Abstract

The paper presents observations of gravity wave-induced temperature disturbances in the Martian atmosphere obtained with the mid-infrared (MIR) spectrometer, a channel of the Atmospheric Chemistry Suite instrument on board the Trace Gas Orbiter (ACS/TGO). Solar occultation measurements of a CO2 absorption band at 2.7 µm were used for retrieving density and temperature profiles between heights of 20 and 160 km with vertical resolution sufficient for deriving small-scale structures associated with gravity waves. Several techniques for distinguishing disturbances from the background temperature have been explored and compared. Instantaneous temperature profiles, amplitudes of wave packets and potential energy have been determined. Horizontal momentum fluxes and associated wave drag have been estimated. The analyzed data set of 144 profiles encompasses the measurements made over the second half of Martian Year 34, from the Solar longitude 165* through 355*. We observe enhanced gravity wave dissipation/breaking in the mesopause region of 100-130 km. Our analysis shows no direct correlation between the wave amplitude and Brunt-Vaisala frequency. It may indicate that convective instability may not be the main mechanism limiting gravity wave growth in the middle atmosphere of Mars.

20 Abstract

The paper presents observations of gravity wave-induced temperature disturbances in 21 the Martian atmosphere obtained with the mid-infrared (MIR) spectrometer, a chan-22 nel of the Atmospheric Chemistry Suite instrument on board the Trace Gas Orbiter (ACS/TGO). 23 Solar occultation measurements of a CO_2 absorption band at 2.7 μ m were used for re-24 trieving density and temperature profiles between heights of 20 and 160 km with ver-25 tical resolution sufficient for deriving small-scale structures associated with gravity waves. 26 Several techniques for distinguishing disturbances from the background temperature have 27 been explored and compared. Instantaneous temperature profiles, amplitudes of wave 28 packets and potential energy have been determined. Horizontal momentum fluxes and 29 associated wave drag have been estimated. The analyzed data set of 144 profiles encom-30 passes the measurements made over the second half of Martian Year 34, from the So-31 lar longitude 165° through 355°. We observe enhanced gravity wave dissipation/breaking 32 in the mesopause region of 100-130 km. Our analysis shows no direct correlation between 33 the wave amplitude and Brunt-Väisälä frequency. It may indicate that convective insta-34 bility may not be the main mechanism limiting gravity wave growth in the middle at-35 mosphere of Mars. 36

³⁷ Plain Language Summary

Gravity waves (GWs) of lower atmospheric origin continuously disturb the Mar-38 tian atmosphere. While propagating upward, their amplitudes grow and eventually GWs 39 break up or dissipate. The deposited momentum and energy are the major mechanisms 40 driving the circulation in the thermosphere above 100 km. Since spatial scales of GWs 41 are relatively small, they are difficult to measure. Atmospheric Chemistry Suite (ACS) 42 instrument on board the ExoMars Trace Gas Orbiter allows for extracting altitude pro-43 files of density and temperature from the troposphere to the thermosphere (20-160 km)44 with high vertical resolution, around 2 km. The instrument measures the solar spectrum 45 occulted by the atmosphere with the carbon dioxide absorption in the middle infrared 46 wavelength range. The observations provide latitudinal and seasonal coverage of the GW 47 activity and its characterization on Mars. Our results allow for the first observational 48 validation of model predictions, quantifying dynamical effects of GWs and constraining 49 Martian general circulation models. 50

51 **1 Introduction**

The structure and circulation of planetary atmospheres are strongly affected by grav-52 ity waves (GWs), which are ubiquitous in any convectively stable atmosphere. They are 53 primarily responsible for energy and momentum transfer from the lower to the upper at-54 mosphere. Historically, GW-induced coupling was extensively studied in Earth's atmo-55 sphere (e.g., see reviews by Fritts & Alexander, 2003; Yiğit & Medvedev, 2015). With 56 the progress in space exploration, the atmosphere of Mars has become the second best-57 studied example. Numerous space missions accompanied by numerical modeling have 58 delivered ample evidence for the importance of GWs on Mars. Some of the Martian GW 59 effects, their commonality and specifics with those on Earth, have been summarized in 60 the recent review by Medvedev and Yiğit (2019). Observational knowledge of GW ac-61 tivity on Mars is crucial but still insufficient for quantifying their effects and constrain-62 ing Martian general circulation models (MGCMs). Our paper addresses this problem by 63 utilizing high-resolution occultation data obtained from the Atmospheric Chemistry Suite 64 (ACS) instrument on board the Trace Gas Orbiter (TGO). 65

Observations of the Martian GWs have been conducted from orbiters by different
 remote sensing techniques and in situ methods. In situ measurements of GW-induced
 density fluctuations in the thermosphere were performed with accelerometers during aer obraking operations by several spacecraft including Mars Global Surveyor (MGS), Mars

Odyssev (ODY), Mars Reconnaissance Orbiter (MRO), Mars Atmosphere and Volatile 70 EvolutioN (MAVEN) and Trace Gas Orbiter (TGO) (Keating et al., 1998; Creasey et 71 al., 2006a; Fritts et al., 2006; R. H. Tolson et al., 2005; R. Tolson et al., 2008; Withers, 72 2006; Jesch et al., 2019; Vals et al., 2019; Siddle et al., 2020). GWs in the upper ther-73 mosphere were also measured by Neutral Gas and Ion Mass Spectrometer (NGIMS) on 74 board MAVEN (Yiğit et al., 2015; England et al., 2017; Terada et al., 2017). Temper-75 ature and density disturbances associated with GWs have been remotely retrieved from 76 stellar, solar and radio occultation data as well as from limb observations (Hinson et al., 77 1999; Creasey et al., 2006b; Ando et al., 2012; Wright, 2012; Heavens et al., 2020; Nak-78 agawa et al., 2020). 79

The shortcoming of many previous GW observation techniques is their limited al-80 titude coverage. For example, in situ measurements were confined to a relatively nar-81 row vertical range in the thermosphere, while radio occultation and infrared limb sound-82 ing allowed for studying the lowermost (0-40 km) part of the atmosphere. Remote sens-83 ing in UV permitted the extension of the altitude coverage. The Spectroscopy for the 84 Investigation of the Characteristics of the Atmosphere of Mars (SPICAM) instrument 85 on board Mars Express (MEX) measured temperature and density profiles between 60 86 and 130 km (Forget et al., 2009). The Imaging Ultraviolet Spectrograph (IUVS) on board 87 MAVEN explored the thermospheric layers (100-150 km) (Medvedev et al., 2016; Gröller 88 et al., 2018). Recently, Nakagawa et al. (2020) obtained temperature profiles from IUVS 89 data spanning the atmosphere from 20 to 140 km with a vertical sampling better than 90 6 km. ACS/TGO is the first IR instrument that allows for measuring in the solar oc-91 cultation mode temperature and density distributions within an even broader range of 92 altitudes (20-160 km). Since April 2018, the Middle InfraRed (MIR) spectrometer, one 93 of the three spectrometers of ACS, delivered several hundreds of profiles, some of which 94 having vertical resolution allowing for the study of GWs. 95

Smaller-scale GW-induced temperature perturbations have to be first separated 96 from the background temperature field associated with the large-scale variations. Although 97 this procedure has been frequently performed in the terrestrial and Martian context, there 98 is no universal technique that can be applied to vertical profiles obtained from different 99 instruments (Ehard et al., 2015). In this work, we explore the sensitivity of several meth-100 ods for extracting GWs from the ACS MIR data and describe their applications for de-101 riving various characteristics of the GW field (amplitudes, wave potential energy, mo-102 mentum fluxes and wave drag) from the first available set of ACS/TGO data. 103

The paper is structured as follows. The ACS/TGO experiment and the instrument 104 itself are outlined in Section 2. Section 3 describes the methods used in this study. In 105 particular, retrievals of temperature profiles from measured spectra are presented in sec-106 tion 3.1, the techniques for extracting wave disturbances are given in section 3.2. Sub-107 section 3.3 describes the derivation of wave activity (amplitude of wave packets) and po-108 tential energy, and 3.4 outlines the calculation of the absolute vertical flux of horizon-109 tal momentum and momentum forcing of the mean flow. The results are presented in 110 section 4. They include a case study (4.1), the spatial distribution of wave characteris-111 tics (4.2), and the relationship between wave amplitudes and the Brunt-Väisälä frequency 112 (4.3). Conclusions are given in section 5. 113

Atmospheric Chemistry Suite Instrument on Board Trace Gas Or biter

ACS is a set of three infrared spectrometers for ExoMars 2016 TGO mission. It has been operating in the Martian orbit since April 2018. ACS consists of the near-(NIR), middle-(MIR) and thermal-infrared (TIRVIM) channels, that altogether cover the broad spectral range of $0.7-17\mu$ m. (Korablev et al., 2018). In this paper, we use the data retrieved from the cross-dispersion echelle MIR spectrometer working in the solar occul-

tation mode in the 2.3-4.2 μ m range. This spectral coverage is achieved with a secondary 121 dispersion grating, which can be rotated to one of 12 positions. During an occultation, 122 the instrument is pointed to the Sun. Each measurement consists of an image at the $640 \times$ 123 512 pixels focal plane array (FPA), which accommodates up to 20 diffraction orders dis-124 persed over FPA by the secondary grating. One occultation covers 0.15-0.3 μ m range. 125 The instrument's resolving power is $\lambda/\Delta\lambda \sim 25\ 000$ and the signal-to-noise ratio varies 126 between 1000 and 10000. The vertical resolution of MIR depends on the integration time 127 $(\sim 2 \text{ s per image})$ and ranges from 0.5 to 2.5 km. The transmission is obtained by divi-128 sion of the solar spectrum passed through the atmosphere to the reference one, which 129 is measured above the altitude of 200 km, where the absorption by the atmosphere is 130 negligible. 131

132 133 In this study, we use the 2.66-2.68 μ m portion of the spectrum from the grating position #4, the echelle diffraction order #223, which includes a wing of the 2.7 μ m CO₂ absorption band (Figure 1a). Strong absorption lines of CO₂ allow for retrieving tem-

Spectroscopy of CO_2 and H_2O absorption in the diffraction order #223 of ACS-MIR (panel A) and an example of retrieved atmospheric temperature and density vertical profiles (panel B). a) Transmission spectra measured at tangent altitudes of 150, 90 and 29 km (red dots) on a background of the best-fitted models (black solid lines); b) Vertical profiles of temperature (left) and atmospheric number density (right) derived from the MCD (black dashed line), from ACS-MIR (red dots), and from ACS-NIR (Fedorova et al., 2020) (green dots). Error bars for the temperature values express 1- σ uncertainties of the retrievals.

perature and density in the Martian atmosphere with good sensitivity.

136 3 Methods

137

134

3.1 Retrieval of Temperature Profiles

The retrieval scheme consists of several iterations. On the first step, we retrieve temperature and pressure from the rotational structure of CO₂ absorption bands in spectral intervals without H₂O lines (see Figure 1a). A priori altitude profiles of T(z) and p(z) as well as one of the CO₂ VMR, are taken from the Mars Climate Database (MCD)

for a specified occultation in MY34 (Millour et al., 2018). On the second step, we simul-142 taneously retrieve temperature and CO_2 concentration, while the pressure profile is kept 143 constant assuming the hydrostatic equilibrium $p_{hyd}(z) = p_0(z_0) \exp\left[-\int_{z_0}^z \frac{g(z')M(z')}{RT(z')} dz'\right]$, 144 where g is the acceleration of gravity, M is the atmospheric molar mass and R is the gas 145 constant. The reference pressure p_0 is chosen at an altitude z_0 , usually around 30-50 km, 146 where uncertainties of the fitting are smallest. We repeat the second step 5-7 times un-147 til the profiles reach convergence. In each iteration, we apply the Tikhonov regulariza-148 tion (Tikhonov & Arsenin, 1977) for the temperature and concentration altitude pro-149 files with a smoothing coefficient less than 5 km. It defines the shortest wavelength to 150 5-6 km when analyzing vertical wavy structures. The third step focuses only on CO_2 and 151 H_2O concentration retrievals over the entire wavenumber range in order #223 (Figure 1a) 152 using the p(z) and T(z) profiles already found. This step is not a subject of the present 153 paper. 154

A similar fitting procedure, including the hydrostatic approximation, has been used 155 in the work by Fedorova et al. (2020) (proprietary code) and Alday et al. (2019) (the NEME-156 SIS code, (Irwin et al., 2008)) in their retrievals of temperature and pressure from the 157 ACS data. We validated our atmospheric temperature and number density profiles with 158 simultaneous and collocated occultation measurements by ACS-NIR (Fedorova et al., 2020). 159 An example comparison is presented in Figure 1b. A weaker CO_2 absorption band at 160 1.58 μm measured by NIR allows for detection up to 110-120 km, or the density of ~ 161 10^{12} cm⁻³, while the band at 2.7 μ m observed by MIR is measurable up to 160-170 km, 162 or $\sim 10^9$ cm⁻³. The lowermost altitude of the temperature profile retrieval is conditioned 163 by the aerosol opacity and by the saturation of the CO_2 absorption lines. 164

Each temperature value in a vertical profile was retrieved by fitting a modeled transmission spectrum J_{mod} to the measured one J_{mes} at a specified altitude. We model the spectra by the Beer–Lambert law

$$J_{mod}(\nu, z) = \exp\left[-\int (\sigma_{CO2}(T, p)n_{CO2}(z') + \sigma_{H2O}(T, p)n_{H2O}(z') + \tau_a)dz'\right], \quad (1)$$

where n(z) are gaseous concentrations, $\sigma(T, p)$ are absorption cross-sections of CO₂ and 168 H_2O correspondingly for specific temperature T(z) and pressure p(z) at an altitude z, 169 and τ_a is aerosol slant opacity. A transfer between the linear $[\text{cm}^{-2}]$ and the volume $[\text{cm}^{-3}]$ 170 concentrations is performed using the well-known "onion-peeling" method with the nu-171 meric integration over all altitude layers z_i above the i-th one. Molecular cross-sections 172 are calculated line-by-line on a basis of the HITRAN2016 database (Gordon et al., 2017) 173 considering pressure-broadening coefficients of the H₂O lines suitable for a CO₂-rich at-174 mosphere (Gamache et al., 2016) and self-broadening in the case of CO_2 . Then we con-175 volve the modeled spectrum by the previously determined instrument line shape (ILS) 176 using wavenumber calibrations (see details in Alday et al., 2019). The fitting procedure 177 is conducted by minimizing the "chi-square" function 178

 $\chi^2 = \sum_i A^2(\nu_i), A(\nu_i) = [J_{mod}(\nu_i) - J_{mes}(\nu_i)]/\delta J, \text{ where } \delta J \text{ are transmittance uncer$ tainties, and the sum is taken over all considered spectral points (pixels). Our optimiza $tion algorithm to search for the <math>\chi^2$ minimum is based on partial derivatives of the Jacobian matrix $\partial A/\partial X$ (Marquardt, 1963), where X is a vector of free parameters, i.e., temperature, CO₂ concentration, H₂O mixing ratio, and aerosol slant opacity. Here, a significant contribution to the Jacobian comes from the rotational absorption lines, which are strongly sensitive to the temperature variability in the spectral range of interest.

3.2 Derivation of Wave Disturbances

Gravity wave-induced perturbations of temperature T' are sought by separating the mean, or background profile $\overline{T}(z)$ from the measured one T(z):

$$T' = T - \overline{T},\tag{2}$$

where the bar denotes an appropriate averaging. Generally, it implies averaging over wave phases, or spatial and temporal scales that are larger than the periods and wavelengths of contributing GW harmonics. In the case of almost instantaneous (with respect to the periods of GWs) occultation profiles, only separation in vertical scales is possible.

John and Kumar (2013) and Ehard et al. (2015) reviewed several common meth-193 ods of the partition of measured temperature and/or density profiles into the "mean" 194 and wave components. They work well if a clear separation in vertical wavelengths does 195 exist between GWs and large-scale motions belonging to the background. This is not al-196 197 ways the case in the Martian atmosphere, because vertical scales of disturbances associated with tides, planetary waves, and other motions may overlap with those due to GWs. 198 It is desirable to retain the former in the background, but one still has to set a vertical 199 scale Λ_z that separates GWs from the larger-scale features. In the following, we assumed 200 $\Lambda_z = 30$ km. This value may lead to an overestimation of the retrieved wave activity 201 by including non-GW perturbations, but at least no large-scale GW components are missed. 202 Concerning the short-wavelength part of the spectrum, the limited vertical resolution 203 favors detection of larger-scale waves, leaving out harmonics with smaller scales unobserved. Alexander (1998) has quantified this "observational filter" and pointed out that 205 some large-scale harmonics refracted by the mean wind beyond the lowest resolution may 206 be missing in observations as well. 207

We explore three methods: spectral filtering, sliding least-square polynomial fit and 208 high-order polynomial fit. The former two have been discussed in relation to lidar and 209 space-based measurements in the atmosphere of Earth (John & Kumar, 2013; Ehard et 210 al., 2015, and the references therein), while the latter was applied to profiles obtained 211 in the terrestrial (e.g., Spiga et al., 2008) and Martian atmosphere (Yiğit et al., 2015; 212 Terada et al., 2017; Jesch et al., 2019). Since the ACS data are distributed irregularly 213 over the altitude, they were first interpolated (oversampled) to an evenly spaced 500-m 214 grid. We used only the temperature data with errors <10 K. Spectral filtering was per-215 formed using Fourier decomposition within sliding 60-km intervals (± 30 km around each 216 point), and zero-order Fourier coefficients were used to calculate the background tem-217 perature. The examples are shown in Figure 2 for two characteristic profiles T(z). They 218 visibly differ: the profile in Figure 2a (orbit 2892n1) contains large-scale disturbances, 219 while the one in Figure 2c (orbit 3251n1) comprises mostly smaller-scale fluctuations. 220 This method yields smooth mean temperature profiles and, as a result, large deviations 221 from the mean (Figure 2b and d). This is in particular obvious below 60 km and in the 222 upper part of the domain (panels b and d). 223

For the sliding polynomial fit, we used a procedure described in the work of Whiteway 224 and Carswell (1995). The background profiles are obtained by fitting cubic polynomi-225 als within the 60-km sliding intervals. Observational errors were used as weights, that 226 assign a significance to the measurements at each altitude. At first, the intervals were 227 shifted up from the bottom to top by a certain distance (shown in Figure 2a and c for 228 2 and 11 km), and then the procedure was repeated for the downward shifts starting from 229 the top. The overlapping values of fits from each range were then averaged. Thus ob-230 tained profiles were then smoothed using a moving average. At the bottom of the pro-231 files, we had to decrease the width of the sliding windows due to large spurious varia-232 tions in fitted polynomials and in order to make most of the observational data. The up-233 per and lower 4 km of thus obtained profiles have to be excluded anyway, because of the 234 poor behavior of fitting polynomials, which cannot be averaged with counterparts from 235 other sliding windows. This method occasionally produces disturbances oscillating not 236 around zero. To correct for these numerical biases, we perform detrending by applying 237 the Theil-Sen estimator (Theil, 1950; Sen, 1968) and fitting a linear function to the per-238 turbation profile. The Theil-Sen estimator is a robust method, which is used for deter-239 mining the linear regression taking the median of the slopes of all lines that can be drawn 240

through the given dataset. The linear function is then subtracted from the profile to ob-241 tain the corrected temperature. 242

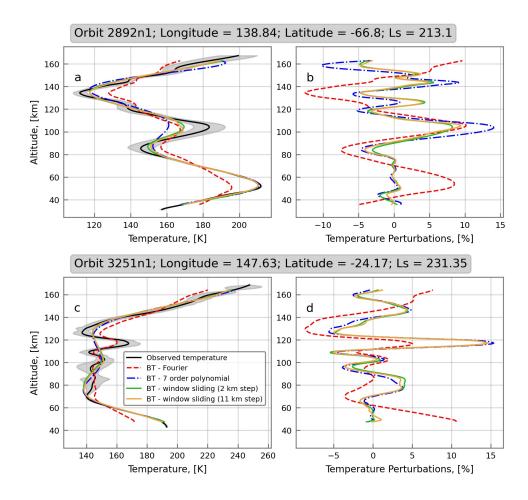

Figure 2. Separation of the observed temperature into the mean and wave components for two characteristic profiles: dominated by large vertical-scale (orbit 2892n1, upper row) and smallscale disturbances (orbit 3251n1, lower row). Left column is for the mean temperature $\overline{T}(z)$, the right one is for the relative perturbations $T'(z)/\bar{T}(z)$ (in percent). The legend describes the applied methods. Red dashed lines correspond to the Fourier decomposition, green and yellow lines are for the sliding polynomial fit with 2-km and 11-km shift steps, correspondingly, and the blue lines are for the 7-th order polynomial fit. The observed temperature profiles are given with the solid black lines. Shaded area denotes the uncertainty of the measurements.

The results for the sliding polynomial fit are plotted in Figure 2 for the 2 and 11 243 km shift steps with green and yellow lines, correspondingly. It is seen that they are very 244 close and, thus, the background and disturbances depend on the sliding step to a minor 245 degree. The method shows some useful features in comparison with spectral filtering. 246 The fitted mean curves in the regions of large-scale disturbances (Case 1) follow the ob-247 served temperature profiles closer (Figure 2a) and are smoother where small-scale struc-248 ture dominates (Case 2) (Figure 2c, between 70 and 130 km). This produces smaller wave 249 amplitudes in Case 1, and reveals more wavy structures in Case 2. Especially plausible 250 results are in the bottom of the profiles, where GWs are expected to have smaller am-251 plitudes (due to larger density). 252

We next explored the technique of fitting higher-order polynomials in the entire 253 interval of heights. In particular, the seventh-order polynomial fit, which was previously 254 used for extracting GWs on Mars (Yiğit et al., 2015; Jesch et al., 2019), produces most 255 plausible results. They are presented in Figure 2 with dashed and dotted blue lines. It 256 is immediately seen that thus obtained wave disturbances are in a very good agreement 257 with those derived by the sliding polynomial fit method, especially for profiles contain-258 ing small-scale features (Figure 2d). For profiles dominated by large-scale perturbations, 259 the agreement is also good in terms of the determined vertical structure of the wave, al-260 though the magnitudes are often exaggerated (Figure 2b). The weak point of the method 261 is that it occasionally produces spurious disturbances near the edges of the vertical do-262 main with vertical gradients of the mean temperature directed opposite to the measured 263 profiles. After careful consideration of the three methods applied to the available mea-264 surements, we selected the sliding third-order polynomial fit as the most appropriate and 265 robust. 266

3.3 Wave Activity and Potential Energy

The GW field is often characterized by the magnitude of fluctuations $|T'| = (\overline{T'^2})^{1/2}$ and wave potential energy (per unit mass)

$$E_p = \frac{1}{2} \left(\frac{g}{N}\right)^2 \overline{\left(\frac{T'}{\overline{T}}\right)^2},\tag{3}$$

where N is the Brunt-Väisäla frequency

$$N = \sqrt{\frac{g}{\overline{T}} \left(\frac{d\overline{T}}{dz} + \frac{g}{c_p}\right)},\tag{4}$$

g is the acceleration of gravity and c_p is the specific heat capacity at constant pressure. 271 The amplitude of the wave packet at a given height |T'(z)| (hereafter called "wave ac-272 tivity") represents an envelope of the measured profile T'(z). We calculated it by per-273 forming Fourier decomposition in each sliding 60-km vertical interval and, based on Parce-274 val's identity, summing up contributions of all harmonics. Examples of thus obtained en-275 velopes and potential energy for the same selected profiles as in section 3.2 are presented 276 in Figure 3. Blue and red dashed lines denote the quantities calculated from the entire 277 spectrum and by accounting for contributions of only two largest harmonics. It is seen 278 that the neglect of shorter-scale harmonics, as was occasionally done in analyses of satel-279 lite observations (e.g., Ern et al., 2004), introduces little error to the estimated GW ac-280 tivity. However, the neglect of short-scale harmonics may lead to a noticeable underes-281 timation of wave potential energy, (cf. Figures 3b and d). 282

283

3.4 Momentum Flux and Momentum Deposition

Another useful characteristic of the GW field is the vertical flux of horizontal momentum, or "momentum flux" for brevity, $\mathbf{F} = (F_x, F_y, 0) = \rho_0(\overline{u'w'}, \overline{v'w'}, 0)$, where ρ_0 is the mean density and (u', v', w') are the components of wave-induced perturbations of wind velocity \mathbf{u}' along with the two horizontal and the vertical axis, correspondingly. Momentum flux is constant for conservatively propagating waves. Breaking/dissipating GWs deposit their momentum to the mean flow, thus inducing an acceleration or deceleration (depending on the sign) of the horizontal flow

$$(a_x, a_y) = -\frac{1}{\rho_0} \frac{d\mathbf{F}}{dz}.$$
(5)

The direction of the flux cannot be determined from the occultation measurements, however total (or absolute) momentum fluxes for a harmonic $F_{k,m} = \sqrt{F_{x,k,m}^2 + F_{y,k,m}^2}$ can

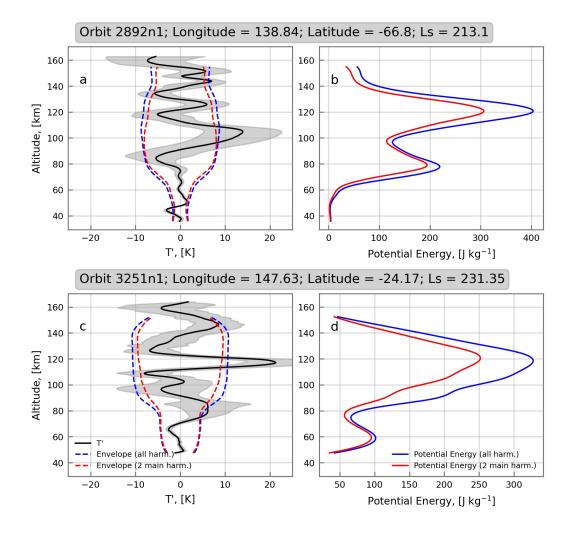

Figure 3. Wave activity |T'| (left column) and potential energy (per unit mass, right column) for the same as in Figure 2 representative profiles. Dashed blue lines indicate quantities calculated for the entire spectrum, dashed red lines are for accounting two longest harmonics only. Shaded areas denote observational errors.

be estimated (e.g., Ern et al., 2004, sect. 4):

$$F_{k,m} = \frac{1}{2}\rho_0 \frac{k_h}{m} \left(\frac{g}{N}\right)^2 \left(\frac{|T'_{k,m}|}{\overline{T}}\right)^2,\tag{6}$$

where k_h and m are the horizontal and vertical wavenumbers, correspondingly, and $|T'_{k,m}|$ is the amplitude. The latter two are found from the Fourier decomposition, whereas k_h cannot be derived from our measurements.

The total flux F is the sum of contributions of individual harmonics $F = \sum_{m} F_{k,m}$. Since the horizontal wavenumber k_h cannot be obtained from the measurements, it, therefore, serves as a scaling factor for the derived profiles of F and momentum forcing (5). The densest atmospheric footprint at a target point in occultation geometry is 400-500 km horizontally, depending on the height. This constrains the upper limit for unresolved wavelengths. In our calculations, we assumed a representative horizontal wavelength $\lambda_h =$ $2\pi/k_h = 300$ km, the value typically used in numerical general circulation models (Yiğit

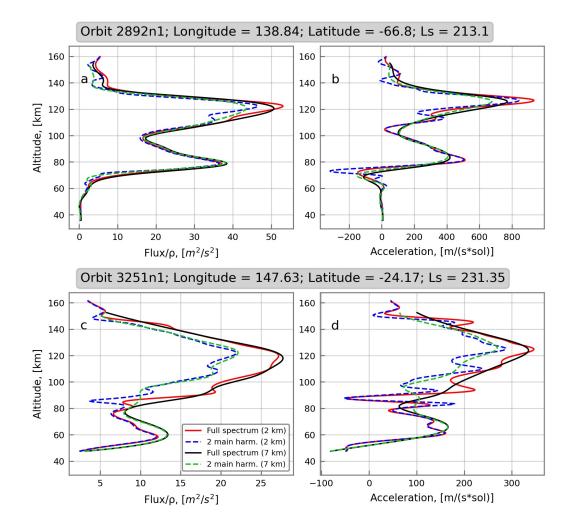

Figure 4. Absolute momentum flux (per unit mass) and the momentum forcing for two representative profiles (orbits 2892n1 and 3251n1, upper and lower rows, correspondingly). The legend describes the profiles calculated using the full spectrum and only two major harmonics along with sliding interval steps 2 and 7 km.

305

strate the sensitivity of the calculations to the used parameters of the technique, we plot-306 ted with different colors the profiles of momentum fluxes (per unit mass) F/ρ_0 and GW 307 momentum deposition, i.e., wave drag a obtained from the full spectrum and taking ac-308 count of only two major harmonics. In addition, the results are shown for the interval 309 shifts 2 and 7 km. It is immediately seen that these details play little role, and the cal-310 culations of fluxes and wave drag are very robust when the measured temperature pro-311 file is dominated by large-scale features (Figure 4, the upper row). It is different for pro-312 files containing smaller vertical-scale disturbances (Figure 4, the lower row): their ne-313 glect leads to an underestimation of the fluxes and wave drag, and the smaller vertical 314 shifts reveal finer structure associated with dissipation of individual spectral harmon-315 ics. 316

4 Results and Discussions

318 4.1 Case Study

Spectral analysis of the obtained set of profiles (described in the next subsection) 319 has demonstrated greater contribution of larger-scale disturbances in all cases. However, 320 each individual profile was unique. Two examples with and without small vertical-scale 321 components have been presented above. We next consider a case with a relatively broad 322 spectrum of wave-like perturbations with large amplitudes (about twice as large as those 323 in orbit 3251n1). The retrieved temperature for the orbit 4926n1 along with the fitted 324 background profile are plotted in Figure 5a. The envelope in Figure 5b clearly shows that 325 the amplitude gradually ceases its exponential growth with height and becomes nearly 326 constant above ~ 110 km. The reason for this so-called wave "saturation" can be seen

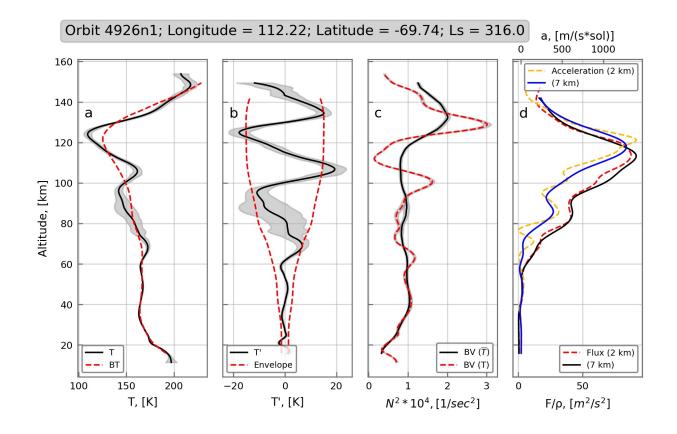

Figure 5. Vertical profiles for the orbit 4926n1. a) The measured (solid black) and fitted mean temperature (red dashed); b) wave temperature disturbance (solid black) and envelope (red dashed); c) Brunt-Väisälä frequency calculated for the mean (black) and net temperature (red dashed); d) momentum flux calculated using 2- and 7-km sliding window shifts (bottom axis, red dashed and solid black lines, correspondingly, and mean flow acceleration ("wave drag", upper axis, yellow dashed and solid blue for the 2- and 7-km steps, respectively). Shading denote observational uncertainties.

327

from the behavior of the squared Brunt-Väisälä frequency $N^2(z)$ (Figure 5c, black). N^2 calculated from the background profiles (Figure 5c) remains relatively constant with height

(up to about 120 km) suggesting convective stability of the mean state. N^2 from the orig-

inal profiles (see Figure 5c, red-dashed) shows large swings associated with temperature

disturbances. Near 110 km, N^2 drops almost to zero as the result of the temperature 332 gradient (associated with a large amplitude of the disturbances) approaching the adi-333 abatic lapse rate. Enhanced wave dissipation due to a combination of physical processes 334 (Yiğit et al., 2018) in the vicinity of the convective instability severely limits the GW 335 amplitude, leading to the decrease of the momentum flux above this altitude and peak-336 ing of the mean flow acceleration (Figure 5d) at almost 2000 m s⁻¹ sol⁻¹. In the ana-337 lyzed data set, such large numbers are not common and occur only occasionally. Appli-338 cation of a smaller vertical shift of sliding intervals shows finer structure of the GW mo-339 mentum flux and drag, but do not significantly modify the magnitudes. 340

4.2 Spatial Distribution of Gravity Wave Activity

In this section, we use the data obtained by the ACS instrument in MY34, at solar longitudes from $L_s = 164^{\circ}$ to 354° . The data set contains altogether 144 occultation profiles: 84 in the northern hemisphere and 60 in the southern one. The latitudesolar longitude coverage is shown in Figure 6 with red and blue dots representing morning and evening occultation measurements, correspondingly. The longitudinal orbit coverage was fairly uniform, and is not discussed here.

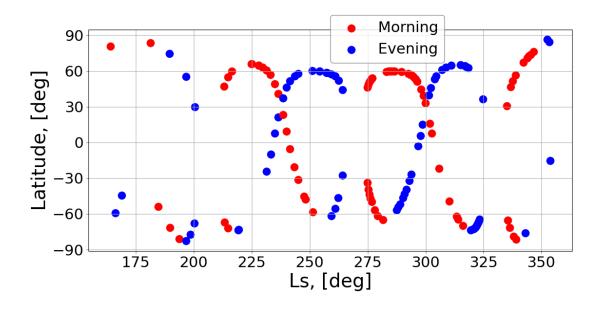

Figure 6. Latitude-solar longitude (L_s) distribution of the ACS MIR occultation profiles used in this study. Morning and evening measurements are shown in red and blue, correspondingly.

347

341

A significant portion of observations were made during the global dust storm of MY34, 348 which started between $L_s = 185^{\circ}$ and 190° , attained its maximum around $L_s = 220^{\circ}$, 349 and gradually decreased until $L_s \approx 290^{\circ}$. A regional storm occurred at the end of MY34 350 between approximately $L_s = 325^{\circ}$ and 345° . Figure 7 presents latitude-altitude dis-351 tribution of the derived GW parameters averaged over the entire period of observations 352 depicted in Figure 6. It shows that the mean amplitude of GW-induced temperature fluc-353 tuations (|T'|, Figure 7a) grows with height reaching up to ~10 K near the top of the 354 domain. At higher altitudes (170-220 km), the in situ measurements with Neutral Gas 355 and Ion Mass Spectrometer (NGIMS) on board MAVEN revealed even larger GW mag-356 nitudes over the same time (Leelavathi et al., 2020; Yiğit et al., 2021). The latitudinal 357

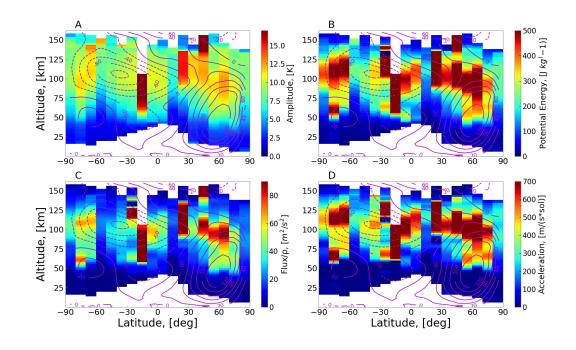

Figure 7. Latitude-altitude cross-sections of the retrieved GW a) amplitudes (in K), b) potential energy (per unit mass), c) vertical fluxes of absolute horizontal momentum (per unit mass) and d) associated momentum forcing (GW drag). The size of the employed latitudinal bins is 10° . Contour lines present the zonal wind (in m s⁻¹) simulated with the MAOAM MGCM for MY34 (https://mars.mipt.ru/data.php) and averaged over the same as in Figure 7 period of observations.

structure of the GW activity in the mesosphere and lower thermosphere is not uniform. 358 For comparison, we overplotted the zonal wind simulated with the Max Planck Institute 359 (MAOAM) MGCM https://mars.mipt.ru/ for MY34 and averaged over the same in-360 terval of L_s as in the observations. The wind distribution varied during this time from 361 the equinoctial to solstitial and back to the equinoctial types. The result reflects the largest 362 contribution of the prograde and retrograde jets during the perihelion solstice. It is seen 363 that the regions with large wave amplitudes encircle the upper edges of two midlatitude 364 jets. This is the result of intensive filtering of individual harmonics by strong background 365 winds. For the wave potential energy, which is a quadratic function of wave amplitudes, 366 this pattern is even more obvious (Figure 7b). 367

Figure 7c shows that GW momentum fluxes reach local maxima near the mesopause 368 (100-125 km) giving evidence of very intensive wave breakdown/dissipation in this re-369 gion. The peaks of the associated momentum deposition approximately coincide (Fig-370 ure 7d). They too wrap around the edges of the jets in the middle atmosphere. It is note-371 worthy that such distribution of the GW drag is very similar to that predicted by a Mar-372 tian GCM (Medvedev et al., 2011, Figures 3 and 7) for the solution and equinox, respec-373 tively, and represents the first (to the best of our knowledge) observational validation 374 of the model predictions. The magnitudes of the GW drag, although defined up to the 375 constant k_h , agree with the simulations (using a similar k_h) as well. 376

377 378

4.3 Amplitude Dependence on Mean Temperature and Brunt-Väisälä Frequency

In situ measurements with NGIMS on board MAVEN showed a clear anti-correlation between relative density fluctuations in the upper thermosphere and the ambient temperature (Yiğit et al., 2015; England et al., 2017; Terada et al., 2017; Vals et al., 2019). It was linked to convective instability as a dominant mechanism that limits growth of GW amplitudes with height (wave saturation). The arguments were based on the relation for a single harmonic (e.g., Fritts et al., 1988, Eq. 6)

$$\frac{|T'|}{\bar{T}} = \frac{|u'|}{|c - \bar{u}|} \frac{N^2}{mg},\tag{7}$$

where |u'| is the amplitude of fluctuations of horizontal velocity in the wave, c is its hor-385 izontal phase velocity and \bar{u} is the background wind. When |u'| approaches $|c-\bar{u}|$, in-386 creasing dissipation limits |u'| thus that the ratio $|u'|/|c-\bar{u}|$ becomes constant. The lin-387 ear convective instability threshold demands a unit ratio, however observations suggested 388 a ratio of 0.7 (Fritts et al., 1988, Eq. 2), and the theoretical consideration of the non-389 linear diffusion mechanism yielded $1/\sqrt{2} \approx 0.707$ (Medvedev & Klaassen, 2000, Sect. 390 7). Regardless of the precise number, (7) establishes proportionality between the am-391 plitude of relative temperature/density perturbations and squared mean Brunt-Väisälä 392 frequency under the saturation condition. Near the exobase, where the majority of NGIMS/MAVEN 393 observations were taken, the vertical gradient $d\bar{T}/dz$ is small and can be neglected in (4), thus giving the inverse proportionality of relative perturbation amplitudes and \overline{T} . 395

ACS/TGO occultation data cover altitudes below the exobase, where $d\bar{T}/dz$ can 396 no longer be neglected. Therefore, we plotted in Figure 8a the amplitudes of relative tem-397 perature perturbations for all orbits as functions of N^2 . It is seen that red and blue dots 398 corresponding to morning and evening measurements show no clear dependence on N^2 399 at all altitudes. To explore this further, we over-plotted the linear regression of the form 400 $|T'|/\bar{T} = \alpha N^2 + \beta$ and put the values of α and β in the legend. The coefficients α are 401 far less than those expected from (7), i.e., several tens or hundreds, depending on the 402 characteristic vertical wavenumber m. The distinction between morning and evening am-403 plitudes is also insignificant, except above 100 km, where morning values are slightly larger. 404

Figure 8b presents the dependencies of amplitudes of relative temperature distur-405 bances as functions of the mean temperature. They are nearly uniform. Although re-406 gression coefficients show a weak negative trends at all altitudes, their magnitudes are 407 much smaller than to those observed previously (of the order of 0.5 to 1) near the exobase 408 (Yiğit et al., 2015; England et al., 2017; Terada et al., 2017; Vals et al., 2019). A sim-409 ilar lack of correlation between GW amplitudes and atmospheric temperature was found 410 from TGO aerobraking measurements at altitudes between 100 and 130 km (Jesch et al., 411 2019, Figure 12). The atmospheric drag data were collected between $L_s = 332^{\circ}$ of MY33 412 and $L_s = 132^{\circ}$ of MY34. The ACS observations after the aerobraking cover the dusty 413 second half of MY34. Thus, the absence of correlation between GW amplitudes and the 414 background temperature in the lower thermosphere appear to be independent of the sea-415 son and dust conditions. In the upper thermosphere, (Leelavathi et al., 2020, Figure 10d) 416 found a positive correlation during the same second half of MY34, instead of a clear neg-417 ative correlation over the first ("non-dusty") half of the year. Our results in the adja-418 cent region (around 140 km) show no visible change, neither strong negative trend pre-419 viously found in the MAVEN/NGIMS observations, nor indication of a positive trend. 420 This means that convective instability may not be the main mechanism responsible for 421 damping GWs in the thermosphere, at least during dust storms. 422

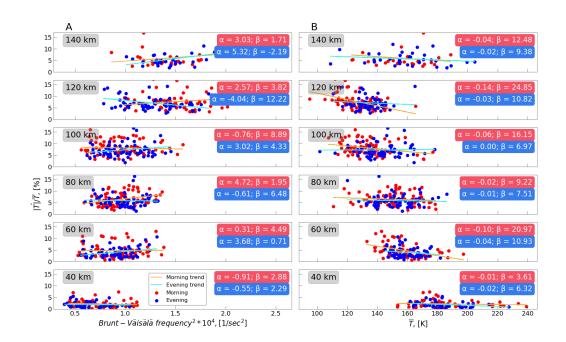

Figure 8. Amplitudes of relative temperature disturbances as functions of the squared Brunt-Väisälä frequency (a) and mean temperatue (b) at different heights. Red and blue dots are for the morning and evening measurements, correspondingly. Linear regressions of the form a) $|T'|/\bar{T} = \alpha N^2 + \beta$ and b) $|T'|/\bar{T} = \alpha \bar{T} + \beta$ are shown with thin solid lines, and the values of the respective coefficients are given in the legends.

⁴²³ 5 Summary and Conclusions

We have presented the results of gravity wave (GW) retrievals obtained from the Atmospheric Chemistry Suite instrument on board the ExoMars Trace Gas Orbiter (ACS/TGO), which observed solar occultation spectra. GW disturbances are derived from the vertical temperature profiles retrieved from one of the three instrument channels - the midinfrared ACS/MIR. The uniqueness of the data is that they continuously cover a broad range of altitudes from the Martian troposphere to the thermosphere (20-160 km) and have a relatively high (0.5 to 2.5 km) vertical resolution.

Several techniques of separating GW components from the background temperature have been studied. The sliding-window least square polynomial fitting method have
demonstrated to be the most robust and effective. The procedure was applied to 144 measurements collected over the second half of MY34 to derive vertical profiles of GW disturbances as well as further wave characteristics: amplitude, wave potential energy, absolute vertical flux of horizontal momentum and absolute momentum forcing produced
by breaking/dissipating GWs ("GW drag"). The main results are listed below.

Amplitudes of GW-induced temperature fluctuations, generally, grow with height,
 while breaking/saturation processes often limit the wave amplitude growth at higher
 altitudes. Based on a half-year average, wave amplitudes are around 8–14 K near
 the mesopause, and often exceed these values in individual profiles.

- 2. The mesopause (100-120 km) is the region of the strongest GW breaking/dissipation, which is evidenced by a local maximum of momentum fluxes and their vertical divergence, i.e., GW drag. Similarly, a large GW drag of hundreds of m s⁻¹ sol⁻¹ in the mesopause region has been demonstrated by MGCMs (e.g., Yiğit et al., 2018).
- 3. The spatial (altitude-latitude) distribution of the wave drag also agrees well with
 modeling results (e.g., Medvedev et al., 2011). This is the first direct observational
 validation of model predictions.
- 449
 4. We did not find positive correlation between amplitudes of relative temperature 450 perturbations and the Brunt-Väisälä frequency at all heights. This correlation is 451 a more general formulation of the anti-correlation found near the exobase (Yiğit 452 et al., 2015; England et al., 2017; Terada et al., 2017; Vals et al., 2019) that ac-453 counts for vertically varying mean temperature.

The presented GW activity retrievals extending from the middle troposphere to the thermosphere, as derived from the ExoMars data, highlight the role of atmospheric gravity waves as a whole atmosphere phenomenon on Mars. Mars' thin and windy atmosphere favors strong gravity wave generation, thus an accurate characterization of gravity waves is absolutely essential for a better understanding of the Martian climate (Yiğit & Medvedev, 2019).
