Abstract

Loss mechanisms act independently or in unison to drive rapid loss of electrons in the radiation belts. Electrons may be lost by precipitation into the Earth's atmosphere, or through the magnetopause into interplanetary space; a process known as magnetopause shadowing. Whilst magnetopause shadowing is known to produce dropouts in electron flux, it is unclear if shadowing continues to remove particles in tandem with electron acceleration processes, limiting the overall flux increase. We investigated the contribution of shadowing to overall radiation belt fluxes throughout a geomagnetic storm starting on the 7 September 2017. We use new, multi-spacecraft phase space density calculations to decipher electron dynamics during each storm phase and identify features of magnetopause shadowing during both the net-loss and the net-acceleration storm phases. We also highlight two distinct types of shadowing; 'direct', where electrons are lost as their orbit intersects the magnetopause, and 'indirect', where electrons are lost through ULF wave driven radial transport towards the magnetopause boundary.

Key Points:

- Multi-point phase space density measurements resolve changes in relativistic electron flux on sub-hour timescales.

- We observed magnetopause shadowing loss and localized electron acceleration during the September 2017 geomagnetic storm.

- 'Direct' and 'indirect' magnetopause shadowing processes identified during both the net-loss and net-acceleration phases of the storm.

Abstract

Loss mechanisms act independently or in unison to drive rapid loss of electrons in the radiation belts. Electrons may be lost by precipitation into the Earth's atmosphere, or through the magnetopause into interplanetary space – a process known as magnetopause shadowing. Whilst magnetopause shadowing is known to produce dropouts in electron flux, it is unclear if shadowing continues to remove particles in tandem with electron acceleration processes, limiting the overall flux increase. We investigated the contribution of shadowing to overall radiation belt fluxes throughout a geomagnetic storm starting on the 7 September 2017. We use new, multi-spacecraft phase space density calculations to decipher electron dynamics during each storm phase and identify features of magnetopause shadowing during both the net-loss and the net-acceleration storm phases. We also highlight two distinct types of shadowing; 'direct', where electrons are lost as their orbit intersects the magnetopause, and 'indirect', where electrons are lost through ULF wave driven radial transport towards the magnetopause boundary.

Plain Language Summary

34   Charged particles with extremely high energies are trapped by Earth's geomagnetic field. These

35   particles form rings around Earth called the Van Allen radiation belts, which vary in intensity.

36   This radiation poses a risk to satellites orbiting Earth, so it is important to understand how

37   changes in geomagnetic conditions produce variations in the radiation belt intensity. In this work

38   we take measurements of electron radiation from many satellites to observe electron 'dropouts',

39   where nearly the entire radiation belt is lost in a matter of hours. We found that it is necessary to

40   use multi-mission measurements to make observations of dropouts because a dropout may occur

41   quicker than a single satellite can traverse the radiation belt. In early September 2017, we

42   observed that movements of the geomagnetic outer boundary, the magnetopause, was

43   responsible for removing electrons, combined with diffusive processes. This agreed with the

44   predictions by previous studies. We further observed that the magnetopause continued to remove

45   electrons from the belt whilst electrons were simultaneously accelerated by fluctuations in the

46   geomagnetic field. This is significant because electrons may be removed from the belt soon after

47   they were created, limiting the overall growth of the radiation belt whilst the magnetopause was

48   compressed.

49   **1 Introduction**

50   The outer radiation belt is a ring of relativistic electrons which are trapped by Earth's

51   magnetosphere, surrounding the Earth at distances from ~3 to 8 Earth Radii above Earth's

52   surface. This population of particles has a range of energies between hundreds of keV to tens of

53   MeV (Mauk et al., 2013), which can pose a hazard to the operation of satellites which lie within

54   the belt (e.g., Baker et al., 1994; Wrenn, 1995; Wrenn et al., 2002). Most of the time, the outer

55   belt is slowly varying, however, during geomagnetic storms the particle flux in the outer belt by

56   change by orders of magnitude in a matter of hours to days (e.g. Baker et al., 1994; Morley et al.,

57   2010). Furthermore, a geomagnetic storm may result in a net-increase, decrease, or no response

58   in radiation belt flux (Reeves et al., 2003). Continuously competing acceleration and loss

59   mechanisms, which act to create or remove relativistic electrons from the magnetosphere,

60   determine the net flux of electrons in the outer belt.

61   Acceleration of electrons can occur via gyro-resonant wave-particle interactions between

62   100's of keV 'seed' electrons and very low frequency (VLF) whistler mode waves (Baker et al.,

63   1998; Horne et al., 2005; Meredith et al., 2002; Summers et al., 1998). Particles may also be

64 energized by drift-resonant wave particle interactions with ultralow frequency (ULF) waves

65 (e.g., Elkington et al., 1999; Mann et al., 2013), or by ULF driven inwards radial diffusion (e.g.,

66 Fälthammar, 1965; Jaynes et al., 2015). This inward diffusion of electrons results in betatron

67 acceleration which energizes electrons. Similarly, electrons are decelerated if they are

68 transported outwards via radial diffusion. If the ring current is enhanced, electrons may also be

69 adiabatically transported outwards, and decelerated (Dessler & Karplus, 1961; McIlwain, 1966).

70   Loss mechanisms act independently or in unison to remove electrons from the radiation

71 belts. Electrons are either lost by precipitation into the atmosphere, induced by wave-particle

72 interactions resulting in pitch-angle scattering (e.g., Miyoshi et al., 2008; Rae et al., 2018;

73 Rodger et al., 2015; Thorne & Kennel, 1971), or through the magnetopause into interplanetary

74 space. The latter process is called magnetopause shadowing, and electrons are either lost directly

75 to the compressed magnetopause intersecting drift paths (direct shadowing) (Green et al., 2004;

76 Kim et al., 2008; Li et al., 1997; Saito et al., 2010) or indirectly if electrons are transported

77 towards the magnetopause boundary and subsequently lost (Brautigam & Albert, 2000; Loto'aniu

78 et al., 2010; Morley et al., 2010; Rodger et al., 2019; Shprits et al., 2006; Turner et al., 2012).

79   Geomagnetic storms produce highly variable electron fluxes because both acceleration

80 and loss mechanisms are enhanced, acting in separate locations and on a variety of timescales. It

81 is understood that the radiation belts have a two-step response to geomagnetic storms; a net-loss

82 phase when the radiation belt flux decreases overall during storm onset, followed by a net-

83 acceleration phase where radiation flux increases overall (Murphy et al., 2018). Electrons are

84 usually lost from the belts before lower energy electrons are accelerated because of the way in

85 which the magnetosphere responds to solar wind structures which drive geomagnetic storms. At

86 storm onset, the magnetopause is often compressed by shock structures in the solar wind (e.g.

87 Dmitriev et al., 2014; Sibeck et al., 1989), resulting in some loss of electrons via magnetopause

88 shadowing. If the compression is large enough, losses due to shadowing are extreme, and the

89 entire outer radiation belt may suddenly decrease by orders of magnitude over a timescale of

90 hours; this is referred to as a dropout (e.g. Borovsky et al., 2009; Onsager et al., 2002). Dropouts

91 are important precursors to the latter net-acceleration phase as they remove both the existing

92 radiation electrons and seed electrons, which limits the number of particles accelerated from this

93 lower energy population (Bingham et al., 2018). The resulting net-loss period may extend into

94 main phase of the geomagnetic storm, then acceleration mechanisms begin to increase the overall

95   electron flux. The net-acceleration phase is delayed compared to the net-loss phase because the

96   timescales of wave driven acceleration and/or ULF driven diffusion is slower (hours to days)

97   (Baker et al., 1994; Boyd et al., 2014; Elkington et al., 2003; Horne et al., 2005; Reeves et al.,

98   2013). It is not known whether magnetopause shadowing continues to contribute to the overall

99   flux during the net-acceleration phase.

100   Because of the fast nature of shadowing, it is extremely hard to study the characteristics

101   of dropout events in detail. So far, magnetopause shadowing observations include identifications

102   of simultaneously compressed magnetopause and a net-decrease in electron flux (e.g., Morley et

103   al., 2010; Rodger et al., 2019) and/or measurements of butterfly pitch angle distributions near the

104   compressed magnetopause (e.g., Kang et al., 2018; Ozeke et al., 2020; Tu et al., 2019). Such

105   pitch angle distributions are an observational feature of shadowing since equatorial bouncing

106   particles (with a high pitch angle) drift to higher radial distances at the magnetopause nose than

107   high latitude bouncing particles (with low pitch angles), therefore high pitch angle electrons are

108   preferentially lost to the magnetopause (Sibeck et al., 1987).

109   It is thought that magnetopause shadowing will have specific characteristics identifiable

110   in phase space density (PSD) (Green & Kivelson, 2004; Loto'aniu et al., 2010; Turner et al.,

111   2012). The collective dynamics of the radiation belts are often determined by using

112   measurements of PSD, transformed into adiabatic invariant space μ, K, and L*. Radiation belt

113   studies have notably used PSD to distinguish localized internal sources of high energy electrons

114   (e.g. Boyd et al., 2014; Chen et al., 2006; Green & Kivelson, 2004; Miyoshi et al., 2003;

115   Selesnick & Blake, 2000) from radial diffusion of an external source (e.g. Degeling, 2008;

116   Jaynes et al., 2018; Ozeke et al., 2019).

117   In order to discern the physical processes occurring during storm times, Turner et al.

118   (2012) presented a schematic of PSD evolution, as a function of L*, during a direct

119   magnetopause shadowing event that results in a dropout (Figure 3, Turner et al., 2012). There is

120   an initial 'high pressure' phase during storm onset where the outer boundary of the radiation belt

121   is compressed such that a significant amount of the PSD distribution is lost to interplanetary

122   space. When the pressure relaxes during the main storm phase, the magnetopause expands and

123   there is a peak in PSD at the minimum radial distance which the magnetopause reached during

124   the compression, and a strong negative gradient in PSD towards the expanded magnetopause.

125   Over time, ULF wave activity during the main phase of the storm will rapidly diffuse the

126   remaining particles down any radial gradients in the PSD profile, resulting in a decrease in the

127   L* location of peak PSD, and a decrease in PSD at all L* compared to the pre-storm distribution.

128   Furthermore, in Figure 1 of Loto'aniu et al. (2010), the authors presented another scenario where

129   a combined negative phase space density gradient and enhanced ULF wave activity will lead to

130   indirect magnetopause shadowing.

131   Whilst PSD has been used to analyze electron dropouts (e.g., Ma et al., 2020; Shprits et

132   al., 2012; Turner et al., 2013; Xiang et al., 2017; Zou et al., 2020), the stages of magnetopause

133   shadowing described by Turner et al. (2012) has not yet been explicitly identified using PSD

134   measurements. This is because dropouts occur on such fast timescales that it is difficult to

135   measure complete PSD profiles in L* on the timescales necessary for this observation with single

136   or even dual spacecraft in geostationary transfer orbits. In this study we investigate the dynamics

137   of PSD during the early September 2017 geomagnetic storm using a new multi-spacecraft dataset

138   of PSD measurements that covers L* = 1.5 to 9. By using a multi-satellite dataset, we can

139   measure PSD with high enough temporal and spatial resolution to investigate whether the Turner

140   et al. (2012) description of a magnetopause shadowing event is accurate.

141

2 Data

2.1 Phase Space Density Measurements

In this paper, we primarily use Phase Space Density (PSD) to characterize the radiation belt response to a geomagnetic storm from 7-10 September 2017. PSD describes the kinematical state of radiation belt electrons using three coordinates of position, and the three components of canonical momentum (Schulz and Lanzerotti, 1974). Since the number of electrons in the radiation belt is sufficiently large and energetic, we can describe gyration, bounce, and drift motions in terms of three adiabatic invariants of motion, namely μ, K, and L* (Roederer, 1970). In this formalism we consider only the phase-averaged motion of particles, reducing the problem to a three-dimensional approximation of the system. We then consider the density of electrons in this phase space, the PSD.

The benefit of using an invariant PSD is that non-adiabatic processes are easily identified by any changes to the PSD distribution; that is, the PSD distribution does not change if only adiabatic changes are occurring to the system (following Liouville's theorem). Furthermore, the PSD distribution in L* is an important characteristic when interpreting indirect magnetopause shadowing processes because the PSD gradient in L* determines the rate of particle diffusion towards this outer boundary.

The electron PSD is here defined in units of $(c/cm/MeV)^3$, following the Committee on Space Research (COSPAR) Panel on Radiation Belt Environment Modelling (PRBEM) recommendations. For each spacecraft and instrument, the adiabatic invariants μ, K, and L* (Roederer, 1970) are computed using the International Radiation Belt Models (IRBEM) library (Boscher, 2013), the International Geomagnetic Reference Field (IGRF) internal field model, and the semi-empirical Tsyganenko 2001 storm (T01s) external magnetic field model (Tsyganenko et al., 2003). Through the September 2017 storm we use PSD measurements from;

- Van Allen Probes MagEIS (Magnetic Electron Ion Spectrometer) and REPT (Relativistic Eletron-Proton Telescope) instruments (Mauk et al., 2013; Blake et al., 2012; Baker et al., 2013),

171   •   THEMIS ESA (Electrostatic Analyzer) and SST (Solid State Telescope)

172   instruments (Angelopoulos, 2009; Angelopoulos et al., 2008; McFadden et

173   al., 2008),

174   •   MMS FEEPS (Fly's Eye Electron Proton Spectrometer) instrument (Blake

175   et al., 2016; Burch et al., 2016),

176   •   GOES MAGED (Magnetospheric Electron Detector) and EPEAD

177   (Energetic Proton, Electron, and Alpha Detector) (GOES N Series Data

178   Book, 2010; Hanser, 2011; Rodriguez et al., 2014),

179   •   GPS (Global Positioning System) Navstar Satellite CXD (Combined X-

180   Ray Dosimeter) (Tuszewski et al., 2004).

181   Each instrument is cross calibrated with the Van Allen Probe B MagEIS measurements.

182   Rather than interpolating PSD observations to find PSD for specific μ and K, as is

183   traditionally practiced, in this study we use PSD measurements which lie within a

184   specified range of μ and K to represent a specific population of electrons. For μ we use a

185   range of ± 2.5%; e.g., for a specified mu of 400 MeV/G, the range is 390 - 410 MeV/G.

186   The range of K used is ± 25%; e.g., for a specified K 0.1 G0.5RE, the range is 0.75 to

187   1.25 G0.5RE. A relatively large range of K was chosen in order to maximize the PSD

188   data available in each distribution across all L*, whilst a small μ range was chosen to

189   limit any overlap between measurements taken by different energy channel ranges for

190   different satellites.

191   2.2 Parameterisation of the Outer Boundary

192   In this study we use both measurements of the magnetopause and calculations of

193   the last closed drift shell (LCDS) when considering the outer boundary of the radiation

194   belts. We calculate the LCDS numerically as the maximum L* at which an electron with

195   a given pitch angle follows a closed drift path in the T01s external magnetic field model,

196   where there is a single magnetic minima along a field line. The magnetopause location is

197   represented by the Shue et al. (1998) magnetopause model, and by measurements of the

198   magnetopause location taken by the THEMIS and GOES spacecraft. We supplement the

199   Shue et al. (1998) model with magnetopause measurements as it has been shown that

200   statistical models may not reflect event specific behavior of the magnetopause location

201   during dynamic magnetopause compressions (Staples et al., 2020). To identify THEMIS

202   magnetopause crossings, magnetic and plasma measurements are taken from the Fluxgate

203   magnetometer (Auster et al., 2008) and the Electrostatic Analyzer (McFadden et al.,

204   2008). For GOES 13 and 15 magnetopause crossings, magnetic field data from the flux

205   gate magnetometers was used (Singer et al., 1996).

206   2.3 Solar Wind Data

207   Solar wind data and geomagnetic indices used are provided by the

208   NASA/Goddard Space Flight Centers OMNI data set through Coordinated Data Analysis

209   Web (CDAWeb; https://omniweb.gsfc.nasa.gov/). Solar wind measurements in this

210   dataset are taken by the ACE, Wind, IMP 8, and Geotail missions, and are propagated to

211   the bow shock nose. The SYM-H index, calculated in a similar manner to Dst index by

212   ground based midlatitude magnetometer stations, is used to indicate geomagnetic activity

213   (Iyemori, 1990; Iyemori et al., 2010; Wanliss et al., 2006). All data used from CDAWeb

214   has 5-minute resolution.

215

216 3 Results

217
Figure 1. The solar wind and magnetospheric conditions for the 6 - 10 September 2017; (a) total
IMF (blue) and the north-south component of IMF BZ (black); (b) solar wind speed; (c) solar
wind dynamic pressure; (d) subsolar standoff distance of the magnetopause, calculated by the
Shue et al. (1998) model (black line), and equivalent subsolar standoff distance measured by

222   THEMIS (blue) and GOES (purple) spacecraft according to Staples et al. (2020); (e) SYM-H

223   index; differential electron flux as a function of L shell, measured by GPS satellites at (f) 0.8

224   MeV and (g) 2 MeV. Interplanetary shocks are indicated by red lines and blue shaded areas show

225   when there are CME ejecta as stated by Shen et al., (2018).

226

227   Figure 1 shows a summary of solar wind, interplanetary magnetic field (IMF),

228   magnetospheric parameters, and radiation belt electron flux between the 6 - 10 of September

229   2017. During the time period there is a complex sequence of interacting interplanetary shocks

230   and coronal mass ejecta (CME) (Scolini et al., 2020; Shen et al., 2018; Werner et al., 2019)

231   which drives an equally complex magnetospheric and radiation belt response. The times of the

232   interplanetary shocks and CME ejecta classified by Shen et al. (2018) are displayed by the red

233   lines and blue shaded areas respectively. Measurements of electron flux at 0.8 MeV and 2 MeV

234   energies are taken by the combined X-ray dosimeter on board LANL GPS Navstar satellites

235   (Tuszewski et al., 2004). As the orbits of GPS satellites are highly inclined, measurements of

236   flux at L shells $\gtrsim$ 5.5 are taken at high magnetic latitudes where fewer electrons complete their

237   bounce orbit, and therefore flux decreases rapidly with L shell.

238   The arrival of the first interplanetary shock is indicated by an increase in solar wind

239   speed (Figure 1b) and dynamic pressure (Figure 1c) by 200 kms-1 and 9 nPa respectively, and an

240   increase in IMF strength by 15 nT (Figure 1a). At 01:00 UT on 7 September 2017, the increased

241   dynamic pressure resulted in a compression of the magnetopause from 11.5 RE to 8 RE (Figure

242   1d), and an increase in SYM-H index from ~ 10 nT to 50 nT (Figure 1e) as magnetopause

243   currents are enhanced by the increased solar wind number density (not shown). Both 0.8 MeV

244   and 2 MeV flux increased by a factor of ~2 at all L shells < 5 (figure f-g). When SYM-H index

245   returned to the pre-storm value of ~ 10 nT, so did electron flux at both energies.

246   The first CME ejecta arrived at 06:50 UT 7 September, accompanied by an IMF BZ

247   rotation, increasing from -10 nT to 9 nT then decreasing to – 8 nT (Figure 1a), and there is an

248   overall decrease in solar wind velocity and dynamic pressure (Figures 1b & 1c respectively).

249   There is no significant change in SYM-H as it returned to ~ 0 nT prior to the first ejecta (Figure

250   1e). The magnetopause began to expand outwards from 8 RE to 10 RE, with THEMIS measuring

251   the equivalent subsolar magnetopause between 8 and 10 Re during this period (Figure 1d).

252   Electron flux decreased by a factor of ~4 compared to the pre-storm flux, for both energies, and

253   at all L shells (Figure 1f-g).

254   The second CME arrived at 16:50 UT 7 September and lasted until 01:00 UT 8

255   September. A second interplanetary shock which (was associated with the third CME) was

256   propagating within this second CME ejecta, and arrived at 22:28 UT 7 September. When the

257   second CME ejecta arrived at 16:50 UT 7 September, solar wind speed and pressure continued to

258   decrease gradually (Figure 1b & c respectively), and IMF BZ decreased from 8 nT to –10 nT

259   (Figure 1a). Interestingly, the magnetopause did not change location significantly (Figure 1d),

260   there was no geomagnetic activity (Figure 1e), and no change to electron fluxes (Figure 1f-g).

261   However, when the interplanetary shock arrived, IMF field strength suddenly increased from 10

262   nT to ~35 nT and BZ decreased further from –10 nT to –32 nT. Solar wind speed increased from

263   500 kms-1 to 700 kms -1, and dynamic pressure increased from 1 nPa to 4 nPa. The

264   magnetopause was compressed within geostationary orbit (~6.6 RE) where there were multiple

265   magnetopause crossings by GOES 13. The Shue et al. (1998) magnetopause model calculated a

266   minimum standoff distance of 7 RE, whereas the equivalent standoff distance calculated for the

267   GOES magnetopause crossings is 5.5 RE. The SYM-H index decreased from 0 nT to a minimum

268   of –142 nT following the shock. The 0.8 MeV electron flux decreased by a factor of ~ 100 across

269   L shells > 5 and ~ 10 for L shells < 5. Similarly, 2 MeV electron flux also decreased following

270   the interplanetary shock, but by a factor of ~1000 for L shells > 5 and a factor of ~100 at L shells

271   < 5. At both energies, this dropout in flux started at the highest L shells first, followed by the

272   lower L shells over a 3-hour time period.

273   Following the second CME ejecta solar wind speed remains high at 800 km s-1 (Figure

274   1b), whilst dynamic pressure fluctuated, increasing from 1 nPa to 6 nPa (Figure 1c). IMF BZ

275   also fluctuated rapidly between –10 nT and 10 nT (Figure 1a). SYM-H began to increase (Figure

276   1e), indicating that the start of the storm recovery phase. The magnetopause expanded outwards

277   to ~ 10 RE, as measured by THEMIS (Figure 1d). Electron flux increased across both energies;

278   0.8 MeV flux increased by a factor of ≳ 10, first limited to L shells < 4.5 but slowly expanding

279   to all L shells prior to the third CME arrival (Figure 1f). The 2 MeV electrons showed a similar

280   increase in flux, though the rate of increase was slower (Figure 1g).

281   The third CME ejecta arrived on 8 September at 11:05 UT and lasted until 17:38 UT.

282   Solar wind speed remained high at 800 kms-1, decreasing to 700 km/s through the ejecta (Figure

283   1b), and solar wind pressure fluctuated rapidly between 2 and 8 nPa (Figure 1c). IMF strength

284   suddenly increased by 8 nT, and BZ rapidly decreased to –10 nT, both field strength and BZ

285   slowly returned to ~ 0 nT by the end of the CME (Figure 1a). SYM-H index decreased from –50

286   nT to a minimum of –120 nT (Figure 1e). The magnetopause was compressed within GEO orbit,

287   as measured by GOES 13 and 15 magnetopause crossings (Figure 1f). The Shue et al. (1998)

288   model is compressed to 7 RE at the subsolar point, and the equivalent subsolar magnetopause

289   calculated from GOES 13 crossing was 5.5 RE, and 3 RE for GOES 15. In actuality, the

290   magnetopause is not compressed to this level at the subsolar point as Van Allen Probe A is at

291   apogee near noon at this time and does not cross the magnetopause. Simultaneous to the

292   compression of the magnetopause, there is a sudden increase in flux for L shells < 5; the 0.8

293   MeV increased by a factor of ~ 10 and 2 MeV flux increased by a factor of ~ 100 (Figure 1f-g).

294   At L shells > 5 there is some reduction in flux, at both energies, compared to the flux at the

295   beginning of the third CME.

296   The fourth CME ejecta arrived at 19:30 UT 8 September and continued until 00:00 UT

297   11 September. Solar wind conditions are no longer recorded in the 5-minute resolution OMNI-

298   database during this period (Figure 1a-c). The magnetopause expanded to 13.5 RE, as measured

299   by THEMIS on 8 September (Figure 1d). For the remainder of the time period, electron flux at

300   both energies, and all L shells, continued to increase to values ~ 10 times greater than the pre-

301   storm flux (Figure 1f-g). The SYM-H index slowly increased during the recovery phase of the

302   storm (Figure 1e).

303

304
Figure 2. Phase Space Density shown as a function of L* over time as measured by multiple spacecraft for 6 - 10 September 2017; panels show PSD values where K=0.1 G0.5 RE and μ is (a) 400 MeV/G; (b) 900 MeV/G. Interplanetary shocks are indicated by red lines, and blue shaded areas show when there are CME ejecta as stated by Shen et al. (2018). The LCDS for K = 0.1 G0.5 RE is overplotted in the black solid line on all three panels. The black triangles indicate the time periods depicted in Figure 3.

Figure 2 shows PSD of electrons measured by Van Allen Probes, THEMIS, MMS, GOES, and GPS. The evolution of PSD where K=0.1 G0.5 RE and μ is 400 MeV/G and 900 MeV/G (panels a and b respectively) is shown as a function of L*. As with Figure 1, solar wind features are indicated by the red lines (interplanetary shocks) and blue shaded regions (CME ejecta).

At the beginning of 6 September, PSD increased rapidly with increasing L* up to L* = 4 for μ = 400 MeV/G, or L* = 4.2 for μ = 900 MeV/G, then increased more slowly with L* beyond that. PSD where μ = 400 MeV/G increased from 1 x10-6 to ~1.2 x10-5 (c/cm/MeV)3 at 3 < L* < 4. At L* > 4, PSD slowly increased with increasing L* from ~1.2 x10-5 to 1.3 x10-5

323 (c/cm/MeV)3. PSD at μ = 900 MeV/G increased rapidly from ~ 1.0 x10-7 to 1.6 x10-6

324 (c/cm/MeV)3 between 3 < L* < 4.2, PSD was approximately constant between 4.2 < L* < 5, and

325 at L* > 6 PSD was between 1.4 x10-6 and 1.0 x10 -6 (c/cm/MeV)3, indicating that PSD

326 decreased at high L*. The LCDS was beyond L* of 7, so was not plotted for this time period.

327   When the first interplanetary shock reached the magnetosphere, the location of spacecraft

328 measurements in L* increased briefly, this indicated that drift paths of electrons moved

329 Earthwards with respect to spacecraft orbits (Figure 2; red line). There were no large changes to

330 the PSD distribution in L* for μ = 900 MeV/G, however the PSD of the 400 MeV/G population

331 doubled. As L* returned to the pre-shock location, the increased PSD returned to the level prior

332 to the interplanetary shock arrival. Simultaneously the LCDS moved inwards to 6.3 L*.

333 When the first CME ejecta reached the magnetosphere at 06:50 UT on 07 September, the LCDS

334 moved inwards to L* ~ 6. PSD decreased across all μ, though these decreases in PSD were not

335 uniform across L* and energies. PSD of the μ = 400 MeV/G population decreased by half

336 between 4 < L* < 5, and by a factor of ~3 at L* >5. PSD of electrons with μ = 900 MeV/G

337 decreased by a factor of ~5 between 4 < L* < 5 and decreased by a factor of ~3 between 3 < L*

338 < 5.

339   The second interplanetary shock arrived during the third CME ejecta. In response, the

340 LCDS was compressed to L* = 3.8 for 2 hours. The PSD at L* > 3.8 could therefore not be

341 expressed in adiabatic coordinates during this time, so we assume these particles no longer

342 followed closed drift paths. At locations within the LCDS, the location of spacecraft

343 measurements in L* decreased. PSD at a given L* did not change significantly for μ = 900

344 MeV/G during this time period. PSD where μ = 400 MeV/G increased by a factor of ~2 at L* >

345 3.2 compared to corresponding measurements prior to the compression.

346   During the interval between the second and third CME ejecta, the LCDS expanded to

347 higher L* of ~ 5.5. In tandem, the location of spacecraft measurements in L* moved outwards

348 (so electron drift paths move inwards with respect to spacecraft orbits). Initially there was little

349 to no change in PSD for μ = 400 MeV/G at a given L*, then PSD increased by a factor of 10

350 over the interval for L* ~ 4. At both μ = 900 MeV/G, PSD decreased by a factor of 10 compared

351 to PSD prior interplanetary shock arrived. Through the remainder of the interval PSD increased

352 by a factor of ~10 at L* ~ 4. Note that for both μ, the latter increase in PSD is limited to L*~4,

353 and PSD at L* > 4 did not increase.

354   Upon the arrival of the third CME ejecta, the LCDS was compressed a second time to L*

355 = 4.4. Simultaneously, PSD at both μ increased by a factor of 10 at L* = 3.6, and PSD decreased

356 with increasing L*. As the LCDS began to expand outwards in L*, PSD began to increase at all

357 L*. When the fourth CME ejecta arrived, the LCDS continued to expand to higher L*, and PSD

358 universally increased at all L* and μ plotted.

359

360

361

362
363 **Figure 3:** PSD profiles in L* for μ of 400 MeV/G (top row) and 900 MeV/G (bottom row) with

364 K = 0.1 G0.5RE. Each column (a-d) shows a single hour time period through different phases of

365 the storm. Symbol colors indicate when measurements were taken within the hour period. Dotted

366 lines show the minimum and maximum L* of the LCDS.

367

368   In order to evaluate whether the Turner et al. (2012) representation of magnetopause

369 shadowing in PSD profiles is accurate for this storm, we selected four different 1-hour time

370 periods throughout the September 2017 storm and created PSD profiles in L*, shown in Figure 4.

371 We selected time periods by considering the phase of the storm (i.e., pre storm, net-loss, or net-

372 acceleration), the data availability of PSD measurements, and whether there were coinciding

373 magnetopause measurements to define the outer boundary. The four time periods correspond to

374 (a) pre-storm, (b) first compressive phase, (b) net-loss phase, and (c) second compressive/net-

375 acceleration phase. Within the hour time periods 15-minute intervals are identified by symbol

376 color so that changes to PSD and the LCDS within the hour can be identified. To give the four 1-

377 hour time periods in the context of the storm as a whole, the time intervals are indicated by black

378 triangles in Figure 2.

379   Prior to the arrival of the first interplanetary shock, Figure 3a shows PSD at both μ

380 increased rapidly between 3 < L* < 4.2. Where μ = 400 MeV/G, PSD continued to increase with

381 increasing L*, reaching maximum measurement of 1.8 x10-5 (c/cm/MeV)3 at L*= 7.4. Where μ

382 = 900 MeV/G the maximum measured PSD was 1.0x10-5 (c/cm/MeV)3 at L* = 4.2, and PSD

383 decreased slightly with increasing L*. During this period, the LCDS was located at L* > 8.

384   During the first compression phase (Figure 3b) the LCDS was located at L* = 5 L at the

385 beginning of the hour, then is further compressed to L* = 3.8 by the end of the interval. PSD

386 profiles at all μ show a clear difference between the first half hour of the interval and the latter

387 half. In the first half hour, PSD at all μ values had a positive gradient with increasing L*, and

388 PSD was measured at a maximum near the maximum LCDS for the interval. In the latter half

389 hour PSD measurements are limited to L* < 3.8. For μ = 900 MeV/G, PSD was measured within

390 the minimum LCDS and was similar to the first half hour. PSD where μ = 400 MeV/G was also

391 measured within the minimum LCDS but increased by a factor > 2 through the half hour.

392   During the net-loss phase (Figure 3c) the LCDS was located at L*~ 5.7 and remained

393   there throughout the interval. Measurements taken through the hour were co-located indicating

394   no substantial changes in PSD profiles through the interval. For both μ, the PSD peaked at L* =

395   3.8, which was the location of minimum LCDS during the compressive phase. PSD had also

396   increased by a factor of 10 or more for L* < 3.8. At L* > 3.8, PSD where μ = 400 MeV/G PSD

397   had a negative gradient with increasing L* until L* = 4.2, and PSD measurements taken by

398   GOES at L* = 5.5 were similar values to those at L* = 4.2. PSD where μ = 900 MeV/G had a

399   strong negative gradient with increasing L* > 3.8. PSD distributions presented during this net-

400   loss phase are characteristic of direct electron losses at L* > 3.8, and subsequent radial diffusion

401   after the magnetopause expanded.

402   During the secondary compression phase (Figure 3d) the LCDS was compressed at L* =

403   4.4 towards the beginning of the phase and expanded slightly to L* = 4.8 by the end of the hour.

404   PSD measurements taken throughout the hour were the constant for a given L*, showing that

405   there were no substantial changes to PSD within the hour. For both μ there were peaks in PSD at

406   L* = 3.7 with an increased PSD compared all previous intervals (Figure 3a-c). PSD at L* < 3.7

407   also increased by a factor ≥ 10 compared to the previous net-loss interval (Figure 3c) at both μ.

408   This growing peak in PSD, and increased PSD at lower L*, indicates localized electron

409   acceleration processes occurring at L* = 3.7, with radial diffusion of electrons away from this

410   location. PSD at L* > 3.7 shows that there was a strong negative gradient as PSD decreased

411   rapidly with increasing L* for both μ. PSD at these higher L* largely did not change compared

412   to the previous net-loss interval, though there were few measurements for comparison at

413   common L* between the two intervals. At L* > 4 PSD universally decreased during the second

414   compression compared to the pre-storm phase; for μ = 400 MeV/G, PSD was up to 10 times less

415   than the pre-storm interval, for μ = 900 MeV/G PSD was up to 1000 times less than the pre-

416   storm interval. In other words, despite the fact that the secondary compression phase lies within

417   the acceleration phase of this geomagnetic storm, losses at L* > 4 mean that the PSD was not

418   replenished to its pre-storm values.

419

4 Discussion

421   We presented an overview of the outer electron radiation belt response to a sequence of
422   interacting CMEs and interplanetary shocks propagating through the solar wind in early
423   September 2017. We used multi-mission, multi-spacecraft observations of both electron flux and
424   phase space density to evaluate the role of magnetopause shadowing in producing changes to
425   electron flux during this event.

426   Between 7 - 10 September there were two interplanetary shocks and four separate CME
427   ejecta propagating through the solar wind. As the solar wind characteristics of this event have
428   already been studied in detail (e.g., Scolini et al., 2020; Shen et al., 2018; Werner et al., 2019),
429   we do not analyze these in detail, instead focusing on the relativistic electron response to these
430   drivers. There was a complex response in electron flux at 0.8 MeV and/or 2.0 MeV energies
431   corresponding to each interplanetary shock or CME ejecta. Most of these flux changes
432   corresponded to changes in measurements of phase space density, indicating that the electron
433   flux response to solar wind driving were largely due to non-adiabatic processes.

434   Not all changes in electron flux were due do non-adiabatic processes. Specifically, in
435   response to the second interplanetary shock arrival, flux measured by GPS satellites decreased by
436   orders of magnitude at all L shells. Corresponding PSD measurements showed that, whilst
437   electrons were irreversibly lost at high L* where drift paths were intersected by the LCDS, there
438   were initially no changes to PSD measured below L* = 3.8. Instead, the location in L* at which
439   GPS satellites were measuring PSD changed, i.e., electron drift paths had moved radially
440   outwards with respect to GPS orbits. Therefore, GPS satellites measured a different part of the
441   PSD distribution, which appeared as a decrease in the measured electron flux on all L-shells.
442   This shows why it is important to consider electron measurements in adiabatic coordinates,
443   rather than flux alone.

444   We presented profiles of PSD in L* at four 1-hour time intervals in Figure 3, chosen to
445   correspond to the four intervals depicted in Figure 2 of Turner et al. (2012). The first interval
446   (Figure 3a) at 17:00 –18:00 UT on 6 September showed the pre-storm distribution of PSD which
447   constantly increased with increasing L* (μ = 400 MeV/G) or reached a peak PSD at L* = 4.2 (μ
448   = 900 MeV/G). The second interval (Figure 3b) showed PSD profiles during a high-pressure

449   phase at 23:00 UT 7 September to 00:00 UT 8 September, during which the magnetopause was

450   measured by geostationary satellites. The LCDS was compressed from L* = 5 to L* = 3.8 during

451   the hour. When the evolution of PSD within the hour was considered, we observed large scale

452   changes to PSD as the LCDS is compressed. Electrons outside of the LCDS are no longer

453   trapped and PSD within the LCDS in the latter half of the hour is distinctly different the pervious

454   half hour for μ = 400 MeV/G. If we were to assume that the PSD did not change within an hour

455   timescale, then these observations would be interpreted as false peaks or troughs in the PSD.

456   These false peaks and troughs are produced by the dynamics of the system rather than non-

457   adiabatic acceleration or loss processes. The third time period (Figure 3c) at 08:00 – 09:00 UT 8

458   September corresponded to the net-loss phase during the storm main phase. The magnetopause

459   and LCDS had expanded outwards and there were dropouts in both electron flux at all L, and

460   PSD at L* > 3.8. PSD profiles at all μ peaked at L* = 3.8, had increased slightly at L* < 3.8, and

461   had decreased by orders of magnitude at L* > 3.8. This was consistent with electron loss due to

462   direct magnetopause shadowing, followed by a redistribution of electrons via radial diffusion.

463   The first three intervals (Figure 3a-c) correspond remarkably well to the PSD dynamics

464   discussed by Turner et al. (2012), despite the complexity of the external solar drivers during our

465   chosen case study.

466   The fourth interval (Figure 3d) does not correspond directly to the schematic in the

467   Turner et al. (2012) study but instead corresponds to a secondary compression of the

468   magnetosphere during the net acceleration phase between 14:00 – 15:00 UT 8 September.

469   During this hour the magnetopause was compressed within geostationary orbit, and the LCDS

470   was compressed to L* = 4.4. At all μ PSD increased for all L*, and there was a clear growing

471   peak in PSD at L* = 3.7 compared to the previous time period, with strong PSD gradients across

472   L*. This is characteristic of a localized non-adiabatic acceleration process, likely due to resonant

473   VLF wave-particle interactions, combined with radial diffusion redistributing electrons down

474   PSD gradients (inwards for L*<3.7 and outwards for L*>3.7), thus increasing PSD at any given

475   L*. Furthermore, we note characteristics which suggest indirect magnetopause shadowing;

476   strong negative gradients in PSD towards the compressed LCDS means that radial diffusion will

477   transport particles towards the LCDS, where they will be subsequently lost. This final interval

478   (Figure 3d) corresponds well to the PSD dynamics during indirect magnetopause shadowing

479   discussed by Loto'aniu et al. (2010).

480   In order to understand how radial diffusion will have acted upon the electron populations

481   shown in Figure 3, we use Van Allen Probe electric and magnetic field measurements to analyze

482   power of field fluctuations. We used in-situ magnetic field observations from the Van Allen

483   probe EMFISIS instrument (Kletzing et al., 2013) and electric field observations from the EFW

484   instruments (Wygant et al., 2013). The magnetic and electric field measurements had a time

485   resolution of 4 seconds. The background magnetic and electric fields were identified by taking a

486   running average over a 20-minute sliding window, and the background fields were then

487   subtracted from the instantaneous measurement. To identify fluctuations, the residual field

488   observations were transformed into a magnetic field-aligned coordinate system, defined by the

489   background magnetic field unit vector (parallel component), the geocentric position vector

490   (azimuthal component), and the poloidal direction. In this transformed coordinate system, the

491   parallel magnetic field perturbation and azimuthal electric field perturbation were selected to

492   estimate the associated power spectral densities using a Morlet wavelet transform. The power

493   spectral density was limited to a frequency range of 1-15 mHz (corresponding to the ULF wave

494   band (Jacobs et al., 1964) and an L-range of $3 < L < 7.5$ as field perturbations cannot be reliably

495   distinguished from the changing background field near orbital perigee.

496   Figure 4 shows the power spectral density of the magnetic field PB (green) and electric

497   field PE (pink) as a function of L^* for the 4 previously specified 1-hour time periods. Magnetic

498   power spectral density is substantially enhanced at an increasing rate through the geomagnetic

499   storm (Figure 4, panels b - d) compared to the pre-storm time period (Figure 4a). Due to data

500   gaps in electric field measurements (associated with spacecraft charging and eclipse events), the

501   number of electric field power spectral density measurements is variable throughout the storm,

502   making it difficult to make comparisons between the four intervals (e.g., Figures 4 a&d).

503   However, during the first compressive phase (Figure 4b), PE appears high with comparable, or

504   greater, magnitudes to PB for corresponding L^*. During the net-loss phase (Figure 4c), PE

505   decreased compared to the previous compressive phase, and was less than PB at all L^*. During

506   the second compressive phase (Figure 4d), there was only one measurement of PE at $L^*=3.7$,

507   which was increased compared to the previous net loss phase (Figure 4c). Some of the

508   differences between the way in which PE evolved through the intervals compared to PB may be

509   due to changes in substorm activity affecting electric potential measured by the Van Allen

510   Probes. Auroral geomagnetic indices (not shown) indicate enhanced substorm activity during this

511   interval, which will produce fluctuations in electric potential in the magnetosphere, and thus

512   contribute towards the power spectral density of the electric field. It is therefore highly likely that

513   PE was enhanced during interval (d) in a similar manner to interval (b). Irrespective of this, the

514   overall rate of diffusion of the electrons is dependent on both the sum of the magnetic field and

515   electric potential fluctuations and the PSD gradient in L*. Therefore, we conclude that outwards

516   radial diffusion was enhanced for both intervals (c) and (d) as both periods have enhanced power

517   spectral densities, and sharp PSD gradients in L*.

518

519
520   **Figure 4:** Estimated magnetic field (green) and electric field (purple) power spectral densities

521   for (a) 17 - 18 UT 6th Sept, (b) 23 UT 7th - 00 UT 8th, (c) 08 – 09 UT 8th, and (d) 14 - 15 UT

522   8th. Each panel shows the power spectral density, summed over a frequency range of 1 to 15

523   mHz, plotted as a function of the L* value. Observations from both Probe A and Probe B are

524   included.

525

526   Unfortunately, without knowing the number of particles accelerated during the local

527   acceleration, we cannot measure the number of particles lost via indirect shadowing to evaluate

528   the respective contributions of indirect and indirect shadowing to overall electron loss. The

529   contributions of each mechanism could instead be estimated by replicating this event with a

530   Finally, we acknowledge possible limitations to this work, specifically the magnetic field

531   model used as it is known to influence calculations of the adiabatic invariants and LCDS (e.g.,

532   Albert et al., 2018). The T01s model was chosen for this work due to its suitability during

533   geomagnetic storm conditions, but different magnetic field models may yield different results.

534   Furthermore, the LCDS may be calculated by either considering Shabansky drift orbits as closed

535   drift paths, whereas other calculations consider these bifurcating orbits as open (Öztürk & Wolf,

536   2007; Shabansky, 1971). In this work, we have used the last non-bifurcated drift shell as the

537   LCDS, which could give an underestimation of the outer boundary to trapped electrons if these

538   electrons following bifurcated orbits return to the radiation belts following the compression.

539

540   **5 Summary**

541   We used multi-point electron phase space density measurements with unprecedented

542   temporal and spatial resolution to analyze magnetopause shadowing in the outer radiation belt

543   during the early September 2017 geomagnetic storm. The September 2017 storm is driven by a

544   set of complex solar wind features, due to four interacting CMEs, with an equally complex

545   radiation belt response.

546   Analysis of PSD demonstrated the capabilities of multi-spacecraft measurements to identify

547   and isolate energization and loss processes with extremely high spatial and temporal resolution:

548

549   • By comparing PSD to flux measurements we identified adiabatic transport of electrons

550   during the event, highlighting the importance of considering adiabatic coordinates to

551   interpret flux changes during geomagnetic storms.

552   • The event exhibited both similarities and differences to the Turner et al. (2012)

553   description of an electron flux dropout. Whereas the first compression of the

554   magnetopause showed the expected PSD responses to direct shadowing, local

555   acceleration and additional shadowing by subsequent solar wind structures led to

556   deviations from the Turner et al. (2012) predictions.

557   • We highlighted the importance of indirect magnetopause shadowing on radiation belt

558   dynamics. Analysis of PSD and ULF wave activity showed signatures of indirect

559   magnetopause shadowing, as described by Loto'aniu et al. (2010).
