq. S1–S6) objectively characterized by statistically fitting parameters to match the reference power-law curve (b=0.84) do reproduce similar sinking particle remineralization rates (Fig. 1b–

d). This is perhaps not a surprise, since we would not consider these functions to be plausible alternatives to the Martin Curve if they could not describe export fluxes at least as well as a power-law.

Nevertheless, the simple exponential and gamma function curves do not fit the reference power-law profile as well as the other functions (Fig. 1b–d) because these profiles cannot capture a strong depth-change in remineralization. The ballast profile has a more complex distribution of biological carbon anomalies in surface, intermediate, and deep waters such that the relationship between export flux and ΔC_{bio} is better captured by considering deeper horizons (e.g. green symbols in Fig. 2 at the 1 km horizon, versus 2 km in Fig. S3b).

Simulations with lower-attenuation profiles result in increased export fluxes (Fig. S4), and vice versa, as with the simulations varying b (Fig. 2). These particulate flux anomalies translate into changes in the distribution of biological carbon, with positive export flux anomalies through the 1 km depth horizon (ΔE_{1km}) corresponding to increase in the biological carbon pool (C_{bio}, Fig. 2), while negative export flux anomalies result in lower biological carbon concentrations. For instance, in RFIT simulations, the exponential and gamma function profiles show an increase in 1 km export fluxes and biological carbon storage, while the reverse occurs for exponential and gamma profiles in AFIT and EFD simulations.

Geographically, stronger ocean interior sinking fluxes tend to redistribute biological carbon into the Southern Ocean and deep North Pacific at the expense of the North Atlantic (Fig. S5–S7), while shallower remineralization tends to increase North Atlantic biological carbon concentrations whilst decreasing concentrations in the Southern Ocean and deep North Pacific. This is a reflection of the accumulation of C_{bio} as a water mass transits the global meridional overturning circulation with the oldest waters upwelling in the Southern Ocean and North Pacific (Kwon & Primeau, 2006; Kwon et al., 2009; Kriest & Oschlies, 2011; Kriest et al., 2012; Romanou et al., 2014). These anomalies of C_{bio} (Fig. S5–S7) account for the direct effects of organic and inorganic particle fluxes. At the same time, changes in biological activity affect surface alkalinity both through carbonate export and surface charged nutrient abundance, which reinforces ocean carbon uptake or outgassing due to the inverse relationships relating carbon and alkalinity to CO_2 solubility (Kwon et al., 2009). However, atmospheric CO_2 anomalies driven

by different remineralization profiles integrate several compensating processes. Indirect carbon changes, including the effect of alkalinity on ocean carbon saturation, regenerated carbon upwelling, as well as unrealized air-sea exchange due to the finite timescale of atmosphere-ocean CO_2 fluxes (Ito & Follows, 2005; Lauderdale et al., 2013, 2017), that are captured by preformed carbon anomalies actually counteract approximately two-thirds of the direct biological ocean carbon storage.

3.3 Evaluating structural uncertainty of the biological pump.

Altering the strength of the biological pump leads to changes in air-sea carbon balance. The reference simulation has a steady-state atmospheric pCO_2 of $269.3\,\mu$atm. Increasing b from 0.70 to 0.98 increases pCO_2 by $46.36\,\mu$atm in this model (range: -21.6–$24.8\,\mu$atm, wide grey bars in Fig. 3a, Table S2). This is higher than the "nutrient restoring" case in Kwon et al. (2009), but lower than their "constant export" case, consistent with our model's dynamic biological productivity and interactive biogeochemistry response.

Alternative profiles with reduced export flux through $1\,$km and reduced biological carbon storage result in increased atmospheric pCO_2, and vice versa (Fig. 3a, Table S3). The double exponential function has the most free parameters (four) and therefore fits the power-law extremely well, producing small differences in atmospheric pCO_2 (less than $2\,\mu$atm). The rational function also agrees well, but could produce larger anomalies if the reference profile's b-value was further from 1.00, i.e. 0.70. Stretched exponential and ballast curves produce moderate changes in atmospheric pCO_2 but are generally smaller than, or similar to, the 0.14 changes in b for the power-law curves (Fig. 3a). However, the simple exponential and gamma function anomalies clearly deviate from the other simulations, with greater biological carbon concentrations and drawdown of atmospheric CO_2 for the RFIT simulations, and the inverse for AFIT and EFD simulations. Export fluxes and remineralization are significantly different in the upper ocean for these parameterizations, which can be explained by their largely invariant attenuation rates with depth (Fig. 1 insets): simple exponential and gamma parameterizations cannot have both short remineralization lengthscales in the upper ocean and long remineralization lengthscales in the deep ocean.

There are multiple ways to compare parametric and structural uncertainty quantitatively. Parametric uncertainty is found by varying the power-law exponent within
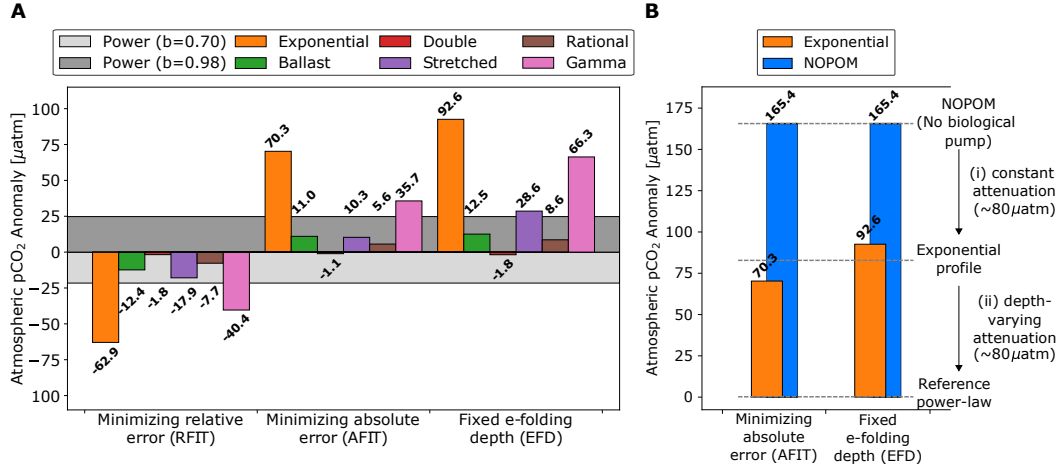

Figure 3. Impact of alternative remineralization curve shape on the air-sea carbon balance (a) atmospheric pCO_2 anomalies (μatm) for remineralization profiles with respect to the reference power-law (b=0.84) for power-law exponent values b=0.70 and 0.98, and statistical fits of alternative profiles "RFIT" (left), "AFIT" (middle), and "EFD" (right). Values are given in Tables S2 and S3; (b) comparison of a simulation with no particulate organic matter production ("NOPOM"), i.e. no biological pump, to the simple exponential profile, and reference power law profile for "AFIT" (left), and "EFD" (right) fits. From a "NOPOM" ocean, establishing (i) a biological pump with an exponential remineralization curve and constant attenuation of sinking particles with depth only draws down roughly 80 μatm atmospheric CO_2, while a further 80 μatm drawdown can be achieved by establishing (ii) a biological pump with a power-law remineralization profile that has decreasing particle attenuation, or increasing remineralization lengthscale, with depth. Thus, biological pump non-linearity appears to be equally important for air-sea carbon partitioning as export and storage of biological carbon.

272 its plausible global range ($b = 0.84\pm0.14$), producing absolute atmospheric pCO_2 anoma-

273 lies of 21.6–24.8 μatm (Fig. 3a, Table S3). For structural uncertainty, the median change

274 in absolute atmospheric pCO_2 is 12.47$\pm$10.67 μatm (b-anomaly equivalent of 0.07$\pm$0.06)

275 across all simulations with alternate functional forms. We choose the median$\pm$median

276 absolute deviation so that our result is robust to large anomalies associated with sim-

277 ple exponential and gamma functional forms. For RFIT, AFIT, and EFD simulations

278 separately, the medians are 15.15$\pm$10.40, 10.65$\pm$7.30, and 20.57$\pm$15.37 μatm, respectively,

279 giving a 15.15$\pm$4.51 μatm grand median (b-anomaly equivalent of 0.09$\pm$0.03). Exclud-

280 ing profiles with largely invariant attenuation rates with depth, i.e. exponential and gamma

281 function profiles, the overall medians for RFIT, AFIT, and EFD are 10.07$\pm$2.32, 7.96$\pm$2.69,

282 and 10.57$\pm$1.98 μatm, respectively, with a 10.07$\pm$0.50 μatm grand median (b-anomaly

283 equivalent of 0.06$\pm$0.00). In summary, our results are largely robust, indicating a struc-

284 tural uncertainty of 10–15 μatm, roughly half of parametric uncertainty for the biolog-

285 ical pump (22–25 μatm, $b = 0.84 \pm 0.14$), analogous to a $\sim$0.08 change in b.

286 ### 3.4 Role of nonlinearity in the biological pump.

287 Much emphasis is placed on the biological pump's effect on climate by significantly

288 lowering atmospheric CO_2 levels, but our exponential and gamma function simulations

289 indicate that having a biological pump (i.e. uptake, export, and depth-dependent rem-

290 ineralization) and an associated biological carbon store is not necessarily sufficient to pro-

291 duce atmospheric carbon drawdown of the expected magnitude, such as a $\sim$200μatm dif-

292 ference between biotic and abiotic oceans (Volk & Hoffert, 1985). To understand what

293 aspects of the biological pump are important for significantly lowering atmospheric CO_2,

294 we ran a simulation ("NOPOM") that represents a hypothetical ocean with no partic-

295 ulate organic matter export. Instead, biological production is channelled into dissolved

296 organic matter that is remineralized near the surface.

297 Atmospheric pCO_2 in NOPOM increases 165.4 μatm (Table S2) with respect to our

298 reference power-law: slightly less outgassing than Volk and Hoffert (1985), but the NOPOM

299 ocean does have biological activity and a small biogenic carbon store. This is roughly

300 twice as large as the outgassing resulting from the use of a simple exponential reminer-

301 alization profile fit to the reference power-law curve in AFIT and EFD simulations (70.3

302 and 92.6 μatm), despite these simulations supporting significant 1 km export fluxes (1.460

303 and 1.238 PgC y^{-1}, only 20% less than the reference power law) as well as large stores

of biological carbon (1830 and 1900 PgC, compared to 176 PgC for NOPOM). Thus, only about half of the biological pump's effect on atmosphere-ocean carbon drawdown ($\sim 80\,\mu$atm) can be attributed to export of particulate organic matter and biological carbon storage (Fig. 3b).

The remaining $\sim 80\,\mu$atm drawdown in atmospheric carbon content is due to the change in shape of remineralization curves between a biological pump represented by AFIT and EFD exponential curves compared to a biological pump represented by the reference power-law profile. Exponential profiles have a constant rate of change of remineralization, or attenuation of the sinking particle flux, with depth (Fig. 1c and d, insets), which results in the majority of the sinking particle flux from the surface ocean being remineralized in the upper 2 km. Export fluxes through this horizon are 0.204 and 0.140 PgC y^{-1}. Alternatively, attenuation for the power-law curve decreases significantly with depth, leading to a substantial 2 km export flux of 0.802 PgC y^{-1}. Thus, for AFIT and EFD exponential profiles, there is much less abyssal biological carbon storage to act as a long-term reservoir of atmospheric CO_2, whereas rapidly decreasing attenuation in the reference power-law supports long-term biological carbon storage.

In other words, decreasing upper ocean particle attenuation, or increasing remineralization lengthscale with depth, appears to be equally important for air-sea carbon partitioning as export and storage of biological carbon (Fig. 3b).

4 Discussion and Conclusions

Atmospheric CO_2 levels are intimately tied to the strength of the ocean's biological pump (Volk & Hoffert, 1985; Ito & Follows, 2005). The challenge of measuring particulate fluxes via sediment traps, optical proxies, or geochemical methods (Martin et al., 1987; Berelson, 2001; Honjo et al., 2008; Henson et al., 2012; Guidi et al., 2015; Pavia et al., 2019), the spatiotemporal variability of fluxes, and the complexity of the governing mechanisms introduce uncertainty into representation of the biological pump in ocean biogeochemistry, ecosystem, and climate models. We explored the impact of structural uncertainty—remineralization profile shape—on atmosphere-ocean carbon partitioning, using seven mechanistically-distinct functional forms of particulate organic matter flux that capture observational spread equivalently well (Cael & Bisson, 2018). In our model, a 0.14 change in the power-law exponent, b, results in a 22–25 μatm change in atmospheric

pCO$_2$, indicating that the structural uncertainty revealed by our simulations of 10–15 μatm is equivalent to $\sim$0.08 change in the global b value. Thus structural uncertainty is roughly half the size of parameteric uncertainty, making it a substantial one-third contribution to our overall estimate of total uncertainty (the sum of structural and parametric uncertainties) in understanding the biological pump. In addition our result is in the upper range of the 5-15 μatm uncertainty associated with regional variation in b (Wilson et al., 2019).

Historically, the focus been on remineralization length*scale* (Kwon et al., 2009), but our results, indicating that vertical gradient in attenuation is a first-order control on climate, imply that multiple length*scales* of attenuation are critical to the biological pump's global impact. Thus, not only is the existence of a biological pump that maintains interior ocean biological carbon stores a key factor in the biological pump's modulation of atmospheric CO$_2$ levels (Volk & Hoffert, 1985), but also a significant decrease of attenuation with depth is necessary to achieve the full amount of drawdown usually attributed to the biological pump (Fig. 3b). Even when the exponential profiles' parameters are determined by matching the e-folding remineralization depth of the reference power-law curve (Kwon et al., 2009), the result is still large atmospheric pCO$_2$ anomalies caused by largely invariant attenuation rates with depth.

Our study evaluates structural uncertainty in the ocean's biological pump in a systematic way. Although previous studies have compared individual, or a subset, of the alternative remineralization curves used here (e.g., Yamanaka & Tajika, 1996; Gehlen et al., 2006; Kriest & Oschlies, 2008; Schwinger et al., 2016; Gloege et al., 2017; Niemeyer et al., 2019; Kriest et al., 2020) with a focus on minimizing model-observational differences, none has attempted to evaluate this structural uncertainty by just changing the shape of the remineralization profile, which we do here by comparing six alternative functional forms statistically fit in three different ways to a reference power-law profile. Despite these profile choices resulting in non-negligible differences in ocean biogeochemical distributions (Kriest et al., 2012; Aumont et al., 2017) and atmospheric CO$_2$ levels (Kwon et al., 2009), comparison of model output to climatological data (Boyer et al., 2018; Garcia et al., 2018) does not significantly change (Fig. S8), such that all the curves still quantitatively reproduce the observations to a similar degree.

As Earth System Models continue to rely on simple biological pump parameterizations, our estimate of structural uncertainty underscores the importance of research aimed at improving the basic mechanistic characterization of the biological pump (Boyd et al., 2019), and particularly the depth-dependence or evolution of these mechanisms. One such improvement is to consider the spectrum of sinking particle properties, such as size (Schwinger et al., 2016; Niemeyer et al., 2019), sinking speeds (Kriest & Oschlies, 2008) or material lability (Aumont et al., 2017), and how they effect export fluxes. These studies often derive components that rely on upper and lower incomplete gamma functions, as well as gamma distributions, but ultimately do not produce gamma function flux profiles. The Rothman and Forney (2007) profile (Eqn. S6) is a special case of the upper incomplete gamma function (where the order, $a=0$). However, statistical fits of integer orders of the upper incomplete gamma function where $a>0$ to the reference power-law ($b=0.84$) are poor (See Fig. S1, including the simple exponential curve, which is proportional to an upper incomplete gamma function of order $a=1$), and as stand-alone remineralization parameterizations may include particle classes whose remineralization profiles may not exist in the ocean. On the other hand, a more general three-parameter upper incomplete gamma function parameterization, $C_g\Gamma(a_g, z/\ell_g)$, fits the Martin curve very well with $a_g \approx -0.8$ (Fig. S1), and would correspond to a constant-sinking reactivity continuum model (Aumont et al., 2017) with a power-law reactivity distribution. However, reactivity continuum models do not a describe reactivity using a power law, and instead use lighter-tailed distributions such as the gamma (Boudreau & Ruddick, 1991), beta (Vähätalo et al., 2010), or log-normal distribution (Forney & Rothman, 2012). Thus we did not include these additional profiles in our biological pump structural error ensemble as there is not a justifiable basis for $a>1$, nor a plausible mechanism for $a<0$, unlike the six alternative remineralization curves presented.

A better process-based understanding is critical to choosing between these parameterizations based on their mechanistic underpinnings and thus reducing structural uncertainty, because empirical fits to flux measurements alone cannot currently do so (Gehlen et al., 2006; Cael & Bisson, 2018). Indeed, there are also no guarantees that more extensively sampled ocean nutrient distributions are able to distinguish between the performance of idealized and more explicit remineralization schemes either (Niemeyer et al., 2019; Schwinger et al., 2016).

In our simulations, the parameterizations were forced to be as similar as possible with regard to the three different criteria (minimizing misfit error or matching the reference e-folding depth of remineralization), but functional forms based on different processes will have different sensitivities to temperature and other phenomena, and therefore will produce divergent projections and different climate feedbacks. Futhermore, each alternative functional form will be associated with its own parametric uncertainty. Unfortunately, significantly less is known about the natural range of parameters associated with the alternative remineralization profiles in the real ocean, because they have not been used as widely as the Martin Curve.

There are other factors that could affect the distribution, export, and depth dependent remineralization of sinking particles, and therefore ocean carbon sink/atmospheric CO_2 sensitivity, that we held the same between simulations. For example, our assumption of a closed carbon cycle with no sediment burial or riverine fluxes may underestimate the biological pump effect on atmospheric CO_2 for the different remineralization profiles by 4–7 times (Roth et al., 2014) on timescales of 10–100 thousand years. Between different models, the overall strength of the deep ocean carbon store may be more dependent on remineralization profile parameters than on different ocean circulations, although circulation impact on upper ocean production would modify the overall relationships shown here (Romanou et al., 2014; Kriest et al., 2020). Vertical grid resolution and numerical diffusion might also result in changes to the ocean carbon sink (Kriest & Oschlies, 2011), although again these changes may not manifest in the short timespan that many more complex coupled ocean-ecosystems are integrated for (Kwon et al., 2009; Schwinger et al., 2016). Despite these challenges, it would be valuable to compare these different functional forms within state-of-the-art Earth System Models, either directly or via implied remineralization profile shape, to improve confidence in projections involving biosphere-climate interactions.

`-cael-export-profile-shape` (Lauderdale & Cael, 2021)

Alternative remineralization profile shapes.

Here we outline the derivation and assumptions behind six different remineralization

profiles. Assuming timescales of sinking (≤ 1 month) are shorter than transport by ocean

circulation (~ 1 year), biological material can be approximated as instantaneously redis-

tributed and remineralized in the vertical. $f(z)$ is the fraction of the flux of particulate

organic matter from a productive layer near the surface (Buesseler et al., 2020) sinking

through the depth horizon z [m].

The most basic curve is a "simple exponential", assuming constant first-order reminer-

alization kinetics and velocity (Banse, 1990; Dutkiewicz et al., 2005; Marsay et al., 2015;

Gloege et al., 2017):

$$f_e(z) = C_e e^{-\frac{z}{\ell_e}}, \tag{1}$$

where and C_e is a scaling coefficient and ℓ_e [m] is a characteristic lengthscale-the ratio of

remineralization timescale and sinking speed.

Including an additional flux of refractory material c to increase the net sinking flux

produces the "ballast" model (Armstrong et al., 2001; Gloege et al., 2017):

$$f_b(z) = C_b e^{-\frac{z}{\ell_b}} + c, \tag{2}$$

while explicitly considering the transformation of labile particles with a characteristic

lengthscale, ℓ_{d1}, and more refractory material with a characteristic length scale, ℓ_{d2} results

in a "double exponential" profile (Lutz et al., 2002):

$$f_d(z) = C_{d1}e^{-\frac{z}{\ell_{d1}}} + C_{d2}e^{-\frac{z}{\ell_{d2}}}. \tag{3}$$

Relaxing the assumption of constant remineralization timescale, and considering a decrease in the rate of remineralization as labile material is preferentially transformed and refractory material is left behind (as in Eq. 1), leads to a "stretched exponential":

$$f_s(z) = C_s e^{-z^{(1-s)}}, \tag{4}$$

where s is a scale factor between 0–1, for example, if marine particles are degrade similarly to marine sediments, $s \approx 0.95$ (Middelburg, 1989; Cael & Bisson, 2018). A three-parameter stretched exponential with z normalized by z_o is used in many applications. However, fitting z_o and s simultaneously is ill-conditioned, i.e. parameter values are not identifiable, so we have used the simpler two-parameter stretched exponential function, which still provides fits well within global particle flux uncertainty (see Fig. 1).

Second-order degradation kinetics leads to a rational form (Suess, 1980):

$$f_r(z) = \frac{C_r}{z + a} \tag{5}$$

where C_r [m] is determined by remineralization and sinking while a [m] is determined by remineralization, sinking, and the initial flux (Cael & Bisson, 2018).

One can model sinking particles as heterogeneous media containing organic carbon, ballast minerals, and heterotrophic bacteria where remineralization slows with time (Rothman & Forney, 2007). This translates to an upper incomplete "gamma" function

curve, $\Gamma(a, x)$, of zeroth order (Cael & Bisson, 2018):

$$f_g(z) = C_g \Gamma \left(0, \frac{z}{\ell_g} \right),$$ (6)

where ℓ_g [m] relates to sinking speed and intraparticle bacterial concentration (Rothman & Forney, 2007; Cael & Bisson, 2018). The upper incomplete gamma function can take any value for order a, and is a component of other remineralization profile studies (e.g. Aumont et al 2017, Kriest and Oschlies 2008). For positive integer values of a, when $a = 1$ then $C_g \Gamma(1, z/\ell_g) = C_g e^{-z/\ell_g}$ (which is the simple exponential profile), and if $a = 2$ then there is a recursion relation where $C_g \Gamma(2, z/\ell_g) = C_g \Gamma(1, z/\ell_g) + C_g z/\ell_g e^{-z/\ell_g}$, and so on. We repeated our statistical fit to the reference power law curve for upper incomplete gamma functions with orders of a between 0–3 (Figure S1). The best fits to the reference power-law (b=0.84) are in fact when $a = 0$ regardless of minimizing absolute or relative errors (AFIT or RFIT), and also in the EFD case. The simple exponential case, equivalent to $a = 1$, is a poor fit to the power-law for all three cases, and the dissimilarity increases where $a > 1$. Indeed, if $a = 2$ or 3 then attenuation increases with depth in the upper ocean, which is uncharacteristic of sinking particle observations and the Martin Curve, and the existence of a particle class whos flux profile would depend on $C_g z/\ell_g e^{-z/\ell_g}$ is unlikely. Thus, we do not run simulations where $a > 1$, which do not correspond to a plausible mechanism for sinking particle remineralization.

A more general three-parameter upper incomplete gamma function parameterization $C_g \Gamma(a_g, z/\ell_g)$ fits the Martin curve very well with $a_g \approx -0.8$ (Figure S1), and would correspond to a constant-sinking reactivity continuum model (Aumont et al., 2017) with a power-law reactivity distribution. However, reactivity continuum models do not a describe

reactivity using a power law, and instead use lighter-tailed distributions such as the gamma (Boudreau & Ruddick, 1991), beta (Vähätalo et al., 2010), or log-normal distribution (Forney & Rothman, 2012) that do not permit closed-form solutions. Again, we do not consider this parameterization as a plausible alternative to the Martin Curve for this reason.

Finally, we note that the "power-law" (Eq. 1) assumes either an increase in sinking speed with depth or a decrease in remineralization rate (Kriest & Oschlies, 2011; Cael & Bisson, 2018).

Coefficients derived by non-linear statistical fit of profiles given by Eqn. S1–S6 to the reference power-law curve are given in Table S1.

Supporting simulation results:

Fig. S2 shows steady-state zonal averages for the power-law simulations where b=0.84±0.14. Particulate organic carbon fluxes in the ocean interior increase when the power-law exponent decreases to 0.70 (Fig. S2, left column) and decrease when the power-law exponent is increased to 0.98 (Fig. S2, right column). The negative feedback between nutrient availability and biological production of particles (e.g. global experiments in Kriest & Oschlies, 2011) can be seen in the surface export flux anomalies (Fig. S2d, f). More efficient export and lower rates of upper ocean remineralization leads to a decrease in recycled nutrient availability, and therefore less overall biological productivity, and lower shallow particulate organic carbon flux when b is reduced (also see globally-integrated community production, ΔB_C, and integrated export fluxes through the deepest annual mixed layer, ΔE_{mld}, values in Fig. S3a and Table S2). However, reduced shallow export

across the deepest mixed layer depth is compensated by lower upper ocean flux attenuation, due to reduced exponent value, resulting instead in enhanced export flux anomalies integrated at 1 km depth. Nutrient availability increases when the remineralization profile is more attenuating in the upper ocean, driving enhanced shallow particulate production and export, but this flux is quickly depleted by the same remineralization profile attenuation, resulting in lower interior ocean export fluxes to the deep ocean.

Biological carbon concentration (C_{bio}) integrates these export fluxes, so that when interior ocean export increases, the deep ocean biological carbon store increases (Fig. S3b), particularly in the Southern Ocean (Fig. S2g), and the deep North Pacific (Fig. S2j), but decreases in the North Atlantic (Fig. S2g) and vice versa (Fig. S2f, i, l) (Kwon & Primeau, 2006; Kriest & Oschlies, 2011; Kriest et al., 2012; Romanou et al., 2014).

The deep ocean store of biological carbon is directly linked to air-sea carbon partitioning, thus greater ΔC_{bio} indicates uptake of atmospheric carbon by the ocean, and pCO$_2$ declines. Conversely, when ΔC_{bio} decreases, that carbon outgasses from the ocean causing atmospheric pCO$_2$ to increase (Table S2).

Fig. S4 shows zonally-averaged anomalies with respect to the reference power-law of export fluxes for the three sets of parameter values and the six different functional forms of remineralization profile. Anomalies largely have an inverse surface-deep ocean contrast, which is captured by the differences in fluxes through the deepest annual mixed layer depth (ΔE_{mld}, Table S3) for the surface ocean changes in particulate export, and fluxes though the 1 km depth horizon (ΔE_{1km}, Table S3) for the deep ocean changes in particulate export. However, the ballast functional form (Eq. S2) has a more complex distribution of

particulate flux anomalies in surface, intermediate, and deep waters associated with the additional refractory flux c, which becomes important when the exponentially decaying labile portion of the sinking flux becomes attenuated to low levels.

Fig. S5–S7 shows Atlantic and Pacific Ocean zonally-averaged anomalies with respect to the reference power-law of the concentration of biological carbon (ΔC_{bio}, Table S3), which integrates the vertical flux and remineralization of particulate organic matter. Again, anomalies largely have an inverse surface-deep ocean contrast, with similar sign anomalies in the older upwelling waters of the Southern Ocean and deep North Pacific, in contrast to the youngest waters in the North Atlantic (Kwon & Primeau, 2006; Kriest & Oschlies, 2011; Kriest et al., 2012; Romanou et al., 2014). The deep ocean store of C_{bio} is inversely proportional to atmospheric CO_2 content (Table S3).

Finally, Fig. S8 shows a comparison of model phosphate fields with the World Ocean Atlas climatology (WOA2018, Boyer et al., 2018; Garcia et al., 2018) for the 21 simulations with different remineralization profiles. Despite reorganization of carbon and nutrient concentrations, comparison of model output to climatological data does not significantly change, underscoring that although these profile choices result in non-negligible differences in ocean biogeochemical distributions (Kriest et al., 2012; Aumont et al., 2017) and atmospheric CO_2 levels (Kwon et al., 2009), the differences are small enough that all the curves still quantitatively reproduce the observations to a similar degree.

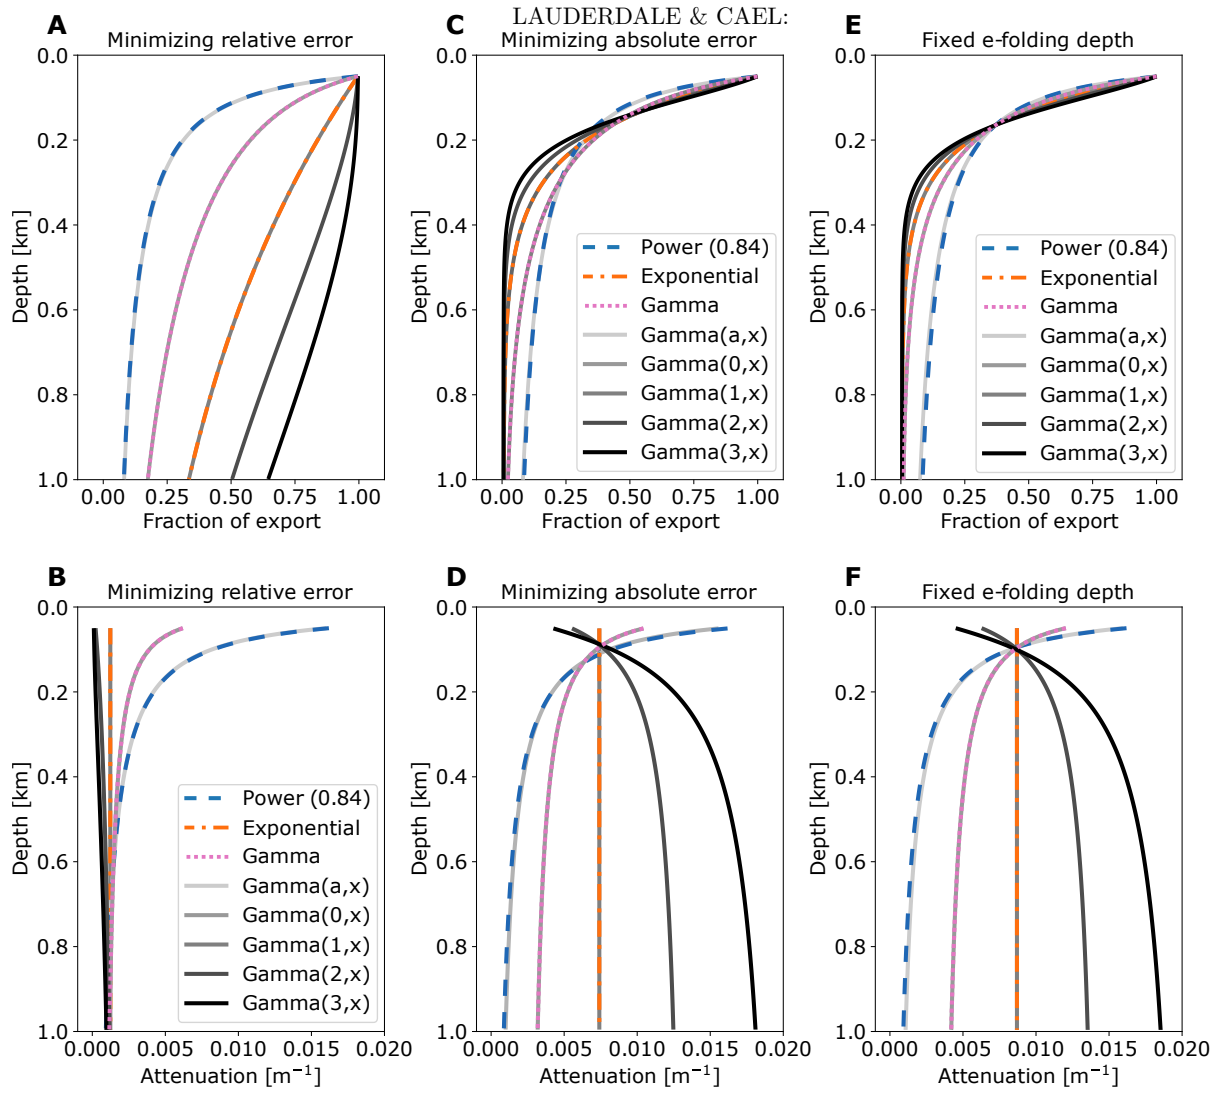

Figure S1. Fraction of sinking particulate organic matter exported from the 50 m surface layer remaining at each depth for different evaluations of the upper incomplete gamma function, $\Gamma(a, x)$, with varying values of the order a (increasing greyscale tones) and coefficients (e.g. Eqn. S6) statistically fit to the reference power-law curve (b=0.84) by (a) statistically minimizing the relative error ("RFIT"), or (c) the absolute error ("AFIT"), and (d) matching the e-folding depth scale of 164 m ("EFD"). "Gamma(a,x)" profiles are cases where the order is determined as part of a three-parameter non-linear fit giving $a \approx -0.8$. Profiles for the reference power-law (b=0.84), simple exponential, and gamma function (Eqn. S6) curves from the main text (Fig. 2) are shown in colored, dashed, lines. Plots b, d, and f show the attenuation rate of the export flux with depth $\left[\frac{1}{f}\frac{\partial f}{\partial z}, m^{-1}\right]$.

March 11, 2021, 10:11pm
Figure S2. Zonal-average properties for power-law simulations where $b = 0.84 \pm 0.14$ (a–c) particulate organic carbon export fluxes (mol C m^{-2} y^{-1}), (d–f) anomalies of sinking particle export flux compared to the reference power-law simulations (i.e. the middle column, mol C m^{-2} y^{-1}), and biological carbon concentration (C_{bio}, μmol C kg^{-1} in the (g–i) Atlantic Ocean, and (j–l) Pacific Ocean. Reference C_{bio} concentrations are shown in the middle column, with anomalies for the decreased and increased values of the power-law exponent, b, in the left and right columns.
Figure S3.   Change in the integrated particle export flux rate [PgC y^{-1}] passing through (a) the horizon of deepest annual mixed layer depth, and (b) the 2 km depth horizon, against integrated biological carbon reservoir anomaly [PgC], both with respect to the power-law curve where b=0.84. Three power-law simulations ($b = 0.84 \pm 0.14$) are indicated by the blue symbols (diamond, cross, and pentagon), circle, square, and triangle symbols indicate that profile coefficients (Eq. S1–S6) were derived by minimizing the relative fit error ("RFIT"), minimizing the absolute fit error ("AFIT"), and fixing the e-folding depth of remineralization ("EFD") to the reference power-law curve. Values are shown in Table S3.

March 11, 2021, 10:11pm
Figure S4. Zonally-averaged export flux anomaly with respect to the reference power-law curve where b=0.84, for the parameter sets where the relative error of the fit is minimized (RFIT, left column), where the absolute error of the fit is minimized (AFIT, middle column), and where the e-folding depth of remineralization is matched to the 164 m of the control curve (EFD, right column), where (a–c) is the simple exponential profile, (d–f) is the ballast profile, (g–i) is the double exponential profile, (j–l) is the stretched exponential profile, (m–o) is the rational profile, and (p–r) is the gamma profile.

March 11, 2021, 10:11pm

RFIT Biological Carbon Anomaly [μmol C kg^{-1}]

Figure S5. Zonally-averaged biological carbon (C_{bio}, μmol C kg^{-1}) anomalies with respect to the reference power-law curve for coefficients minimizing the relative error of the fit (RFIT) in the Atlantic Ocean (left column) and Pacific Ocean (right column) using (a–b) exponential, (c–d) ballast, (e–f) double exponential, (g–h) stretched exponential, (i–j) rational, and (k–l) gamma function remineralization profiles.
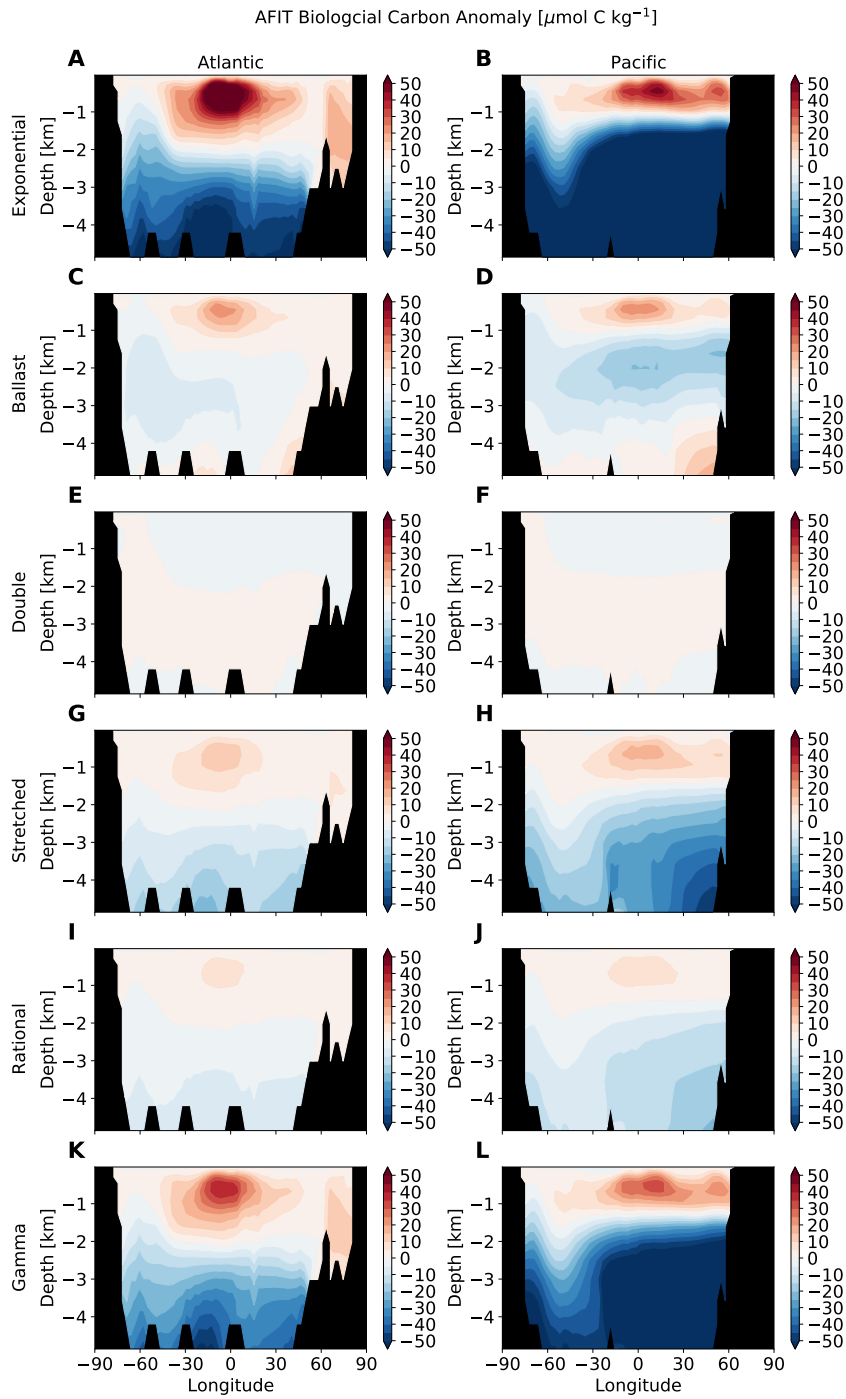

Figure S6. Zonally-averaged biological carbon (C_{bio}, μmol C kg^{-1}) anomalies with respect to the reference power-law curve for coefficients minimizing the absolute error of the fit (AFIT) in the Atlantic Ocean (left column) and Pacific Ocean (right column) using (a–b) exponential, (c–d) ballast, (e–f) double exponential, (g–h) stretched exponential, (i–j) rational, and (k–l) gamma function remineralization profiles.

March 11, 2021, 10:11pm
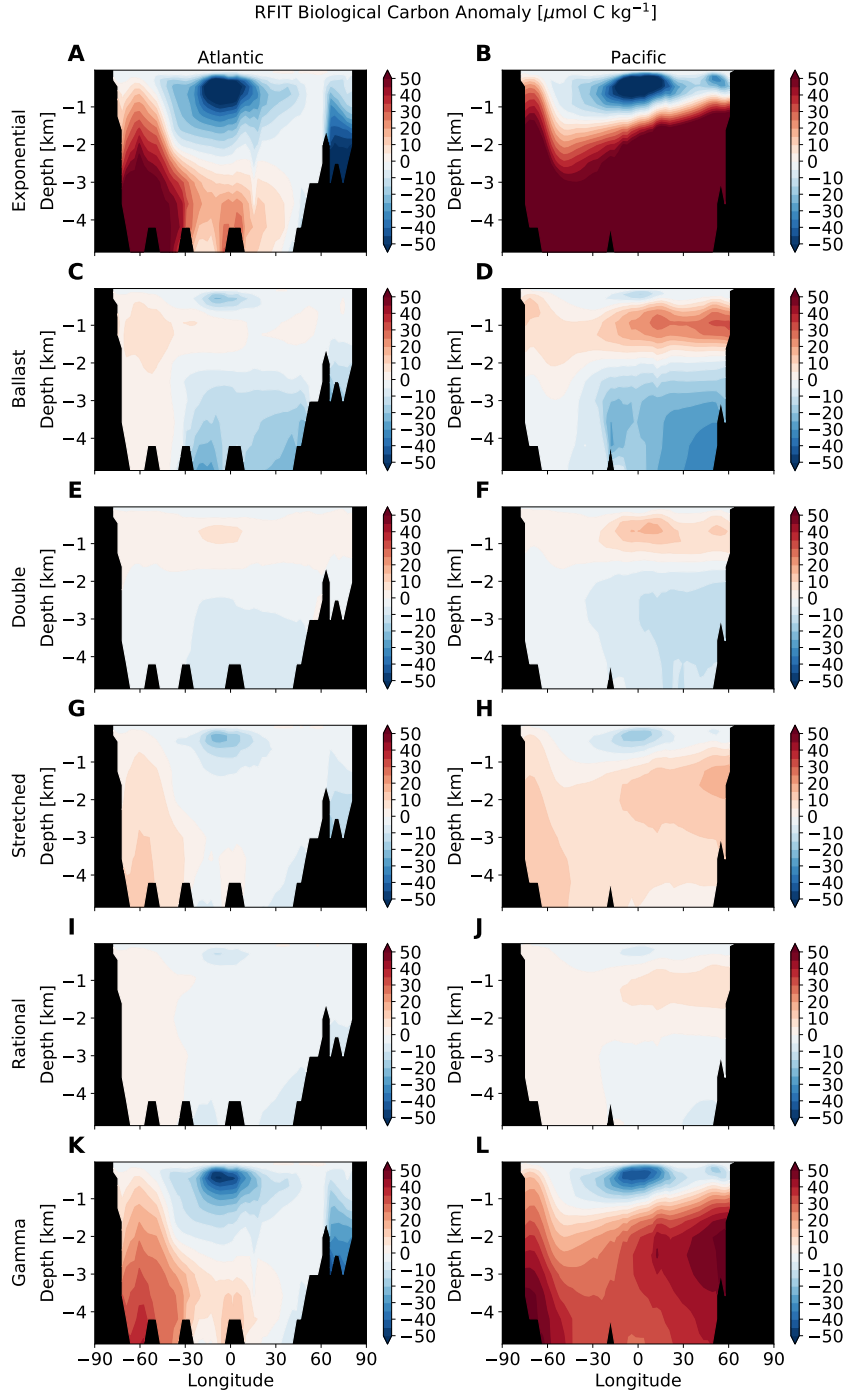

EFD Biological Carbon Anomaly [μmol C kg^{-1}]
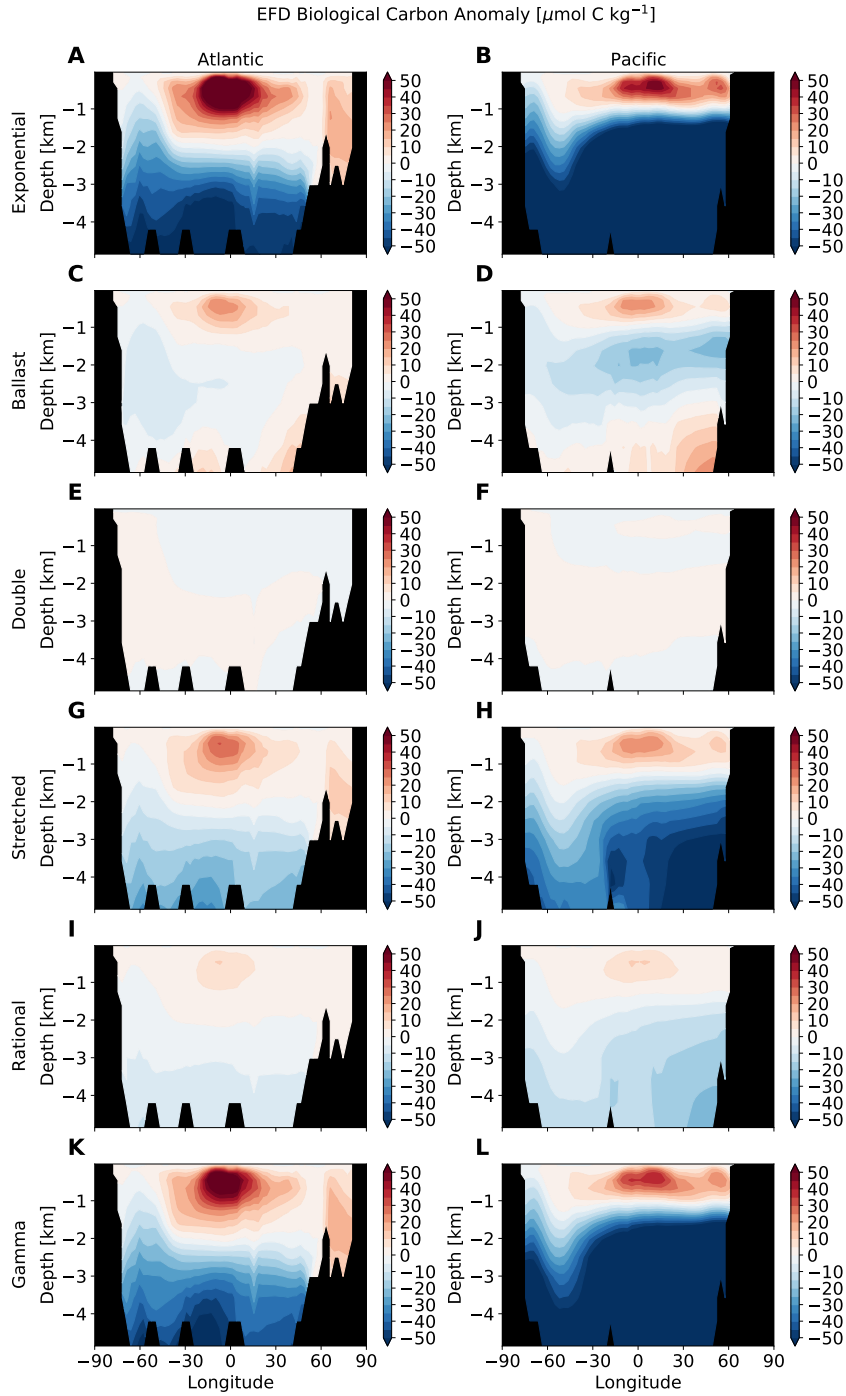

Figure S7. Zonally-averaged biological carbon (C_{bio}, μmol C kg^{-1}) anomalies with respect to the reference power-law curve for coefficients matching the 164 m e-folding depth (EFD) in the Atlantic Ocean (left column) and Pacific Ocean (right column) using (a–b) exponential, (c–d) ballast, (e–f) double exponential, (g–h) stretched exponential, (i–j) rational, and (k–l) gamma function remineralization profiles.

March 11, 2021, 10:11pm
Figure S8. Model phosphate concentrations [PO$_4$, μmol kg^{-1}] for each remineralization profile against observations from the World Ocean Atlas 2018 (WOA18, Boyer et al., 2018; Garcia et al., 2018) colored by model depth. The black dashed line indicates a 1:1 relationship. Model-data likeness is evaluated by the Pearson correlation coefficient, R, and the root-mean-squared concentration error, $RMSE$. Although remineralization profile choices result in non-negligible differences in macronutrient distributions, the differences are small enough that all the curves still quantitatively reproduce the observations to a similar degree.

March 11, 2021, 10:11pm

Table S1. Parameter values and fit statistics for remineralization functions (Eq. S1–S6). Each function was matched to the reference power-law (Eq. 1) with exponent b=0.84 by statistically minimizing the relative ("RFIT") or absolute ("AFIT") misfit of the curves, or by matching e-folding remineralization depth scale ("EFD"), Fig. 2b–d. Note different units of coefficients. Goodness of fit is evaluated by $\mathcal{S}$, the Standard Error of Regression (smaller numbers indicate better fit).

Table S2.   Supplementary quantities for power-law remineralization simulations with exponents of b=0.70, 0.84, and 0.98, as well as the "NOPOM" simulation where there are no particulate organic matter export fluxes. Reference rates/concentrations are presented for the control power-law curve where b=0.84, while values presented for simulations where b=0.70, 0.98, and NOPOM are anomalies with respect to the control. ΔB_C is the change in globally-integrated rate of net community production, ΔE_{mld}, ΔE_{1km}, and ΔE_{2km} are the change in areally-integrated particulate organic carbon export flux through the deepest mixed layer depth, 1 km, and 2 km horizons, respectively, ΔC_{bio} is the globally-integrated change in biological carbon (evaluated as dissolved inorganic carbon minus the preformed carbon concentration), and ΔpCO_2^{atm} is the change in atmospheric CO_2 partial pressure.

		Exponent (b)			
		0.70	0.84	0.98	NOPOM
C_p	m^b	1.000	1.000	1.000
