**Abstract**

Following collapses of the neighbouring Larsen A and B ice shelves, Larsen C has become a focus of increased attention. Determining how the prevailing meteorological conditions influence the surface melt regime is of paramount significance for understanding the dominant processes causing melt and ultimately for predicting its future. A new, high-resolution (4 km grid spacing) Met Office Unified Model (MetUM) hindcast of atmospheric conditions and surface melt processes over the central Antarctic Peninsula during the period 1998-2017 is developed for this purpose. The hindcast is capable of reliably simulating observed near-surface meteorology and surface melt conditions over Larsen C. In contrast with previous model simulations, the MetUM captures the observed east-west gradient in surface melting associated with foehn winds, as well as the inter-annual variability in melt shown in previous observational studies. The hindcast is applied to two case studies – the months preceding the collapse of the Larsen B ice shelf in March 2002 and the high-foehn, high-melt period of March-May 2016 - to test its ability to reproduce the atmospheric effects that contributed to considerable melting during those periods. The results suggest that the MetUM hindcast is a reliable tool with which to explore the dominant causes of surface melting on Larsen C.

15

16  **Key Points:**

17  - We present a new high-resolution, multi-decadal hindcast of atmospheric conditions and
18    surface melt processes over the Larsen C ice shelf

19  - The model hindcast reliably captures the observed location, frequency and interannual
20    variability of foehn events on Larsen C

21  - The hindcast captures the foehn-induced distribution and interannual variability of
22    surface melt patterns on Larsen C

23

**Abstract**

Following collapses of the neighbouring Larsen A and B ice shelves, Larsen C has become a focus of increased attention. Determining how the prevailing meteorological conditions influence the surface melt regime is of paramount significance for understanding the dominant processes causing melt and ultimately for predicting its future. A new, high-resolution (4 km grid spacing) Met Office Unified Model (MetUM) hindcast of atmospheric conditions and surface melt processes over the central Antarctic Peninsula during the period 1998-2017 is developed for this purpose. The hindcast is capable of reliably simulating observed near-surface meteorology and surface melt conditions over Larsen C. In contrast with previous model simulations, the MetUM captures the observed east-west gradient in surface melting associated with foehn winds, as well as the inter-annual variability in melt shown in previous observational studies. The hindcast is applied to two case studies – the months preceding the collapse of the Larsen B ice shelf in March 2002 and the high-foehn, high-melt period of March-May 2016 - to test its ability to reproduce the atmospheric effects that contributed to considerable melting during those periods. The results suggest that the MetUM hindcast is a reliable tool with which to explore the dominant causes of surface melting on Larsen C.

**Plain Language Summary**

Scientists are concerned about floating ice shelves on the Antarctic Peninsula because several shelves have collapsed there in recent decades, due partly to melting at the surface. However, our understanding of what causes these ice shelves to melt is limited by the lack of observations in the region, and so numerical models are an extremely useful tool to explore this. This study showcases a new high-quality model dataset that is able of capturing the major patterns of surface melting and atmospheric conditions over ice shelves on the Antarctic Peninula. It represents an improvement on previous studies and can be reliably used to simulate melt and meteorology on ice shelves like Larsen C. The ability of the hindcast to capture these processes is tested by applying it to two case studies – the period just before the collapse of the Larsen B ice shelf in March 2002, and a period in March-May 2016 when exceptionally high melt and intense foehn winds were observed on the Larsen C ice shelf. This suggests that the hindcast is suitable for exploring the causes of ice shelf surface melting in the region.

## 1 Introduction

The Antarctic Peninsula has become a recent focus of attention because of the pace of environmental change there. Changes in the atmosphere and cryosphere have co-occurred: notably, surface warming of up to 3°C between 1951-2000 in the northern Antarctic Peninsula (Turner et al., 2016) has coincided with the loss of mass from more than half of the twelve ice shelves surrounding the Antarctic Peninsula since 1947, including the dramatic collapse of the Prince Gustav and Larsen A and B ice shelves (Cook & Vaughan, 2010). The loss or thinning of ice shelves contributes to sea level rise because their ability to buttress upstream grounded ice is reduced, accelerating tributary glaciers and hence the input of ice into the ocean (Rignot et al., 2004, Borstad et al., 2013; Trusel et al., 2015, Fürst et al., 2016).

The collapse of the Larsen A (in 1995) and B (in 2002) ice shelves on the east side of the Antarctic Peninsula was induced by hydrofracturing, whereby water-filled crevasses widen as a result of the hydrostatic pressure acting at the crevasse tip (Scambos et al., 2000; Kuipers Munneke, 2014). Surface melting is the most important driver of destabilisation via this mechanism because it triggers a series of glaciological processes that begins with firn densification (Scambos et al., 2000; van den Broeke, 2005; Holland et al., 2011). Surface meltwater percolates into the porous firn layer during summer, and once the firn becomes saturated with refrozen meltwater over many seasons, begins to collect in ponds on the surface because it cannot drain away (Scambos et al., 2000; Kuipers Munneke et al., 2014). This allows hydrofracturing to occur, leading to ice shelves disintegrating extremely rapidly: over about a month in the case of Larsen B (Scambos et al., 2003). The southward progression of ice shelf collapse on the east side of the Antarctic Peninsula indicates that Larsen C, the largest remaining ice shelf in this region, may become unstable in the near future (Rott et al., 1996; 2002; Scambos et al., 2003; Bevan et al., 2017).

Larsen C is located at approximately 66°S – 69°S and has an area of ~47,000 km2. Its climate is dominated by the influence of cold, continental air masses that flow off the Antarctic plateau as a southerly barrier jet (Parish, 1983). However, foehn winds, which are generated when air is forced over the steep terrain of the Antarctic Peninsula mountains, are also relatively frequently observed over Larsen C during periods of westerly and north-westerly flow, and these

83    dramatically alter the local climate and surface energy balance (SEB) for hours or days at a time

84    (Cape et al., 2015; Elvidge et al., 2015; 2016; Elvidge & Renfrew, 2016; Kuipers Munneke et al.,

85    2018; Elvidge et al., 2020). Luckman et al. (2014) and Bevan et al. (2018) used satellite

86    measurements to show that annual meltwater production on Larsen C is highest in the north,

87    where temperatures are closer to the melting point, and in inlets close to the mountains, where

88    foehn winds are most intense and frequent (Turton et al., 2018; Elvidge et al., 2020). These

89    foehn induced east-west gradients in melt are also seen in borehole and air content measurements

90    that indicate firn densification in inlets (Hubbard et al., 2016; Bevan et al., 2017; Holland et al.,

91    2011).

92    Foehn events are associated with both "jet" and "wake" regions over the Larsen C downwind of

93    mountain passes, with the "jet" regions being relatively windier-but-cooler compared to the

94    calmer-but-warmer "wake" regions (Elvidge et al.,2015; Elvidge et al., 2020). However, despite

95    their importance for inducing melt over Larsen C, a reliable long-term estimate of how

96    frequently foehn events occur and their associated impacts on SEB has not yet been made.

97    Estimates of their frequency have been made only at single AWSs or locations on the ice shelf

98    (Turton et al., 2018; Weisenekker et al., 2019) or over a relatively short time periods of a year or

99    less (King et al., 2017; Kirchgaessner et al., 2019; Elvidge et al. 2020).

100    Regional climate models have been increasingly used in recent years to assess melting and near-

101    surface meteorology on Larsen C. These models successfully simulate the temperature and solar

102    radiation-driven north-south gradient in melting, but struggle to reproduce the east-west gradient

103    in melt associated with foehn winds (e.g. van Wessem et al., 2016; Datta et al., 2019). This is

104    largely a result of limitations in the modelling techniques used, such as insufficient horizontal

105    resolution or restrictive numerical approximations when simulating the dynamics of foehn winds

106    in complex orography, and therefore its impact on SEB, and consequently melting. For example,

107    although Datta et al. (2018 & 2019) find enhanced surface melting and foehn occurrence in inlets

108    on the southern part of Larsen C using the Modèle Atmosphérique Regionale at a spatial

109    resolution of 10 and 7.5 km, it is only found in the strongest foehn cases, resulting in a much

110    weaker east-west gradient in climatological melting than observed.

111 Recently Elvidge et al. (2020) using the UK Met Office Unified Model (MetUM) at a spatial

112 resolution of 1.5 km became the first study to adequately capture the east-west gradient of foehn-

113 driven melting on Larsen C and, importantly, to explain the drivers of melt in terms of boundary-

114 layer processes affecting the SEB. However, the relatively short (6 month) period considered by

115 that study promotes the need for a comprehensive and long-term (multi-decadal) model dataset

116 that realistically includes the primary atmospheric processes contributing to the SEB and surface

117 melt on Larsen C. This study will address this outstanding issue.

118 Firstly, and most importantly, a regional configuration of the MetUM at a spatial resolution of 4

119 km, which is able to resolve the foehn-driven melting over the Larsen ice shelves, will be

120 presented and the output validated against automatic weather station (AWS) observations.

121 Second, the ability of the MetUM to capture the observed spatial gradients and absolute totals of

122 surface melting, and determine the dominant atmospheric drivers of these, will be examined.

123 This will be done by evaluating surface melt and foehn occurrence over Larsen C during the

124 main hindcast period 1998-2017, and by simulating two case studies: 1) the Larsen B ice shelf

125 prior to its collapse in 2002, and 2) the Larsen C ice shelf during a concerted period of high melt

126 / high foehn that occurred in 2016 (Kuipers-Munneke et al., 2018). In this paper, we present the

127 first model-based multi-decadal climatological maps of surface melt and foehn occurrence for

128 Larsen C. Note that analyses of these, including an evaluation of the primary causes of surface

129 melt, will be developed further in a subsequent manuscript.

130

131 **2 Data and Methods**

132       2.1 Observational data

133 We use available AWS data from four stations, which are shown in Figure 1 and referred to as

134 AWS 14, 15, 17, and 18. The longest record of any of the stations is from AWS 14, which covers

135 the period January 2009 – December 2017, while AWSs 15, 17 and 18 cover the periods January

136 2009 – June 2014, February 2011 – March 2016 and November 2014 – December 2017,

137 respectively. AWS 14 and 15 are both located on a flat and homogeneous region of the Larsen C

138 ice shelf, meaning that measurements taken at these stations are representative of a wider area, as

139 demonstrated in King et al. (2015). Conversely, both AWS 17 and 18 are located in inlets at the

140    base of steep topography, where the meteorology is highly localised. AWS 17 sits on the

141    remnant Larsen B ice shelf, in Scar Inlet, while AWS 18 is located in Cabinet Inlet, close to the

142    foot of the mountains in the north-west of the Larsen C ice shelf.

143    All stations measure the near-surface meteorology and we then derive the full SEB, although

144    turbulent flux estimates were not available from AWS 15 at the time of analysis. The

145    instrumentation used at the AWSs is described in detail in Kuipers Munneke et al. (2012). The

146    turbulent fluxes are calculated using the bulk method, by applying the SEB model of Kuipers

147    Munneke et al. (2009). Corrections are made to the unventilated temperature data to adjust for

148    positive biases in calm, sunny conditions after Smeets (2006) and Smeets et al. (2018), while

149    shortwave fluxes are corrected for the tilt of the sensor according to the routine of Wang et al.

150    (2016).

151    The SEB is formulated as follows:

152    $$E_{tot} = LW_{\uparrow} + LW_{\downarrow} + SW_{\uparrow} + SW_{\downarrow} + H_S + H_L + G_S \qquad (1)$$

153    where $E_{tot}$ is the net sum of energy received at the surface, $LW_{\uparrow}$ and $LW_{\downarrow}$ are the upwelling and

154    downwelling components of LW radiation, respectively, $SW_{\uparrow}$ and $SW_{\downarrow}$ are the upwelling and

155    downwelling components of SW radiation, respectively, and $H_S$, $H_L$ and $G_S$ are the surface

156    sensible, latent and ground heat fluxes, respectively. All fluxes are defined as positive when

157    directed towards the surface.

158    Surface melt energy $E_{melt}$ is defined as in King et al. (2015), as:

159    $$E_{melt} = \begin{cases} E_{tot} & T_S \geq 0°C \\ 0 & T_S < 0°C \end{cases} \qquad (2)$$

160    such that melt only occurs when there is a surplus of energy at the surface ($E_{tot}$ in Equation 1 is

161    positive) and the surface temperature, $T_S$, is at or above the melting point.

162    2.2 Regional climate model description

163    In this study the MetUM is run in a high-resolution atmosphere-only limited area configuration.

164    The MetUM contains a non-hydrostatic, fully compressible dynamical core, referred to as

165 ENDGAME (Even Newer Dynamics for General Atmosphere Modelling of the Environment),

166 with semi-implicit time stepping and semi-Lagrangian advection. Atmospheric prognostic

167 variables are the dry virtual potential temperature, Exner pressure, dry density and three-

168 dimensional winds, and moist prognostics such as hydrometeors and specific humidity are

169 advected as atmospheric tracers (Walters et al., 2017). Prognostic variables are discretised

170 horizontally on an Arakawa-C grid and a terrain-following hybrid vertical coordinate with

171 Charney-Phillips staggering used in the vertical.

172 An inner model domain that includes much of the Antarctic Peninsula and surrounding waters

173 (Figure 1) is nested within a global version of the MetUM to dynamically downscale the global

174 model output to higher resolution, as in Orr et al. (2014) and Gilbert et al. (2020). The global

175 model is run using Global Atmosphere 6.1 physics (Walters et al., 2017) and has N768 resolution

176 (equivalent to a horizontal resolution of approximately 17 km at mid-latitudes). The inner

177 domain has 70 vertical levels (with 40 below 5500 m), and uses a rotated latitude-longitude grid

178 to maintain uniform horizontal resolution of 4.0 km. Although Elvidge et al. (2015) argued that a

179 horizontal grid spacing of around 1.5 km was necessary to resolve foehn winds over Larsen C,

180 this argument was based on the previous version of the dynamical core. Recent improvements

181 incorporated in ENDGAME (Wood et al., 2014) have resulted in a more accurate representation

182 of the flow response to orography, meaning a spatial resolution of ~4 km is now sufficient

183 (Gilbert et al., 2020).

184 The inner domain runs using the Regional Atmosphere (RA) configuration 'RA1M' physics

185 package described in Bush et al. (2020), with modifications to the parameterisation of large-scale

186 cloud and precipitation as described in Gilbert et al. (2020). Gilbert et al. (2020) showed that this

187 was the optimum model configuration currently available for this region and recommended that

188 it be used for further work examining SEB and melt. Full details of the model physics and

189 parameterisations used are given in Gilbert et al. (2020).

190 Because of the important influence of the mountains (and land-sea interactions – see Orr et al.

191 (2005, 2014)), the default model orography and coastline were updated using better resolved

192 datasets. The updated land-sea mask is based on the Scientific Committee on Antarctic Research

193 Antarctic Digital Database coastline, version 7.0 (released January 2016 and available at

194 https://www.add.scar.org/). The orography is based on the Ohio State University Radarsat

195 Antarctic Mapping Project (RAMP) 200 m resolution Antarctic digital elevation model (Liu,

196 2015), and is converted for use in the MetUM by interpolating the dataset onto the 4.0 km inner

197 domain and applying a 2D 1-2-1 filter with convolution.

198

199 **Figure 1**. Map of the Antarctic Peninsula MetUM inner model domain at a spatial resolution of 4

200 km, with the locations of the four AWSs used for validation indicated with green crosses. The

201 map is centred on the Larsen C ice shelf and its tributary inlets, on which AWS 14, 15 and 17 are

202 located. The map also shows the remnant Larsen B ice shelf on which AWS 17 is located. The

203 height of the model orography is indicated with coloured contours and is derived from the

204 RAMP 200 m elevation model (Liu, 2015). Ice shelves are shown in white.

205

206         2.3 Method

207 The MetUM is primarily used to produce a model hindcast of the northern and central Antarctic

208 Peninsula and Larsen C region over the period 1 January 1998 to 31 December 2017. An

209 additional shorter run is also undertaken to focus on the conditions over Larsen B prior to its

210 collapse. This case study spans the period 1 September 2001 – 31 March 2002 and uses a

211 modified land-sea mask that includes both the Larsen A and B ice shelves.

212

213 In both the 20-year hindcast and shorter case study runs, the global model is initialised from

214 ERA-Interim reanalysis (Dee et al., 2011), and its output is used to provide forcing for the

215 regional climate model / inner domain at 4.0 km horizontal resolution (Figure 1). The model is

216 re-initialised every 12 hours and runs for 24 hours. The first 12-hour periods are considered spin-

217 ups and discarded; while the second 12-hour periods are concatenated together to produce a

218 continuous time series spanning the period of interest. Frequent re-initialisation ensures that the

219 circulation in the inner domain is well constrained and does not drift (Sedlar et al., 2020; Lo et

220 al., 2008), while the discarding of spin-up periods ensures that smaller-scale features are

221 adequately represented. Surface (2D) variables are outputted 3-hourly and 3D variables are 6-

222 hourly, which is considered sufficient temporal resolution to capture key processes such as

223 foehn. A full list of output variables is given in the appendix.

224

225 The occurrence of foehn winds in the model is calculated using two methods that vary in

226 computational expense. To compute the occurrence of model foehn winds at grid points

227 corresponding to AWSs (Tables 3 and 4), an isentrope-based method adapted from the broad-

228 scale approach of King et al. (2017) is adopted, with an additional stipulation that surface

229 warming and/or drying must also be simulated. Whereas King et al. diagnose foehn occurrence

230 across the ice shelf as a whole, in this study the algorithm is used to detect foehn occurrence at

231 each model grid cell. The algorithm is as follows:

232

233 • Determine the strength of the westerly component of the wind, u , at a location at least

234    one Rossby radius of deformation, λR, westwards / upwind of the Antarctic Peninsula.

235    λR is calculated as λR = Nh/f, where N is the Brunt-Väisälä frequency, typically 0.01 s$^{-1}$,

236    h is the height of the mountain barrier, approximately 1500-2000 m on the Antarctic

237    Peninsula, and f is the Coriolis parameter. The wind is averaged between 250 m and a

238    height Z1 in a manner similar to Elvidge et al. (2015) and referred to as $u_{Z1}$, where Z1 is

239    just above the peak height of orography, i.e. it is characteristic of the average westerly

9

240   flow impinging on the Antarctic Peninsula. If $u_{Z1} \geq 2$ m s$^{-1}$ (and there is therefore a clear

241   west-east cross-barrier flow) then for each model grid point:

242   o   Find the potential temperature at Z1, $\theta_{Z1}$, and trace this isentrope directly

243       eastwards across the mountain barrier

244   o   Determine the minimum elevation, Z2, of $\theta_{Z1}$ on the lee side of the mountains

245       over Larsen C

246   o   Determine the maximum change in height of the isentrope $\theta_{Z1}$ upwind and

247       downwind of the barrier, i.e. Z3 = Z1 – Z2.

248   o   For a model grid point, if over any 6 hour period Z3 > 500 m AND 1.5 m air

249       temperature, Tair, increases AND 1.5 m relative humidity, RH, decreases, then

250       foehn conditions are detected.

251   As this approach is extremely computationally expensive it cannot be used for every grid point in

252   the model domain. Hence, to produce spatial maps of foehn occurrence over the entire Larsen C

253   ice shelf, the method of Turton et al. (2018) was adapted. Turton et al. detect foehn conditions

254   when, over a 12-hour period, one of the following conditions is met:

255   a)   Decrease in relative humidity, RH, below the 10th percentile

256   b)   Decrease in RH below a location-specific threshold

257   c)   Decrease in RH below the 15th percentile plus a 3°C increase in $T_{air}$

258   We adopt conditions a) and c), plus include a further stipulation that there be a westerly wind

259   component ($u_{Z1} > 2.0$ m s$^{-1}$), as above. Sensitivity tests (not shown) showed that the two methods

260   of identifying foehn events produced comparable results.

261

262   **3 Results and Discussion**

263        3.1 Model hindcast validation

264   The MetUM hindcast is validated at all AWSs shown in Figure 1 using all available observations

265   and taking the closest model gridpoint to each AWS. Missing data are linearly interpolated for

266   validation purposes. Initial inspection of time series at each station (not shown), reveals that

267   AWS 17/18 and AWS 14/15 are similar enough to justify being grouped. The means of the time

268   series at AWS 14/15 and AWS 17/18 are hereafter presented as "ice shelf" and "inlet" stations,

10

269  respectively. Because the full SEB was not available at AWS 15, ice shelf values for $T_S$, $H_L$, $H_S$,

270  $E_{tot}$ and $E_{melt}$ are taken from AWS 14 only. The full SEB is available at both inlet stations. Table

271  1 shows observed and modelled annual mean values and the 5th and 95th percentiles for surface

272  variables at inlet and ice shelf stations during the hindcast period. Observed and modelled

273  statistics in Table 1 are given for the observational period available for each station. Scatterplots

274  of observed vs. modelled near-surface variables at AWS 14 during the entire observational

275  period for that station (January 2009 - December 2017) are shown in Figure 2. Validation results

276  at all stations are broadly similar to those for AWS 14, so for brevity, only results from AWS 14

277  are shown in Figure 2 because it has the longest observational record. These are discussed below.

278  As also shown by Kuipers Munneke et al. (2018), Gilbert et al. (2020) and Elvidge et al. (2020),

279  the MetUM model at a spatial resolution of 4 km or finer is able to reliably simulate

280  meteorological conditions and consequently the SEB and surface melt over Larsen C in all

281  seasons. This is confirmed by both Figure 2 and Table 1. As shown in Table 1, annual mean $T_{air}$,

282  $T_S$, wind speed and relative humidity are positively biased by 2.1°C, 2.4°C, 0.91 m s$^{-1}$ and 2.7%,

283  respectively, at inlet stations and 2.1°C, 3.1°C, 0.81 m s$^{-1}$ and 3.8%, respectively, at ice shelf

284  stations. This makes the MetUM hindcast on average slightly warmer, windier and moister than

285  observations, which is also clear from Figure 2.

286  The warm bias in air and surface temperatures is likely at least partially related to the

287  representation of boundary layer mixing in the MetUM and a documented warm bias in ERA-

288  Interim (Fréville et al., 2014; Dutra et al., 2015). Because $T_{air}$ and $T_S$ are biased by different

289  amounts, the near-surface temperature gradient is too small, which contributes to biases in $H_S$.

290  Wind and relative humidity biases may be related to the representation of features and processes

291  such as orography, form drag and surface roughness (Wood & Mason, 1993), the representation

292  of foehn events and foehn jets, the surface and snow schemes, or the influence of the coastline

293  (Orr et al., 2005; 2014). Additionally, the seasonal cycle and timing of weather events in the

294  MetUM hindcast (not shown) matches well between model and observations, which produces

295  high correlation coefficients (Figure 2) and low RMSEs for most parameters in Table 1.

296  The inter-percentile range for most variables in Table 1 is captured relatively well by the

297  hindcast, except for relative humidity and $H_S$. The 5th percentile of observed relative humidity

298 and the 95th percentile of $H_S$ are much lower and higher, respectively, at inlet stations than ice

299 shelf stations due to the effect of foehn winds. However, the hindcast does not capture this

300 completely: the 5th percentile of modelled inlet relative humidity is over-estimated by 7.9%

301 while the 95th percentile of HS is 7.1 W m$^{-2}$ too large in the model. This is likely caused by the

302 positive temperature bias shown in Table 1.

303 In Table 1 the annual mean downwelling radiative fluxes are simulated to within 10% of their

304 observed values at all stations and the model SW albedo ($SW_\downarrow/SW_\uparrow$) is simulated to within 1%

305 and 3% of observed values at inlet and ice shelf stations, respectively. Positive biases in $T_S$ and

306 Tair cause $LW_\uparrow$ to be over-estimated by 2.9% annually at all stations, generating an energy

307 deficit at the surface (and negatively biased mean net radiation $R_{net}$, (calculated as $LW_{net}$ +

308 $SW_{net}$), shown in Figure 2). This causes annual mean daily mean $E_{melt}$ to be under-estimated by

309 17-31%, particularly at inlet stations.

310 Negative $E_{melt}$ biases are largest during December-February (DJF, not shown) when the majority

311 of melting occurs, and during foehn events. These biases in $E_{melt}$ during foehn events, and the HS

312 and relative humidity biases noted above, are consistent with previous findings that the MetUM

313 under-predicts the magnitude of foehn-driven $E_{melt}$ fluxes. For example Gilbert (2020) found that

314 although the MetUM was able to capture the timing and duration of the foehn cases examined,

315 the magnitude of $E_{melt}$ was under-estimated. To summarise, at all stations and in all seasons, the

316 hindcast is able to simulate observed surface meteorological variables reliably and to broadly

317 capture SEB components, although $E_{melt}$ is under-estimated. Most of the biases in SEB terms

318 stem from a warm temperature bias.

**Table 1.** Summary statistics for inlet and ice shelf stations in observations and model output. Mean values, as well as the fifth and ninety-fifth percentiles of daily mean surface variables are given, where abbreviations and units are as follows: $T_S$: surface temperature (°C); $T_{air}$: 1.5 m air temperature (°C); RH: relative humidity (%), FF: 10 m wind speed (m s$^{-1}$); P: surface pressure (hPa); $SW_\downarrow$: downwelling shortwave radiation (W m$^{-2}$), $SW_\uparrow$: upwelling shortwave radiation (W m$^{-2}$); $SW_{net}$: net shortwave radiation (W m$^{-2}$); $LW_\downarrow$: downwelling shortwave radiation (W m$^{-2}$); $LW_\uparrow$: upwelling shortwave radiation (W m$^{-2}$); $LW_{net}$: net shortwave radiation (W m$^{-2}$); $H_S$: sensible heat flux (W m$^{-2}$); $H_L$: latent heat flux (W m$^{-2}$); $E_{tot}$: sum of all (W m$^{-2}$); $E_{melt}$: melt flux (W m$^{-2}$). All fluxes are positive when directed towards the surface.

**Figure 2**. Scatterplots of observed vs. modelled daily means of surface and near-surface variables at AWS 14. Correlation coefficients (r values) are given in the bottom right-hand corner of each panel: all values are statistically significant at the 99% level. The dashed line in each plot indicates perfect agreement between model and observations, while the solid line shows the line of best fit, calculated by a linear least-squares regression. Panels a – d show surface meteorological variables: surface temperature, $T_S$; near-surface (1.5 m) air temperature, $T_{air}$; 1.5 m relative humidity; and 10 m wind speed; and panels e – h show surface energy budget terms: downwelling longwave, $LW_\downarrow$; downwelling shortwave, $SW_\downarrow$; net radiative, $R_{net}$ and melt, $E_{melt}$, fluxes, defined as positive towards the surface.

15

354     3.2 Modelled meltwater production: Larsen C, from 1998 to 2017

355   Figure 3 shows cumulative annual simulated meltwater production for all full melt years

356   included in the hindcast period (a total of 19 melt years, starting August 1998 and ending July

357   2017), where melt years are defined as in Bevan et al. (2018) from August-July. This is the first

358   spatial map of mean surface meltwater production on Larsen C derived from a multi-year model

359   simulation. Table 2.  contains mean and maximum cumulative annual melt totals for the whole

360   Larsen C ice shelf and shows that mean cumulative melt ranges from 86 mm w.e. yr$^{-1}$ in 2010/11

361   to 188 mm w.e. yr$^{-1}$ in 2006/07, with maxima simulated in inlets peaking at 1025 mm w.e. yr$^{-1}$ in

362   2016/17.

363

364   The simulated spatial pattern of meltwater production (Figure 3) is consistent with satellite

365   observations of surface melting (e.g. Bevan et al., 2018; Luckman et al., 2014), with a clear

366   north-south gradient across the ice shelf, and more melting observed in inlets. The hindcast also

367   simulates peak mean meltwater production during the high melt years identified in Bevan et al.

368   (2018), for example the 1998/99, 2006/07, 2015/16 and 2016/17 melt seasons, when ice-shelf

369   averaged cumulative annual melt of 117 mm w.e., 187 mm w.e., 157 mm w.e. and 161 mm w.e.,

370   respectively, is modelled. The spatial patterns of surface melt shown in Bevan et al. (their Figure

371   6) are quite closely reproduced in Figure 3, for example more intense melting in inlets during

372   2015/16, 2016/17 and 2013/14 is successfully reproduced, as are the relatively low melt years of

373   2009/10, 2010/11 and 2014/15. Years where melt is shown in satellite observations but not the

374   hindcast include 2001/02 and 2002/03, and the hindcast simulates more melt during 2006/07 than

375   is shown in Bevan et al. (2018). Overall, however, the model's ability to reproduce the major

376   patterns of melting, particularly the east-west gradient and concentration of meltwater production

377   in inlets and the slopes immediately above is extremely encouraging and further justifies the use

378   of the MetUM as a tool for studying this region.

379

380   Simulated mean annual meltwater production amounts over Larsen C (Figure 3, Table 2) are also

381   comparable to those derived by Trusel et al. (2013), who used satellite data and modelling to find

382   ice-shelf integrated mean meltwater production of 220 mm w.e. yr$^{-1}$ over the period 1999-2009,

383   exceeding 400 mm w.e. yr$^{-1}$ in the north-western inlets, and Trusel et al. (2015) who show

384   contemporary melt rates over Larsen C of ~300 mm w.e. yr$^{-1}$. Comparable hindcast-simulated

385  values for 1998-2017 are 132 mm w.e. yr$^{-1}$ for all of Larsen C, and 536 mm w.e. yr$^{-1}$ for inlets

386  only, taking maximum meltwater production rates as a proxy for inlet melting (maxima are

387  always observed in inlets). This suggests that the MetUM may under-estimate surface melting

388  when averaged across the whole ice shelf, consistent with the results shown in Section 3.1.

389  Although the ice-shelf-mean meltwater totals do not compare exactly in absolute terms with the

390  satellite-based observations, the distributions do compare well. Further, it is notable that

391  maximum values simulated in the north-western inlets during high melt years (up to 797 mm

392  w.e., 602mm w.e. and 1025 mm w.e. in Mill Inlet, on the south-west of Larsen C, during

393  2013/14, 2015/16 and 2016/17, respectively, and up to 780 mm w.e. in Cabinet Inlet (the

394  location of AWS 18), in the north-west, during 2006/07) exceed the ~725 mm w.e yr$^{-1}$ observed

395  over Larsen B before its collapse (Trusel et al., 2015).

Figure 3. Total annual cumulative snow melt amount (in mm meltwater equivalent per year, mm w.e. yr$^{-1}$) across the Larsen C ice shelf for each melt year (August - July, defined as in Luckman et al., 2014 and Bevan et al., 2018) in the period 1998-2017. The 50 m elevation contour is given, approximately the height of the modelled ice shelf at the grounding line. The bottom right subplot shows the mean annual cumulative snow melt amount for all melt seasons.

**Table 2.** Total and maximum modelled meltwater production over the Larsen C ice shelf and tributary glaciers during each melt year (August-July) in the hindcast period. Annual ice shelf-integrated and maximum modelled meltwater production greater than one standard deviation above the mean are indicated with bold underlined text, while modelled meltwater production less than one standard deviation below the mean is indicated with italic underlined text. The mean and standard deviation ("SD") are shown in the bottom two rows.

| Melt year | Ice shelf mean annual total meltwater production (mm w.e.) | Maximum annual total meltwater production (mm w.e.) |
|---|---|---|
| 98-99 | 117 | 762 |
| 99-00 | 157 | 488 |
| 00-01 | *99* | 422 |

| **SD** | 26 | 178 |

410       3.3 Modelled meltwater production: The 2001/02 melt season, prior to the break-up of
411       Larsen B

412 Having established that the MetUM is able to realistically simulate the magnitude and spatial

413 patterns of surface melting observed on the Larsen C ice shelf, we now consider as a case study

414 the period immediately preceding the collapse of Larsen B. Figure 4 shows the cumulative melt

415 amount simulated over the seven-month time period prior to Larsen B's collapse, from the

416 additional shorter run for the period 1 September 2001 – 31 March 2002 (with the Larsen B ice

417 shelf still intact). Mean cumulative surface melt of 340 mm w.e. is modelled across the Larsen B

418 ice shelf during 1 September - 15 February, peaking at 664 mm w.e. in the foot of the mountains

419 (Figure 4). This magnitude of melt is comparable to the value of ~725 mm w.e. yr$^{-1}$ reported by

420 Trusel et al. (2015) to have been observed prior to its collapse. Particularly, melting in inlets

421 close to the grounding line (approximately in the vicinity of the 50 m elevation contour given in

422 Figure 4) could have destabilised the ice shelf in a critical area. Melt-induced thinning in the

423 vicinity of the grounding line has been shown to reduce ice shelf buttressing capacity more

424 considerably than elsewhere on the shelf (Khazendar et al., 2016).

425

426 **Figure 4**. Cumulative surface melt amount simulated during the period 1 September 2001 – 15

427 February 2002 over the Antarctic Peninsula domain (with the Larsen B ice shelf still intact, main

428 figure) and zoomed in over the Larsen B ice shelf only (inset). The 50 m elevation contour is

429 shown in both plots as the black contour.

430    The ability of this model run to capture the causes of this extensive melting are next examined.

431    In the simulation, the majority of melting occurred mid-November - February, with sustained

432    daily mean modelled ice-shelf melt fluxes and meltwater production of 8.4 W m$^{-2}$ and 2.2 mm

433    w.e., respectively. Van den Broeke (2005) reports that the 2001/02 melt season was three times

434    longer than the average of the preceding five summers because of the synoptic conditions, which

435    established anomalously low sea ice concentrations in the Weddell Sea (east of Larsen B) and

436    strong foehn flow. Figure 5a shows the mean modelled meteorological conditions across the

437    entire Antarctic Peninsula domain, and over Larsen B (Figure 5b) during the period 10

438    November 2001 – 1 March 2002. During this period, the melt point was frequently reached (not

439    shown), allowing melting to occur, especially in a narrow band along the foot of the mountains

440    in the northwest of the ice shelf, where $T_{max}$ was also frequently above 0°C (Figure 5b).

441

442    Low wind speeds (<3 m s$^{-1}$) over Larsen B and strong upwind westerly flow caused by an

443    anomalously deep Amundsen Sea Low suggests that foehn were important in producing higher

444    surface melt fluxes. This is also suggested by Cape et al. (2015), who show a strong correlation

445    between the monthly mean number of melt days and monthly mean foehn frequency anomaly

446    over Larsen B during this period, and is further supported by the positive and negative mean $H_L$

447    and $H_S$, respectively, shown in Figure 5c and 5d. Large negative and positive $H_L$ and $H_S$ fluxes of

448    the order of 100s W m$^{-2}$, respectively, are simulated in the lee of mountains upstream of Larsen

449    B, suggesting an influx of warmer, drier air produced by foehn flow. During this period, this

450    generates mean $E_{tot}$ fluxes averaged across Larsen B of 2.0 W m$^{-2}$, driving melt whenever surface

451    temperatures exceed the melting point.

452

**Figure 5**. Mean modelled synoptic meteorological conditions and SEB components during 10 November 2001 - 1 March 2002, when melt was occurring. Panels a) and b) show mean meteorological conditions, where coloured shading shows the mean daily maximum 1.5 m air temperature throughout this period, and contours and vectors give mean sea level pressure and 10 m winds, respectively. Note that the land-sea mask includes the Larsen A and B ice shelves. Mean conditions are shown in panel a) while the inset (panel b) shows conditions over the Larsen B ice shelf only. Note that the temperature and wind speed scales are altered in the inset to show more detail. Panels c) - f) show mean surface energy fluxes ($H_L$, $H_S$, $E_{tot}$ and $E_{melt}$, respectively) over the Larsen B ice shelf, in units of W m$^{-2}$.

463        3.4 Frequency of foehn events: Larsen C, from 1998 to 2017

464    The frequency of foehn events at inlet and ice shelf stations is diagnosed using the isentrope-

465    based method detailed in Section 2.3. Table 3 shows summary statistics (mean, median and

466    standard deviations) of foehn occurrence at inlet and ice shelf stations for the hindcast period,

467    decomposed into seasons, and given as an annual average. The modelled spatial distribution of

468    foehn occurrence across the Larsen C ice shelf is shown in Figure 4, computed using the method

469    of Turton et al. (2018) detailed in Section 2.3.

470

471    Consistent with previous studies (e.g. Turton et al., 2018; Wiesennekker et al., 2018; Datta et al.,

472    2019; Elvidge et al., 2020) the highest foehn frequencies are simulated in the immediate lee of

473    steep elevation, with foehn events occurring on average 16% of the time annually at inlet stations

474    and 13% of the time at ice shelf stations (Figure 6, Table 3), comparable values to those cited in

475    the aforementioned studies. A clear gradient is evident in Figure 6 with foehn frequency

476    declining with distance from the mountains. The gradient is qualitatively similar to the gradient

477    in surface melting shown in Figure 3, with higher melt simulated in the northwest and in inlets,

478    suggesting a contributory role for foehn in causing surface melt. The importance of foehn in

479    driving melt will be evaluated in Part 2 of this study. Foehn events are most common during

480    September-November (SON) at all locations and standard deviations are highest in December-

481    February (DJF) and MAM, indicating higher inter-annual variability in foehn occurrence in these

482    seasons (Table 3). In recent years, unusually high foehn-driven surface melting has been reported

483    in non-summer seasons, particularly MAM 2016 (Kuipers Munneke et al., 2018), which is
484    discussed in detail next.

485

486

**Figure 6**. Annual modelled foehn occurrence and melt duration over the Larsen C ice shelf for the hindcast period. Foehn occurrence is shown as the mean percentage of time over the period 1998-2017 where foehn conditions are diagnosed over Larsen C, using the surface-based foehn diagnosis method of Turton et al. (2018) with an additional requirement, as in King et al. (2017), that there be a westerly wind component ($u_{Z1} > 2.0$ m s$^{-1}$). See methods for more details.

503 **Table 3.** Summary seasonal modelled foehn frequency statistics for ice shelf and inlet stations on

504 the Larsen C ice shelf over the period 1998-2017. Means, medians and standard deviations

505 ("SD") are given for each season and annual totals. Values are calculated using the isentrope-

506 based method described in section 2.3.

|  |  | Mean | SD |
|---|---|---|---|
| Ice shelf | DJF | 11.2% | 3.7% |
|  | MAM | 12.1% | 3.9% |
|  | JJA | 13.4% | 3.3% |
|  | SON | 14.5% | 3.1% |
|  | ANN | 12.7% | 2.4% |
|  |  | Mean | SD |
| Inlet | DJF | 15.4% | 4.0% |
|  | MAM | 15.4% | 3.7% |
|  | JJA | 16.1% | 3.0% |
|  | SON | 18.5% | 2.7% |
|  | ANN | 16.1% | 1.9% |

507

508 3.5 Frequency of foehn events: Larsen C, MAM 2016

509 Unusually frequent and intense foehn flow was simulated in the hindcast during the second half

510 of MAM 2016 (Table 4), the period also examined in Kuipers Munneke et al. (2018). Only two

511 years of observations were used in the Kuipers Munneke et al. study, which made it impossible

512 to determine how anomalous these conditions were. However, the 20 years of hindcast data

513 presented here make it possible to contextualise these findings.

514

515 Mean meteorological conditions during April 15 – May 31 2016 are shown in Figure 7a. Strong

516 cross-peninsula flow is simulated and mean near-surface daily maximum air temperatures are

517 5.8°C warmer than climatology for the period, causing surface temperatures to frequently reach

518 the melting point and for air temperatures to climb as high as 12.6°C in Mill Inlet on the 25 May

519 2016 (the peak of the case identified in Kuipers Munneke et al. (2018) as being strongest in the

520 entire AWS 18 observational record).

521

522 This synoptic situation creates optimum conditions for foehn to occur. Panels b – f in Figure 7

523 show mean anomalies for individual SEB components during April 15 – May 31. Increased

524 surface temperature produces modest negative $LW_\uparrow$ and $LW_{net}$ anomalies (Figure 7b) but the

525 turbulent fluxes differ considerably from the climatology. Negative $H_L$ anomalies leeward of the

526 mountains (Figure 7c) indicate that the air is drier than the climatology and that sublimation

527 occurs over Larsen C. Extremely positive sensible heat anomalies (Figure 7d) are modelled east

528 of the mountain crest and extend across the ice shelf as foehn flow mixes warm, dry air towards

529 the surface. This strong foehn effect generates mean $E_{tot}$ anomalies (Figure 7e) of up to 76.8 W

530 $m^{-2}$ in the lee of the mountains. Mean $E_{melt}$ anomalies (Figure 7f) of up to 61.1 W $m^{-2}$ are

531 simulated wherever $E_{tot}$ is positive, as mean maximum air temperatures are above 0°C in almost

532 all locations (Figure 7a). These modelled anomalies agree well with the observational and model

533 data presented in Kuipers Munneke et al. (2018), which show that foehn events produced by the

534 isentropic drawdown mechanism (Elvidge & Renfrew, 2016) delivered large sensible heat fluxes

535 (up to 300 W $m^{-2}$ in the strongest case) that were responsible for driving melting during May

536 2016.

537 **Table 4.** Mean modelled MAM foehn occurrence during the model hindcast period ("1998-2017

538 mean"), mean modelled MAM foehn occurrence during the hindcast period plus one standard

539 deviation ("Mean + SD") and modelled foehn occurrence during MAM 2016 ("MAM 2016") at

540 each station. As in Table 3, these values were computed using the isentropes-based method

541 described in section 2.3.

| AWS | 1998-2017 mean (%) | Mean + SD (%) | MAM 2016 (%) |
|---|---|---|---|
| AWS 14 | 13.9 | 17.6 | 22.8 |
| AWS 15 | 10.3 | 13.5 | 18.3 |
| AWS 17 | 15.7 | 19.3 | 21.5 |
| AWS 18 | 15.1 | 18.9 | 24.2 |

542
543

544 Figure 8 shows that the associated $E_{melt}$ anomalies result in anomalous cumulative meltwater

545 production over Larsen C, with 29 times more melt (5.7 Gt) produced during the MAM 2016

546 season than in the 1998-2017 MAM climatology (0.2 Gt), representing 35.4% of the meltwater

547 production for the 2015/16 melt year (August-July, 16.0 Gt). This value is consistent with the

548 23% of annual meltwater production reported by Kuipers Munneke et al. (2018) for the period

549 January-December 2016.

550

551    The mean modelled MAM 2016 meltwater production anomaly over Larsen C relative to the

552    model MAM climatology is shown in Figure b, with maximum simulated melt along a transect

553    shown in Figure 8a. Maximum melt fluxes along the transect are highest in the immediate lee of

554    the mountains, and diminish rapidly with distance from the peak of orography as warm, dry

555    foehn air is increasingly mixed into cold ambient air masses. Regions of elevated melt exist

556    further out onto the ice shelf in some regions, with "streams" of higher melt emanating from the

557    mouths of inlets. The locations of these qualitatively match with the foehn "jet" regions

558    identified by Elvidge et al. (2015), which are typically cooler but experience higher wind speeds

559    during foehn events. They are downstream of mountain passes which channel flow and enhance

560    wind speeds, but cause air to be sourced from lower altitude, meaning that it is cooler when it

561    reaches the surface than in adjacent "wake" regions. Because the events during MAM 2016 are

562    so intense and ambient temperatures are so high, the relatively cooler jet temperatures do not

563    limit melting, and the elevated wind speeds enhance the sensible heat flux enough to drive
564    extremely intense melting in these jet regions.

**Figure 7**. Mean modelled synoptic meteorological conditions and surface flux and temperature anomalies during 15 April – 31 May 2016. Panel a) shows mean modelled meteorological conditions, where colours indicate the mean daily maximum 1.5 m air temperature anomaly (in °C), contours show mean sea level pressure (hPa) and vectors show mean 10 m wind speed and direction. Panels b) to f) show flux anomalies, in W m$^{-2}$, of $LW_{net}$, $H_L$, $H_S$, $E_{tot}$ and $E_{melt}$, respectively. In all panels the anomalies are calculated relative to the 1998-2017 model climatology for 15 April – 31 May. Blue colours indicate negative anomalies while red colours show positive anomalies.
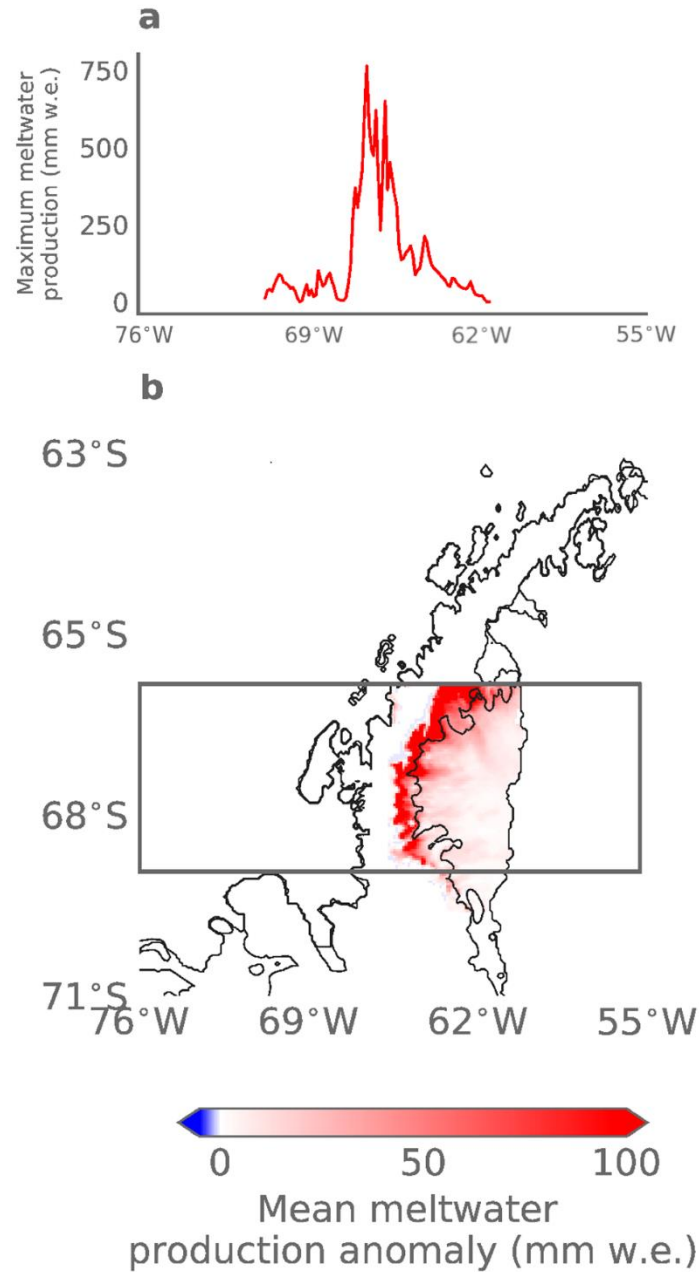

**Figure 8.** Mean meltwater production over Larsen C during 15 April – 31 May 2016. Panel a) shows the maximum cumulative melt produced along an east-west transect, indicated by the grey box in panel b). Panel b) shows the mean cumulative meltwater production anomaly with respect to the 1998-2017 model climatology for 15 April – 31 May.

## 5 Conclusions

The high-resolution regional model hindcast presented here is a novel dataset with which to evaluate meteorology, SEB and surface melt over the central Antarctic Peninsula. The hindcast reproduces the spatial patterns of surface melting on Larsen C identified from satellite observations, which are known to be linked to the incidence of foehn winds. This is the first multi-decadal hindcast of surface melt, meteorology and SEB to do so, and builds on Elvidge et al. (2020), which uses a similar configuration of the MetUM to explain the influence of foehn winds on the SEB of Larsen C during a shorter six-month period. Further, by re-visiting a case study of the period immediately preceding the collapse of the Larsen B ice shelf, we show that the hindcast captures both the magnitude of surface melting observed on Larsen B prior to its collapse, and that it reproduces the driving meteorological conditions implicated in its disintegration.

The long-term spatial distribution of foehn wind occurrence on Larsen C is mapped for the first time and closely matches the patterns of surface melting seen in satellite datasets, further implying a prominent role for foehn in driving melting. Compared to other years in the hindcast, much higher foehn frequency was simulated in MAM 2016, which was the subject of Kuipers Munneke et al. (2018). Exceptionally high foehn occurrence in this season (more than two standard deviations above the mean at three of the four AWSs considered) produced very large sensible heat flux anomalies, which drove positive $E_{tot}$ and $E_{melt}$ fluxes. These results indicate that the large proportion of melt, 23%, observed in the period April-October (taken to be 'winter' in Kuipers Munneke et al., 2018) was much higher in 2016 than it has been in other years in the hindcast.

Future work will further explore the causes and implications of surface melting on Larsen C. Part 2 of this study will use the hindcast model output to identify the most important meteorological drivers of surface melting on Larsen C, specifically by quantifying the influence of foehn winds, cloud phase and large-scale circulation on the SEB.

**Appendix**

**Table A1.** Available output variables from the MetUM hindcast, including variable standard
names, units, output frequency, vertical levels and availability. Full details of how to access the
data are given in the data availability section of this paper.

| Standard name | Model units | Output time | Vertical levels | Availability |
|---|---|---|---|---|
| near-surface air temperature | K | 3 hr, inst. | 1.5 m | CEDA archive |
| surface temperature | K | 3 hr, inst. | surface | CEDA archive |
