#### Abstract

Crater morphology and surface age of asteroid (162173) Ryugu are characterized using the high-resolution images obtained by the Hayabusa2 spacecraft. Our observations reveal that the abundant boulders on and under the surface of the rubble-pile asteroid affect crater morphology. Most of the craters on Ryugu exhibit well-defined circular depressions, unlike those observed on asteroid Itokawa. The craters are typically outlined by boulders remaining on the rim. Large craters (diameter >100 m) host abundant and sometimes unproportionally large boulders on their floors. Small craters (<20 m) are characterized by smooth circular floors distinguishable from the boulder-rich exterior. Such small craters tend to have dark centers of unclear origin. The correlation between crater size and boulder number density suggests that some processes sort the size of boulders in the shallow (<30 m) subsurface. Furthermore, the crater size-frequency distributions (CSFDs) of different regions on Ryugu record multiple geologic events, revealing the diverse geologic history on this 1-km asteroid. Our crater counting analyses indicate that the equatorial ridge is the oldest structure of Ryugu and was formed 23-29 Myr ago. Then, Ryugu was partially resurfaced, possibly by the impact that formed the Urashima crater 5-12 Myr ago. Subsequently, a large-scale resurfacing event formed the western bulge and the fossae 2-9 Myr ago. Following this process, the spin of Ryugu slowed down plausibly due to the YORP effect. The transition of isochrons in a CSFD suggests that Ryugu was decoupled from the main belt and transferred to a near-Earth orbit 0.2-7 Myr ago.

## 42 Key Points:

- Craters on asteroid Ryugu are documented and counted based on the high-resolution
   images obtained with Hayabusa2's telescopic camera.
- Crater morphology on Ryugu ranges from distinct >100-m circular depressions to <10 m smooth texture outlined by boulders.</li>
- 47 Crater chronology reveals multiple resurfacing events on each hemisphere 2-11 Myr ago
   48 and Ryugu's departure from the main belt < 7 Myr ago.</li>

#### 50 Abstract

Crater morphology and surface age of asteroid (162173) Ryugu are characterized using the 51 high-resolution images obtained by the Hayabusa2 spacecraft. Our observations reveal that the 52 abundant boulders on and under the surface of the rubble-pile asteroid affect crater morphology. 53 54 Most of the craters on Ryugu exhibit well-defined circular depressions, unlike those observed on asteroid Itokawa. The craters are typically outlined by boulders remaining on the rim. Large 55 56 craters (diameter >100 m) host abundant and sometimes unproportionally large boulders on their floors. Small craters (<20 m) are characterized by smooth circular floors distinguishable 57 from the boulder-rich exterior. Such small craters tend to have dark centers of unclear origin. 58 The correlation between crater size and boulder number density suggests that some processes 59 sort the size of boulders in the shallow (<30 m) subsurface. Furthermore, the crater size-60 frequency distributions (CSFDs) of different regions on Ryugu record multiple geologic events, 61 revealing the diverse geologic history on this 1-km asteroid. Our crater counting analyses 62 indicate that the equatorial ridge is the oldest structure of Ryugu and was formed 23-29 Myr 63 ago. Then, Ryugu was partially resurfaced, possibly by the impact that formed the Urashima 64 crater 5-12 Myr ago. Subsequently, a large-scale resurfacing event formed the western bulge 65 and the fossae 2-9 Myr ago. Following this process, the spin of Ryugu slowed down plausibly 66 67 due to the YORP effect. The transition of isochrons in a CSFD suggests that Ryugu was decoupled from the main belt and transferred to a near-Earth orbit 0.2-7 Myr ago. 68

#### 69 Plain language summary

Japan's asteroid explorer Hayabusa2 visited the carbon-rich, 1-km asteroid named Ryugu. One 70 71 of the onboard cameras took many pictures of asteroid's surface. In order to know the history of this asteroid, we estimate the age of different geologic units by counting craters. We also 72 documented how the craters on this asteroid look, to help understand the geology of the carbon-73 rich world. We found that the mountain range running along the equator formed some 30 74 75 million years ago. About 5-12 million years ago, the meteorite impact that formed the biggest 76 crater on this asteroid likely scattered soil around, erasing nearby craters that existed before. Then, about 2-9 million years ago, the western half of this asteroid was wiped out by a large-77 scale movement of rocks and pebbles that build this asteroid, because the asteroid was spinning 78 fast and unstable at that time. Then, sometime between 0.2 and 7 million years ago, this asteroid 79 left the home of asteroids located between Mars- and Jupiter orbits, and came to the orbit 80 passing near the Earth. During its journey to the near-Earth orbit, the spin of the asteroid slowed 81 down because of the very weak but effective force by heat radiation from surface rocks. 82

#### 83 **1 Introduction**

(162173) Ryugu is a top-shaped C-type asteroid explored by the Hayabusa2 spacecraft. 84 A series of observations by the telescopic optical navigation camera (ONC-T) and the near 85 infrared spectrometer (NIRS3) revealed the geomorphology and visible/near infrared spectra 86 87 of this asteroid (Sugita et al., 2019; Kitazato et al., 2019). Ryugu exhibits an equatorial ridge and an east-west dichotomy outlined by two fossae (Sugita et al., 2019; Watanabe et al., 2019). 88 89 The western hemisphere, which exhibits the western bulge that stretches approximately 180-300°E, is characterized by slightly (a few %) darker v-band albedo (Sugita et al., 2019) and a 90 smaller number density of boulders (Michikami et al., 2019) compared with the eastern 91 hemisphere. The different characteristics between the two hemispheres suggest different 92 lithologies and/or a complex geologic history on this small, 1-km-diameter asteroid. The 93 equatorial ridge shows spectral slopes bluer than mid-latitudinal regions, suggestive of mass 94 movement away from the equator or lithology/surface properties different from the rest of the 95 asteroid (Sugita et al., 2019, Morota et al., 2020). The coincidence of the east-west dichotomy 96 with the fossae suggests that global deformation played a key role in forming the dichotomy 97 (Kikuchi et al., 2019; Hirabayashi et al., 2019). However, the mechanism responsible for the 98 east-west dichotomy formation remains unclear. The homogeneous surface normal albedo 99 (Yokota et al. in revision) of the whole surface does not support a simple two-body merge 100 scenario as the origin of the dichotomy. Proposed hypotheses include structural deformation 101 under fast rotation in the past (Hirabayashi et al., 2019) and consequences of large oblique 102 impact on Ryugu (Matsumoto et al., 2020). Thus, determining the ages of both hemispheres is 103 104 key to understand the evolution of Ryugu.

105 As with other asteroids that have been explored by spacecraft, impact craters are among the most ubiquitous geologic features on Ryugu. Investigating the crater statistics and 106 morphology gives hints on the geologic history of the asteroid, crater erasure processes, spin 107 evolution, subsurface structures that are otherwise hidden, and physical properties of the 108 surface. For example, the initial report by Sugita et al. (2019) showed that the crater model age 109 of Ryugu ranges from 9 Ma to 160 Ma depending on the degree of cohesion of the surface 110 materials. Their study, however, was based on a global crater counting analysis, which did not 111 take the different geologic units into account and therefore could simplify the complex history 112 of Ryugu. For example, the east-west dichotomy and the bluer color of the equatorial ridge 113 suggest different geologic histories, surface properties, or ongoing mass movement on these 114 units. Subsequently, more detailed investigation on the spatial distribution of craters was 115

116 conducted, finding a latitudinal variation in crater number density (Hirata et al., 2020). Crater 117 depth-to-diameter (d/D) ratios were then measured based on the shape model of Ryugu 118 (Noguchi et al., 2021).

However, the ages of individual geologic events have not been studied. Detailed 119 120 morphology of craters on Ryugu, which is important for chronologic and geologic investigation, has not been studied extensively yet either. Understanding crater populations at the smaller size 121 range (diameter < 20 m) is also important for providing insights into more recent, or potentially 122 ongoing geologic processes on Ryugu. Smaller craters can be statistically considered to have 123 formed more recently than much larger ones. Therefore, the size-frequency distributions of 124 such small craters may constrain the timescale of their formation and erasure processes, which 125 126 directly control the surface geology of the asteroid. The global crater size-frequency distribution (CSFD) measured by Sugita et al. (2019) showed the paucity of small craters (20-127 30 m) on Ryugu, suggesting that the smaller craters are likely erased by some surface processes, 128 such as ejecta blanketing, seismic shaking, or regolith convection (Miyamoto et al., 2007). 129 Morphological observation is useful for examining such size-sorting processes. In fact, the SCI 130 impact experiment showed that a large amount of ejected materials came back to the surface, 131 leading to material burial in a relatively wider regions (Arakawa et al., 2020). Better 132 understandings of the small crater statistics would also shed light on the unique orbital 133 evolution that Ryugu may have experienced recently (Morota et al., 2020). 134

Surface age can give constraints on the spin evolution of Ryugu as well. Recent work 135 136 using finite element analyses implies that Ryugu's top shape was made by global deformation under a fast spin state (~3.5 hr period) in the past (Hirabayashi et al., 2019; Watanabe et al., 137 2019). The fast-spin state might have been achieved upon the gravitational reaccumulation of 138 Ryugu after the catastrophic disruption of the parent body that made this rubble-pile asteroid 139 (Michel et al., 2020). Later, Ryugu's spin may have stochastically evolved (Statler, 2009; 140 Bottke et al., 2015) but eventually slowed down to the current spin period of 7.6 hr by the 141 Yarkovsky-O'Keefe-Radzievskii-Paddack (YORP) effect. The duration of the fast spin state 142 and the timescale of spin-state evolution are key observables to test this YORP-induced spin-143 144 evolution hypothesis.

The morphology of impact craters is also important information to understand the cratering processes in a microgravity environment and surface/subsurface properties of a rubble pile asteroid, including porosity (Wünnemann et al., 2006), boulder-surface interaction (Tatsumi & Sugita, 2018), and subsurface structure (Hirata et al., 2009 for Itokawa; Veverka et al., 1999 for Mathilde; Bart et al., 2011). Steep local topography usually seen on craters
allows investigation of the surface modification process and the surface properties. Craters may
also be used to see vertical structure, such as subsurface layers with distinct strength (Arakawa
et al., 2020).

153 The purpose of this study is to determine the ages of major geologic events by means of crater chronology and morphological investigation of craters. In this study, we use high-154 resolution images of Ryugu that have been obtained since the initial global observations 155 (Kitazato et al., 2019; Sugita et al., 2019; Watanabe et al., 2019) to further characterize the 156 statistics and morphology of craters. We identify crater candidates within these images and 157 build a new catalogue of craters down to 3 m in diameter. Then, we estimate both relative and 158 159 absolute ages of individual geologic units based on crater chronology (section 4). Finally, using the newly established crater list and CSFD, we will discuss the geologic history of this C-type 160 161 asteroid from the catastrophic disruption of its parent body through its transfer to the current near-Earth orbit. The spin-state evolution is also discussed based on the surface ages. 162

163 **2 Data and Methods** 

164 The dataset, crater morphological levels, definition of geologic units, and method used 165 to derive crater statistics are described in this section.

166 2.1 Dataset

We used ONC-T v-band (i.e., 550 nm) images obtained from multiple altitudes, 167 including global image data from 20 km (i.e., Hayabusa2 spacecraft's nominal hovering 168 altitude) and 5 km (mid-altitude operation), as well as those of limited coverage from 3 km. 169 The spatial resolutions of these images were approximately 2, 0.5 and 0.3 meters per pixel 170 (m/pix), respectively. Craters were visually identified with the image data globally acquired 171 172 from the altitude of 5 km while Ryugu spins 360° (global observation campaign). Multiple stereo image pairs covering Ryugu were also produced from these images and used for finding 173 circular depressions, taking the spatial distribution of boulders and surface textures into 174 account. Then individual images were mapped on the shape model of Ryugu 175 (SHAPE SFM 3M v20180804; Watanabe et al., 2019) to derive the diameter and location of 176 each candidate crater (circular feature). The small body mapping tool (sbmt) was used for this 177 analysis. Each candidate crater was categorized into different confidence levels based on 178 individual morphology (Section 2.2). We also used even higher-resolution images (0.2 m/pix) 179 obtained during the low-altitude operation dedicated to find the crater formed by the Small 180

Carry-on Impactor (SCI) in April 2019 (Arakawa et al., 2020), to identify and measure craters 181 smaller than 20 m. This SCI crater-search mosaic covers an area of 0.37 km<sup>2</sup> (~14% of the 182 entire surface) at approximately 50°N-50°S and 260-340°E, which spans both eastern 183 hemisphere and western bulge. Craters smaller than 10 pixels (2 m for those imaged during the 184 SCI crater-search campaign) were regarded at the resolution limit. The phase angles of the 185 images used for the global observation and SCI crater search were 15°-32° and 20°-27°, 186 respectively. All images were processed using the standard calibration pipeline (Suzuki et al., 187 2018; Tatsumi et al., 2019). Crater color indices, such the ratio of b-band (0.48 µm) and x-band 188  $(0.86 \ \mu m)$  reflectance (b/x slope) and a color contrast between crater interior and exterior 189 190 ("red/blue" identifier), were measured by Morota et al. (2020) and cited in this study. The depth-to-diameter ratios (d/D) of individual craters (Noguchi et al. 2021) were cited in our 191 192 crater catalogue as well.

193

### 2.2 Crater morphological levels

We investigated every stereo pair and found that crater candidates have different 194 degrees of morphological confidence from clear circular depressions to rather ambiguous 195 196 quasi-circular features without obvious depressions. The confidence levels of craters found in this study were assigned based upon the following definitions. Confidence level 1 (CL1) is a 197 198 circular depression with a crisp circular rim; CL2 is a depression with a more ambiguous but circular rim; CL3 is a quasi-circular depression with a partially circular rim suggestive of 199 perturbed or broken crater rim; CL4 is a quasi-circular feature defined by a circular pattern of 200 boulders. The CL4 crater candidates exhibit no resolvable and quantifiable depression in their 201 interior. Note that the confidence levels can be affected by viewing geometry and illumination 202 effects, so CLs 1 and 2 may occasionally be interchangeable. Future studies focusing on crater 203 profile measurements may revise the CLs derived in this study, but our classification is 204 sufficient for the scope of this survey. We regarded the candidates of CL1-3 as impact craters 205 and used them for the following crater size-frequency distribution (CSFD) analyses. It was 206 difficult to establish the threshold of the crater depth between CL 3 and CL 4 because of 207 208 multiple factors, such as presence of boulders on crater floors, lighting condition, viewing geometry, and uncertainty of the shape model. Nevertheless, the overall distribution of d/D209 ratios of the craters on Ryugu (Noguchi et al., 2021) suggest that the craters shallower than 210 d/D = 0.05 are not detected as a depression. 211

212 2.3 Geologic units

In this study, we categorized the surface of Ryugu into multiple units: the eastern 213 214 hemisphere (EH), western bulge (WB), equatorial ridge (EQR; Ryujin Dorsum), high latitudes, and trough (Figure 1). The eastern and western hemispheres, which show different boulder 215 number densities and v-band albedo at the phase angle of 30°, are divided by the Horai and 216 Tokoyo Fossae, the narrow depression systems possibly connected to each other around the 217 218 south pole (Sugita et al., 2019). The areas of eastern and western hemispheres are 1.77 and 219 0.93 km<sup>2</sup> including the ridge, respectively. The high-resolution crater observations compensate for such small counting area by allowing us to find > 100 craters down to a few 220 m in diameter (Section 3), while the small number statistics still potentially obscures subtle 221 differences in absolute ages. The western bulge is defined as a hemispherical region outlined 222 by the fossae, reaching the equatorial ridge at 180°E and 300°E. The eastern hemisphere is 223 defined as the remainder of the asteroid's surface. In this study, the equatorial ridge was 224 defined by the belt centered at the equator with a width of ~160 m (10°N to 10°S), which 225 corresponds to elevation higher than ~30 m (Kikuchi et al., 2020). The ridge coincides with 226 the area characterized by bluer spectral slopes (Sugita et al., 2019). The equatorial belt (0.58 227 km<sup>2</sup>) spans both the eastern hemisphere and western bulge. The regions with the latitudes 228 higher than 10°N or 10°S were also defined to compare the crater population at the equator 229 and that at higher latitudes. The total area of the two fossae, defined by Sugita et al. (2019), 230 is 0.18 km<sup>2</sup>. Individual craters are assigned to the units based on the location of their centers. 231 Because the equatorial ridge spans both hemispheres, craters on the ridge were also assigned 232 233 to either EH or WB. For example, a crater at the ridge on the eastern hemisphere is categorized into both EH and EQR in the CSFDs. 234

236 Figure 1. Definition of the crater-counting areas overlaid on a global map (dark blue: equatorial ridge, magenta: western bulge, yellow and sky-blue: SCI crater search footprints on the eastern 237 hemisphere and western bulge, respectively). Fossae are highlighted in brown. The eastern 238 hemisphere is defined by the entire area outside the western bulge. Craters found by the global 239 survey in this study are shown as well (red circles; solid circles are those with confidence levels 240 (CLs) 1-3, dotted circles are those of CL 4). 241

235

#### 243

2.4 Crater size-frequency distributions (CSFDs)

The cumulative CSFDs were constructed for the individual units and fitted with crater 244 chronology model functions. No binning was used for the plots. Resulting absolute model ages 245 depend on model assumptions, such as crater production function, chronology function, and 246 crater scaling rules. The surface properties, including target density, porosity, cohesion, and 247 boulder size, were incorporated into the crater scaling rule as input parameters. We adopted the 248 models and parameters employed by Sugita et al. (2019) and Morota et al. (2020) in deriving 249 absolute model ages (Table 1). The models used the intrinsic collision probabilities  $P_i$  for both 250 main-belt asteroids (MBA) and near-Earth asteroids (NEA), the population of MBAs and 251 252 NEAs (Bottke et al., 2005; O'Brien and Greenberg 2005), and mean impact velocities in each orbit (Bottke et al., 1993, 1994). The two models were used to examine the model dependence 253 of ages, as well as to derive residence time in each orbit. Error bars associated with each data 254 point were calculated by  $\pm N^{1/2}/S$ , where N is the cumulative number of craters and S is the area 255 of individual units. Errors in model ages reflect uncertainties in counting statistics and do not 256

include any systematic uncertainties in the crater chronology functions. The crater scaling rule 257 by Tatsumi & Sugita (2018) was used to address the armoring effect on the boulder-rich surface 258 of Ryugu. We assumed that the cohesion of Ryugu is neglectable and the gravity controls the 259 crater formation (i.e., gravity scaling) to calculate the absolute age of each geologic unit 260 (Arakawa et al., 2020). We also assumed that these surface conditions hold for the entire Ryugu 261 surface. The sources of the model uncertainty include the target disruption energy Q<sub>D</sub>\* and 262 impactor population. For example, changing QD\* from 1000 J/kg to 100 J/kg would yield a 263 factor of three younger model age. This uncertainty will be addressed when the disruption 264 energy of Ryugu's material is determined with the returned samples. Furthermore, the impactor 265 size-frequency model from Bottke et al. (2005) to O'Brien & Greenberg (2005) would yield a 266  $\sim$ 30% younger model age because the number of small impactors is greater in the latter model. 267

The software tool craterstats was used to fit the observed CSFDs to the crater 268 production function and to derive fitting errors (section 4). The crater diameter ranges and 269 number of craters used for the fitting were 70-80 m (6 craters) and > 100 m (11 craters) for the 270 global crater data; 10-15 m for the SCI crater-search area (10 craters); > 100 m for the 271 equatorial ridge (4 craters); 60-100 m (11 craters) and > 120 m (8 craters) for the eastern 272 hemisphere; > 50 m (8 craters) for the western bulge; > 40 m for the north (15 craters) and 273 south (14 craters) hemispheres. In addition to the cumulative plots, R-plots were also 274 constructed to observe differential size-frequency distributions of the craters. Three diameter 275 data were binned to improve the statistics. They were also used to estimate the crater retention 276 ages at different crater diameters by the intersections between the CSFDs and multiple 277 isochrons (Section 4.4). 278

### 283 **3 Crater morphological observation**

In this section, the morphology of craters on Ryugu is documented. In section 3.1, by taking advantage of the high-resolution images obtained during several descent operations, we conduct crater characterization and update the list of crater candidates published previously (Sugita et al., 2019; Hirata et al., 2020). In section 3.2, we describe the details of selected craters on Ryugu. In section 3.3, we discuss the morphological features of craters in different size ranges. In section 3.4, we discuss the possible subsurface structure of Ryugu.

#### 290

#### 3.1 Crater candidates and their morphology

More than 100 crater candidates larger than 10 m were found on Ryugu as a result of 291 292 the present crater survey (Table 2). We newly identified 40 crater candidates, including 15 candidates larger than 10 m (crater IDs 87-101). Crater candidates larger than 3 m were also 293 294 identified and used to construct size-frequency distributions. Ten crater candidates are larger than 100 m in diameter; 36 candidates are larger than 50 m. Despite the boulder-rich surface, 295 craters on Ryugu are more easily identifiable than those on the rubble-pile asteroid Itokawa 296 (Hirata et al., 2009). Ryugu's larger size and comparatively homogeneous topography could 297 be responsible for this difference. 298

<sup>301</sup> 

Note. 40 crater candidates have been added to the list in Hirata et al. (2020). Half of the craters smaller than 20 m were found in the high-resolution images obtained during the SCI-cratersearch operation. Crater IDs are based on Hirata et al. (2020). Depth-to-diameter ratios (d/D) are from Noguchi et al. (2021). Crater color indices (b/x slope and "red/blue" identifier) are from Morota et al. (2020). Note that newly identified craters are not necessarily sorted by diameter. Geologic units: eastern hemisphere (EH), western bulge (WB), equatorial ridge (EQR), trough (TR).

309

#### 310

#### 3.2 Observations of prominent craters on Ryugu

Here we document individual craters exhibiting prominent features, which may have 311 important information for Ryugu's history, geology, and impact cratering process. Included are 312 seven craters larger than 100 m in diameter, some smaller craters around them, and a few less 313 obvious crater candidates. We selected the large craters because CSFDs suggest that those 314 larger than 100 m were not significantly modified by subsequent erasure processes and thus 315 record crater formation on Ryugu more directly. Also, they are large enough for the observation 316 of their floors, while smaller craters are more subject to degradation (discussed in Section 4). 317 These craters exhibit a variety of morphological features and are representative of individual 318 units: the largest crater Urashima on the equatorial ridge, Momotaro and Kibidango as a large 319 crater doublet spanning from the ridge to a high latitude in the southern hemisphere, Cendrillon 320 at a high latitude in the northern hemisphere, Kolobok on the most heavily cratered region, 321 Kintaro on the rim of the trough, and Brabo on the western bulge. 322

Furthermore, boulders associated with the craters are described in this section because crater formation on a rubble-pile asteroid involves fragmentation, ejection, and displacement of boulders. Boulder number density, size, and shapes thus have the information on original surface/subsurface structure and/or crater formation processes. In fact, size-sorting of boulders was observed at the artificial impact experiment (Kadono et al., 2020): some boulders were excavated but left on the floor, while finer materials were ejected. This observation suggests that some boulders on the crater floors represent material originally buried in the subsurface.
Thus, observing the boulders in craters is important for characterizing Ryugu's geology in the
vertical direction.

Urashima (7°S, 93°E, 290 m) is the largest crater on Ryugu (Figure 3a). The northern 332 333 rim of the crater cuts the equator, excavating the original ridge by approximately 40 m in depth. Despite Urashima's deep excavation, the largest boulder found in Urashima is approximately 334 335 20 m in size on its western rim. The small number of such large boulders in this crater, as compared to the half-diameter Kibidango crater (described in the following paragraph) implies 336 that the subsurface of the equatorial ridge is composed of relatively fine materials compared to 337 the high-latitudes. The eastern side of the rim is lower than the western side, forming a 100-m 338 339 wide plateau. The cross section of Urashima is a conical shape (Namiki et al., 2019) which is often observed in laboratory cratering experiments on granular material (e.g., Oberbeck, 1971). 340 341 The conical shape might have been formed by slumping of crater walls as is seen in experiments. This observation suggests that the post-impact modification stage was controlled 342 by the gravity even though it is very low on Ryugu. Darker materials are exposed at the bottom 343 of this crater, the feature consistent with the morphology of the SCI crater (Arakawa et al., 344 2020). This dark deposit, which remains dark with a photometric correction (Sugita et al., 2019), 345 could be due to either dark, rough, or porous material (Cloutis et al., 2018). Other hypotheses 346 include crushed dark boulder, remnant of a dark impactor, or possibly another stratigraphic 347 layer exposed on the crater bottom. Shock darkening or impact melt is unlikely because of the 348 low shock pressure expected on Ryugu (Keil et al., 1997). Traces of mass wasting are observed 349 in this largest crater. A possible 80-m wide, 5-m thick slump is observed on its southeastern 350 wall, whose leading edge makes the crater bottom appear a deep pit (Figure 2b). The slope-351 352 facing flanks of some boulders on the northwestern wall (boulders B1 and B2) are covered by finer materials, while their opposite sides are not. This feature is the evidence for smaller-scale 353 354 downslope regolith migration into this crater. A slope streak (Kikuchi et al., 2019, Sugita et al., 2019) on the southwestern wall are well resolved as a boulder chain at this image resolution 355 (Figure 2b). A very large boulder named *Ejima saxum* (~60 m wide, ~30 m tall) sits just outside 356 the southern rim. The northwestern side of Ejima saxum exhibits a sharp flank running parallel 357 to Urashima's rim, while the other facets exhibit hummocky surfaces with gentler slopes. 358

The craters named *Momotaro* (15°S, 51°E, 183 m) and *Kibidango* (31°S, 47°E, 131 m) are a relatively fresh-looking example of crater doublet (Figure 2d). These craters were most likely formed by two separate impacts, given the comparable crater sizes and low speed of

ejected material to make secondary craters. Stratigraphically, the southern crater Kibidango 362 overlies Momotaro because the northern rim of Kibidango intrudes into the Momotaro crater. 363 Nevertheless, the latter Kibidango-forming impact did not significantly destroy the 364 morphology of predated Momotaro. This observation suggests a low seismic efficiency (i.e., 365 the conversion ratio of impactor's kinetic energy to seismic energy) on Ryugu, which is 366 consistent with the artificial impact experiment by SCI (Arakawa et al., 2020; Nishiyama et al. 367 2020). These craters are particularly rich in boulders and this could reflect the subsurface 368 structure of this region and/or crater formation process. In the Momotaro crater, for example, 369 a large elongated boulder (~30 m long) is observed on the eastern rim with its longer side 370 371 oriented toward the crater center; another elongated boulder occurs almost vertically with respect to the surface (Figure 2f), which could be the results of an intense boulder reorientation 372 373 during the impact event. Very large (30-50 m), flat and bright boulders are seen on the southern crater wall of Kibidango. Along with the 70-m wide, 10-m thick flat block located at 100 m 374 375 west of Kibidango, the high abundance of large boulders is consistent with the boulder-rich nature of the high latitude reported by Michikami et al. (2019). On the surface of the flat 376 377 boulder lies fine-grained material suggestive of ejecta from some craters.

The eastern part of Momotaro's floor is also particularly rich in several-to-10-m angular 378 boulders with a color similar to that of large bright boulders in Kibidango. The western half in 379 contrast shows finer boulders of a redder spectral slope (Sugita et al., 2019). Various 380 interpretations are possible to account for the particular high boulder number density. The 381 boulders originally on/under the surface could have been excavated or even crushed upon the 382 impact that made Momotaro; the impact that made overlying Kibidango could have broken the 383 original rim of Momotaro, scattering the bright boulders into its floor as ejecta, given the 384 resemblance of the color of boulders; an exposure of subsurface boulders; a result of mass 385 movement from the equator; or immature boulder breakdown due to thermal fatigue. A smaller 386 387 crater (~20 m) overlies the northern rim of the Momotaro crater (Figure 2e). Its smooth interior suggests that the subsurface of the Momotaro's rim ( $\sim 2$  m), which is potentially ejecta deposits, 388 389 is made of fine-grained material, in contrast to Momotaro-crater's interior.

Figure 2. (a) Geological context of the Urashima crater. The northern rim crosses the equatorial 393 ridge. The eastern rim is punctuated by a plateau ("P"). Ejima saxum is located just outside the 394 southern rim (hyb2 onc 20180801 162509 tvf 12d). (b) Urashima in close-up. Finer 395 materials partially cover large (~20 m) boulders (B1, 2) on their high-geopotential side, a 396 feature suggestive of mass flow into the crater. Dashed curve "F" shows the front of the putative 397 398 slumping. A series of short arrows indicate possible linear streak composed by linearly aligned boulders (hyb2\_onc\_20181003\_142939 tvf 12d). (c) Urashima crater and the Ejima boulder 399 (white arrow) showing the flat flank (hyb2 onc 20180301 080258 tvf l2d). (d) Geological 400 context of the Momotaro and Kibidango craters (hyb2 onc 20180801 170957 tvf l2d). (e) 401 Close-up of Momotaro's floor, which is very rich in angular boulders 402 (hyb2\_onc\_20181004\_062159\_tvf\_l2b) (f) Sharp elongated boulder sticking out at 403 Kibidango's rim (white arrow). Note the very large flat boulders lying crater's southern rim 404 (hyb2 onc 20190301 084153 tnf 12d). 405

Figure 2 (continued). (g) Geological context of the Cendrillon and Kolobok craters 407 (hyb2 onc 20190228 113636 tvf l2b). (h) Northern part of Kolobok. White arrows indicate 408 angular boulders discussed in the text. Dashed circle in Kolobok shows the smaller crater on 409 the crater floor (hyb2 onc 20180720 090130 tvf 12d). (i) Cendrillon crater with large 410 boulders on the rim (white arrows) (hyb2 onc 20190228 113636 tvf 12b). (j) Geological 411 context of Kintaro (hyb2 onc 20180801 144909 tvf 12d). (k) Kintaro's floor in close-up. 412 Prominent boulders ("A" and "B") lie in the crater. A smaller crater with dark center is on the 413 crater rim (smaller dashed circle) (hyb2\_onc\_20190404\_220403\_tvf\_l2d). (l) Brabo crater. A 414 415 smaller crater with dark center is on the rim (smaller dashed circle). (hyb2 onc 20181003 191510 tvf l2d). 416

406

The *Cendrillon* crater (28°N, 6°W, 230 m) is the largest crater located outside the equatorial ridge (Figures 2g, i). This crater provides critical hints on Ryugu's subsurface at a middle-to-high latitude because the ridge is probably covered by thick materials transported over the course of the surface evolution. The crater interior is smooth as a whole, but larger (several to 15-m) boulders tend to occur on the southern wall. Portions of a few dark, hummocky boulders are exposed on the northern half of the rim (~45°N). The surface texture of the boulders resembles those of other hummocky boulders/massifs at similar latitudes of the north hemisphere. The deep interior of Ryugu could be made of such hummocky boulders,
which were too large to migrate to the equator even in the fast-spin period in the past. Spectrally,
Cendrillon is one of the reddest craters on Ryugu (Table 2). If reddening is caused by space
weathering, both the color of the crater floor and size suggest that this crater is one of the oldest
on Ryugu.

The Kolobok crater (0.7°S, 330°E, 221 m) is a very boulder-rich, saddle-shaped crater 430 on the equatorial ridge (Figures 2g, 2h). A number of 10- to 20-m angular boulders are scattered 431 on the floor, which is consistent with the boulder-rich surface around the crater. A bright and 432 mottled boulder (Sugita et al., 2019; Tatsumi et al., 2020) is exposed on the northern wall ("A" 433 in Figure 2h). This boulder could have been excavated by an impact from subsurface since it 434 435 is buried in the crater. Stereometric analyses indicate that the crater floor exhibits very rough and complex topography, most likely because numerous boulders hindered the crater 436 437 excavation process. Crater #30 excavates the western floor (Figure 2h). The floor between the crater and the angular boulder ("C" in Figure 2h) is anomalously flat (Namiki et al., 2019; 438 Sugita et al., 2019). This may be because of mass wasting from the equatorial ridge on the east, 439 or burial by ejecta deposit from the crater. The area around Kolobok is one of the most heavily 440 cratered regions on Ryugu (Hirata et al., 2020). Two craters are overlying Kolobok's northern 441 rim (Figure 2h). Across the ridge to the south, two craters are also located just outside the 442 southern rim. Such craters at different diameters provide a good sense of vertical boulder size 443 sorting on Ryugu. For example, the largest Kolobok crater shows a greater number density of 444 boulders both on the floor and on the wall, while other smaller craters (100 m and 35 m) near 445 the Kolobok crater exhibit smoother floor with boulders only on their rims. Figure 2h shows 446 that a number of boulders larger than ~10 m occur in Kolobok (D = 221 m), while crater #11 447 (D = 100 m) hosts only one such boulder and crater #41(D = 40 m) does not host any. Though 448 some of the boulders could have been transported from the outside of the crater, this trend 449 suggests that the large boulders occur in craters with a depth of >10 m, while smaller boulders 450 are buried at shallower depth of only a few meters. 451

The *Kintaro* crater is located where the Tokoyo fossa crosses the equatorial ridge (Figures 2j, k). A remarkable  $30 \times 50$  m, 10-m-high boulder is on the western wall. This boulder exhibits a very complex lithology, being a possible breccia of bright clasts embedded in darker matrix ("A" in Figure 2k). The boulder appears to have a layered structure as well. The top of the boulder is sloping towards the crater center, suggesting that it sits on the crater wall rather than being buried in the ground. This boulder may have been exposed upon the crater-forming

impact given Ryugu's microgravity condition, as observed on the SCI experiment (Arakawa et 458 al., 2020). If this extremely large boulder was excavated from the ridge upon the Kintaro-459 forming impact, the boulder should have been transported to the subsurface of the ridge before 460 the impact, when the ridge was being formed. This scenario requires a ridge formation process 461 that can transport a boulder as large as  $\sim 50$  m to the equator. The breccia-like texture of this 462 boulder suggests a low mechanical strength, which also has implications for the transportation 463 mechanism. A sharp, triangular boulder is buried at the crater floor ("B" in Figure 2k). A small 464 crater that is located just 30 m northwest of the crater rim (#69, 14 m) exhibits a smooth floor 465 with a dark center, which is commonly observed in this crater size range. Such a dark center 466 could reflect the property of the material exposed/produced at the crater center, such as highly 467 porous materials (Sakatani et al., in revision). 468

The Brabo crater (3°N, 230°E, 142 m) is located at the approximated center of the 469 470 western bulge (Figures 21) and is the largest crater on this hemisphere. This crater is comparable to the Momotaro and Kintaro craters in terms of its size and the distance from the equator, but 471 its interior is much smoother than those craters. This is consistent with the lower boulder 472 number density of the western bulge (Michikami et al., 2019). A prominent ~20-m angular 473 boulder is seen on the northwestern floor. It is unclear if this boulder was excavated from the 474 subsurface or was transported from another place on this asteroid. A smaller crater (#64, 17 m) 475 excavates the northwestern wall. The interior of this crater is even smoother than Brabo's floor 476 and its center is darker than the surrounding suggestive of a regolith property distinct from the 477 surrounding materials, as is often observed on such 10- to 20-m sized craters. 478

479 In addition to the relatively obvious craters, some quasi-circular features (QCFs) are found on Ryugu. Figure 3 shows the crater candidate located at 31°S, 284°E (crater ID=80). 480 This feature is outlined by a partially circular pattern formed by 5-10-m sized boulders 481 stretching into the Tokoyo fossa. The diameter of the QCF is 112 m. Such a circular occurrence 482 of boulders is also observed for other higher confidence craters (e.g., Figures 2h, l). The interior 483 of this QCF is not necessarily smoother than the materials outside the candidates. If this 112-484 m QCF is a crater, then the boulders and materials filling these craters require efficient material 485 486 transport or crater degradation processes. If we assume that this QCF had an original d/D of 0.1, a regolith layer thicker than 10 m would be necessary to fill up this crater. Based on the 487 topography, Matsumoto et al. (2020) proposed that an irregular depression at ~15°N, ~45°E 488 might be a highly degraded crater. However, adding this depression into the CSFD would not 489 significantly change the implied age value. Besides this irregular-shaped depression, the QCFs 490

larger than 50 m are found only on the latitudes higher than 30°. This could be an observational 491 bias because most of the high-resolution observations were conducted from Ryugu's 492 approximate equatorial plane, but the facts that the craters are less obvious in the higher 493 latitudes and the crater number density itself is lower there (Hirata et al. 2020) suggest higher 494 crater degradation rates at the higher latitudes, or different surface properties, such as cohesion 495 and boulder number density. While further study is needed to address this issue, we hypothesize 496 that this latitudinal dependence may result from fast resurfacing processes or mass movement 497 at high latitudes. 498

506 3.3 Crater morphology at different sizes

As seen in the previous section, craters on Ryugu have different morphological 507 properties (e.g., floor, infilling, rim, boulders) at different size ranges. First, the craters larger 508 than 100 m (Figures 4a-c) often contain a number of >10-m angular boulders. Such large 509 510 boulders tend to lie on the crater rim, forming a circular pattern outlining the crater. Some of these boulders are partially buried by finer materials. A few prominent boulders often remain 511 512 on the crater floor, too. Some of such intra-crater boulders were probably exposed by impact excavation as observed by the SCI impact experiment (Arakawa et al., 2020). Crater interiors 513 exhibit a complicated and hummocky morphology, but generally smoother infilling material 514 occurs while sometimes punctuated by large angular boulders. Craters on the equatorial ridge 515 have saddle-shaped floors as shown in the significantly different east-west and north-south 516 crater cross sections (Noguchi et al., 2021), presumably due to the original topography. 517 Urashima and Kolobok craters overlap the ridge, indicating that the equatorial ridge is older 518 than these craters. Some craters exhibit raised rims, suggesting gravity-controlled cratering on 519 Ryugu (Sugita et al., 2019), which is consistent with the results from the SCI experiment 520 (Arakawa et al., 2020). These large craters exhibit conical shapes rather than simple bowl 521 shapes (Namiki et al., 2019). While the ejecta from the artificial crater was darker than the 522 surrounding surface by ~20% (Arakawa et al., 2020), no obvious ejecta blankets or rays were 523 found around the natural craters. 524

525 Craters with the diameter of 20-100 m (Figures 4d-f) tend to have smoother floors than 526 larger craters, with less abundant boulders. Their floors are generally lacking boulders 527 compared to the surface around the craters, a feature consistent with smaller craters described 528 below. Some craters of ~20-30 m in diameter exhibit dark centers. Interpretations of the 529 different albedo include different grain sizes, formation of a central pit, degree of compaction, 530 freshness of the material, or crushed dark boulders. It might also be related to dark and fine 531 material lofted upon Hayabusa2 touchdown (Morota et al., 2020).

Craters smaller than  $\sim 20$  m (Figures 4g-i) are characterized by areas smoother than those of larger craters. Craters smaller than 10 m (Figure 4i) are mainly identified as a contrast in textures: smooth circular interior and rougher exterior, while it is difficult to determine if they have any bowl-like depression. This texture can be interpreted that the boulders were removed from the surface, creating a circular feature of smooth appearance outlined by apparently unaffected boulders. The boulders that have been at the impact site were likely either ejected or pulverized.

Table 3 summarizes the observations: large craters (>100 m) on Ryugu are circular or 539 saddle-shaped depressions hosting numerous >10 m boulders. They exhibit complex floor 540 morphology. This could be due to interaction with original asteroid topography and buried 541 boulders. Small craters (< 20 m) are smooth circular features lacking in boulders than their 542 exterior. Craters of ~50 m show intermediate features: smoother interior than exterior and 543 simpler floor morphology than largest craters. The general trend between boulder number 544 density and crater size (Watanabe et al., 2020) is observed, which is very similar to that 545 observed for Bennu (Walsh et al., 2019; Bierhaus et al., 2019). Compared to another rubble-546 pile asteroid Itokawa, where crater candidates are shallow and ambiguous depressions lacked 547 in raised rims, the craters on Ryugu are much more distinct and sometimes exhibit raised rims. 548

Figure 4. Morphology of craters on Ryugu at different size domains. (a-c) Large craters (D > D)550 551 100 m), typically associated with large angular boulders on their floors. 3.4 Implications for subsurface structure of Ryugu inferred from crater-floormorphology

The geomorphology of craters at different sizes provides clues on Ryugu's subsurface 570 structure. Here we discuss the vertical structure of Ryugu's shallow subsurface by comparing 571 the morphology of crater floors of different size ranges. Craters smaller than ~20 m exhibit 572 smoother interiors compared to larger craters. It is unlikely that a crater-forming impact crushes 573 all of the boulders on/below the surface to form the smooth floor because a number of intact 574 large boulders are observed in larger craters. In fact, both the SCI experiment and laboratory 575 studies show displacement of boulders in the craters rather than fragmentation of them 576 (Arakawa et al., 2020; Tatsumi & Sugita, 2018), except for the boulder directly hit by the 577 projectile. Thus, we interpret that the smooth crater floors observed for the craters with D < 20578 m suggest that the crater-forming impact removes boulders on the surface, exposing finer 579 580 materials just below the surface boulders or at very shallow ( $\sim 2$  m) subsurface (Figure 5).

Although a regional variation is observed in boulder number density (i.e., higher latitudes exhibit more boulders), the apparent richness of boulders in the craters larger than 50 m in turn implies that the finer material did not reach the depth of 5-30 m. The Kolobok crater region is a good example to explore the size sorting because three craters with different diameter occur in close proximity. The finer materials under the blocky surface could be the fragments of surface blocks produced by impact gardening and/or thermal fatigue. Alternatively, the smooth interior could be due to vertical size sorting processes on Ryugu.

Possible mechanisms for the size-sorting effect, in which larger boulders (several 588 meters) remain on the very top surface, whereas smaller boulders (< 1 m) occur just below the 589 surface, include regolith convection (Miyamoto et al., 2007), mass motion at the crater 590 591 modification stage, surface material flows, and ejecta blanketing. Regolith convection is thought to be activated by seismic shaking (Yamada et al., 2016). Though the SCI experiment 592 593 revealed low seismic efficiency at least for the impact that formed a 15 m crater (Arakawa et 594 al., 2020; Nishiyama et al., 2020), the seismic energy deposited by a large-scale impact that would form a >100-m crater, needs to be evaluated. If granular convection takes place on 595 Ryugu, this process would sort the size of particles because small particles can travel much 596 more easily while larger rocks remain at the surface. Given the boulder-rich surface of Ryugu, 597 large boulders buried under the surface might work as a wall of a convection cell. Although v-598 band images do not show clear features of ejecta around natural craters on Ryugu, the SCI 599 experiment showed a clear ejecta blanketing process (Arakawa et al., 2020), implying that 600 global ejecta blanketing can work as another sorting process. A possible explanation for size 601 sorting during crater formation is that smaller particles are ejected more easily than larger 602 particles: larger particles need higher kinetic energy and momentum to be ejected (Melosh, 603 604 1989). Also, smaller particles can also be blown off due to solar radiation pressure, solar winds, and other non-gravitational forces. Therefore, only larger boulders can come back to the 605 surface of Ryugu. The thickness and deposition rate of ejecta on Ryugu should be addressed in 606 a future study taking Ryugu's spin rate into account. The finer material inside small craters is 607 also observed on Bennu (DellaGiustina et al. 2020). Other examples of size-sorting processes 608 observed on asteroids include ponded deposits on Eros (Cheng et al., 2002). Possible processes 609 forming such extremely fine deposits include electrostatic levitation of fine materials 610 (Robinson et al., 2001) and seismic shaking (Veverka et al., 2001). Some craters on Itokawa 611 612 also exhibit similar fine deposits on crater floors (Hirata et al., 2009). In contrast, natural craters on Ryugu do not show such ultra-fine deposits on their floors. 613

615

Figure 5. Cross section of Ryugu's shallow subsurface inferred from crater morphology. A 616 few-m-thick layer of fine-grained material is inferred between the boulder-rich surface and 617 several-m deep subsurface. 618

619

#### 4 Crater chronology of Ryugu 620

In contrast to the previous section, which focused on crater morphology, this section focuses 621 622 on the history of Ryugu based on crater chronology. In section 4.1, we report the crater number density of each unit and discuss the stratigraphic relations on Ryugu. In section 4.2, the crater 623 624 size-frequency distributions of different regions on Ryugu are reported. The model ages are derived with isochron fitting. In section 4.3, we discuss the regional difference of the model 625 ages. In section 4.4, the geologic history of Ryugu is reconstructed based on the age data and 626 627 their interpretations. The ages of Ryugu as a near-Earth asteroid (after being decoupled from the main belt) and as a main-belt asteroid are discussed. In section 4.5, the spin evolution and 628 YORP effect are discussed based on the chronology data. 629

630

631

#### 4.1 Relative ages based on stratigraphic relations and crater number density

The stratigraphic relationships among the different units are not necessarily clear on 632 Ryugu because of the very limited number of cross-cutting features. The equatorial ridge at 633 least predates the largest craters that cut the ridge (Urashima, Kolobok, Momotaro, and 634 Kintaro), suggesting that the ridge is the oldest structure on Ryugu. The stratigraphic age of 635 the trough relative to the ridge, eastern hemisphere, and western bulge is unclear. The trough 636 does not appear to cut the ridge based on the topography. The trough outlines both 637 hemispheres without clear crosscutting features. The ridge formation could have been ongoing 638 when the western bulge formed because the equatorial ridge running on the western bulge is 639 almost perfectly circular as well (Watanabe et al., 2019). The Brabo crater, the largest one on 640

the bulge, should be younger than the western bulge formation. The lack of morphological 641 features representing stratigraphic relations underlines the importance of crater number 642 density measurements. 643

Crater number densities provide an independent measure of relative age for geologic 644 645 units because they are independent of chronology models. Thus, before applying the craterchronology models, the crater number densities at different units and diameter ranges were 646 647 measured (Table 4). Table 4 shows crater number densities at different diameter bins to address the processes potentially observed in different spatial/time scales. For example, crater statistics 648 649 at >100 m in diameter suggests different resurfacing history that reaches > 10 m in depth between the eastern hemisphere and western bulge. The crater records at 50-100 m show the 650 651 transition of isochrons, which suggest a resurfacing event in a short time period (see section 4.2). The similarity of crater number density N(D > 10 m) among multiple units suggests that 652 653 the timescale of erasing 10-20 m craters does not differ between the eastern hemisphere and western bulge. This is potentially because of the ongoing surface processes, such as surface 654 flow. 655

The equatorial ridge shows the highest crater number density N(D > 10 m) among the 656 units addressed in our study, although statistical significance is sometimes poor due to the small 657 number of craters on Ryugu. The crater number density of the equatorial ridge on the eastern 658 hemisphere is slightly larger than that of the ridge on the western bulge at an insignificant level. 659 The crater number density on northern and southern hemispheres are statistically equivalent, 660 but the regions at latitudes higher than 10° have significantly smaller crater number density 661 than the equatorial ridge. 662

663

Unit	Area (km <sup>2</sup> )	N(D > 10  m) (km <sup>-2</sup> )	N(D > 20  m) (km <sup>-2</sup> )	N(D > 50  m) (km <sup>-2</sup> )	N(D > 100 m) (km <sup>-2</sup> )	Model Diam age eter range (Ma) (m)

Note. Errors were calculated by  $\pm N^{1/2}/S$ , where *N* is the cumulative number of craters and *S* is the area of individual units. The Kintaro crater was not assigned to Eastern hemisphere nor Western bulge because it is located at their boundary. The data from the global crater survey were used. Absolute model ages derived in section 4.2 and diameter range used for fitting are shown.

670

671 4.2 Crater model ages

The crater size frequency distributions are constructed based on the crater list on Table 2 and fitted with the MBA- and NEA-model functions (see section 2.4 for details). First, we use the NEA chronology function to derive the age that Ryugu spent in the near-Earth orbit. Then the CSFDs in different crater size ranges are measured.

Figure 6 shows CSFDs with the global observation data and those with higher-676 resolution SCI-crater-survey images. The shape of the CSFD is consistent with that obtained 677 from a global crater catalogue at >30 m, with the crater number density twice as high as that 678 of the global CSFD. This higher crater number density is because the SCI-crater-survey 679 operation was carried out at a region that hosts craters more than Ryugu's global average 680 (Figure 1). The CSFD obtained for the SCI-crater search region exhibits a transition of 681 isochrons at  $D \sim 10-15$  m (Figure 6). The transition was not reported in the previous studies 682 because of the limitation of image resolution (0.5 m/pix). The higher-resolution images (0.2 683 m/pix) revealed the presence of the upturn in the CSFD in this diameter range and the deviation 684 from the crater production function (i.e., paucity of small craters) at craters smaller than 10 m. 685 Secondary craters will not contribute to the CSFDs because the speed of ejecta that would hit 686 the ground is limited to less than the escape velocity of 0.27 m/s. Such a slow impact would 687 688 not form an apparent crater on the ground covered with the boulders, when the target disruption energy  $Q_D^*$  is taken into account. The younger isochron at D = 10-15 m corresponds to  $0.22 \pm 0.05$  Ma with the MBA model (Figure 6a), while it yields  $7.2 \pm 1.6$  Ma with the NEA model (Figure 6b). The isochron is consistent with that of "blue craters," presumably fresh craters which are interpreted to be formed in the near-Earth orbit (Morota et al., 2020) (Figure 6b). The CSFDs for the global observation data yielded  $8.1 \pm 2.5$  Ma at D > 100 m and  $4.1 \pm 1.1$  Ma at 70-80 m with the MBA model (Figure 6a).

695

696

Figure 6. Crater size-frequency distribution obtained with the global observation campaign
(black circles) and SCI crater-search operation carried out from a lower altitude (blue circles).
The CSFD for "blue craters" (Morota et al., 2020) is shown in open squares. Data fitted with
(a) MBA model and (b) NEA model. Age errors are derived from isochron fitting.

701

Isochron fitting for the large craters on different units (> 120 m for EH and EQR, > 50 702 m for WB) yielded the absolute model ages of the equatorial ridge, eastern hemisphere, and 703 western bulge as  $23 \pm 14$  Myr,  $11.7 \pm 4.2$  Myr, and  $2.1 \pm 0.9$  Myr, respectively (Figures 7a, b). 704 Here we report MBA model ages because the craters were most likely formed in the main belt: 705 if these craters were formed in the near-Earth orbit, the surface of Ryugu would be ~30 times 706 older, which is too long for Ryugu to stay as a near-Earth asteroid in a typical dynamical 707 timescale of ~40 Ma (Michel and Delbo 2010). The eastern and western ridges were 708 statistically equivalent given the error bars. 709

- The CSFD of the western bulge shows no evidence of isochron transition at D > 40 m, suggesting a simple bombardment history in the main belt after the resurfacing of craters of all diameter ranges. In contrast, the CSFD of the eastern hemisphere using the global observation data can be divided into two regimes. The craters of 50-100 m in diameter were well fitted by an isochron of  $4.9 \pm 1.6$  Myr (MBA model), while those larger than 120 m yielded the age of  $11.7 \pm 4.2$  Myr (MBA model) (Figure 7b). However, the crater data reconstructed with the SCI crater-search images did not show the transition of the isochron on the eastern hemisphere.
- The CSFD for the *Tokoyo* and *Horai* fossae coincides with that for the western bulge (Figure7b) although the statistics is poor because the number of craters was only three.
- The CSFDs constructed for the southern and northern hemispheres outside the ridge show that the crater data on the latitudes higher than 10° do not follow the standard production function (Figure 7c).

**Figure 7.** Crater size frequency distribution and isochron fitting for the craters on (a) the equatorial ridge (10°N-10°S), (b) east/west hemispheres and fossae constructed from global observation and higher-resolution SCI crater-search (CS) images, and (c) higher latitudes (10°N-90°N and 10°S-90°S). ### 4.3 Regional difference of ages and possible reasons

We now discuss the ages of the individual units on Ryugu using the age data obtained 730 from Figures 6 and 7. Here, a near-Earth asteroid tends to be more exposed to impacts when it 731 reaches the aphelion that is near or in the main belt (O'Brien and Greenberg, 2005; Sugita et 732 al., 2019). The bombardment in the main belt continues until the orbit of the NEA is decoupled 733 from the main belt. Thus, the ages of 7 Ma (NEA chronology model) and 0.2 Ma (MBA 734 chronology model) correspond to the earliest and latest timing (upper and lower age limits) 735 when the asteroid was decoupled from the main belt, respectively (Figure 6). If the former is 736 737 the case, the  $7.2 \pm 1.6$  Myr period spent in near-Earth orbit should be added to the main-belt model ages. 738

739 First, we compare the model ages in the latitudinal direction. The equatorial ridge is the oldest structure on Ryugu, as suggested in Table 4. The isochron indicates that the asteroid 740 spent  $23 \pm 14$  Myr in the main belt (Figure 7a). For the early decoupling scenario, in which 7 741 742 Myr spent in the near-Earth orbit (Figure 6b) is added to the main-belt ages, the ridge was formed 30 Myr ago while Ryugu was rotating more than twice as fast as it is now (Watanabe 743 et al., 2019). The craters larger than 100 m might have reached the empirical saturation level, 744 745 and therefore the ridge could have been even older than 30 Ma. Nevertheless, the close proximity of large craters on Ryugu, such as Momotaro and Kibidango, suggests that 746 obliteration/modification of preexisting craters by seismic shaking is inefficient on Ryugu and 747 thus crater saturation level could be higher on this asteroid. Despite the hemispherical 748 749 resurfacing on the western bulge (discussed in the following paragraph), the crater number densities of the eastern and western ridges were statistically equivalent (Figure 7a). This result 750 is a constraint for the type and magnitude of the resurfacing process. The nonstandard crater 751 population on latitudes higher than 10° supports a continuous, gradual crater obliteration 752 process rather than a single resurfacing event that would result in a transition in isochrons. One 753 candidate process that accounts for the lack of craters only at middle-to-high latitudes would 754

be mass movement induced by evolving geopotential. The preservation of craters on the ridge 755 suggests that the mass motion did not reach the ridge to erase the craters there, possibly because 756 of the lack of movable material or because of geopotential barriers. The mass and intensity of 757 the latitudinal mass movement would be the key to addressing the crater population at the 758 middle-to-high latitudes. Another possible mechanism to make the latitudinal crater density 759 variation is that craters did not occur at the high latitudes as much as on the equator. Such crater 760 depletion on the higher latitudes could be because of different surface properties between the 761 equatorial region and the higher latitudes (e.g., cohesion, boulder size, boulder number density). 762 Although the SCI impact experiment revealed gravity-controlled cratering on the ridge 763 (Arakawa et al., 2020), further quantitative studies on armoring and cohesion are needed to 764 765 address the lack of craters on the higher latitudes.

Next, we compare the CSFDs of the eastern hemisphere and western bulge (Figure 7b). 766 First, the best-fit isochrons (i.e., those with diameter > 60 m for EH and that of > 50 m for the 767 WB) reveal that the western bulge possesses significantly smaller number of craters than the 768 eastern hemisphere, indicating the presence of dichotomy in terms of crater number density. 769 Deformation analyses provide one possible mechanism for this hemispherical, semi-global 770 resurfacing event through the relaxation of stress in the asteroid: the imperfect axisymmetric 771 772 shape of Ryugu may have induced a deformation mode that resurfaces only one side of the asteroid (Hirabayashi et al., 2019). In other words, the western bulge was resurfaced due to 773 mass movement driven by structural deformation. Note that we do not rule out any deformation 774 mode: a landslide or internal deformation. It is challenging to identify the source impact or 775 events that induced the global deformation in a reliable way, since any perturbation could have 776 induced such a relaxation (Hirabayashi et al., 2019). Nevertheless, one possible candidate 777 778 would be the Brabo crater, which is located at the center of the western bulge. If this is the case, the Brabo crater itself caused but survived the resurfacing event, a constraint on the scale and 779 mechanism of the formation of the western bulge. 780

The transition of isochrons on the eastern hemisphere at 11.7 Ma (D > 120 m) and 4.9 Ma (D = 60-110 m, Figure 7b) suggests that the craters smaller than 110 m were obliterated ~5 Myr before Ryugu left the main belt (i.e., 5 or 12 Myr before the present with MBA/NEA models). If the depth-to-diameter ratio (d/D) of a fresh crater is 0.1 on Ryugu (Noguchi et al., 2021), materials up to 10-m thick would be needed to erase the craters smaller than 100 m. One possible source of such a large-scale resurfacing is the ejecta deposition and/or topographic diffusion by Urashima, the largest crater on Ryugu. In fact, the crater number density decreases

as crater location comes closer to the Urashima crater (Figure 8). For the ejected material to 788 cover 1-4 crater radii with the thickness of 10 m, for example, 50% of the volume of Urashima 789 crater needs to be deposited on the surface. This amount of material is comparable to the result 790 of a simple model calculation using the ejecta scaling rule (Housen and Holsapple, 2011), dry-791 sand parameters, escape velocity of 0.275 m/s, as well as the Z-model (Maxwell, 1977), in 792 which approximately 80% of ejecta returns to Ryugu. The apparent lack of craters around 793 Urashima as compared to the Kolobok area (Figure 1) is consistent with this interpretation. 794 Although the seismic efficiency on Ryugu was found low by the artificial impact experiment, 795 796 the seismic shaking due to the Urashima-forming impact could also have degraded a number of craters nearby because the seismic energy with this 290-m crater formation is still high 797 enough to induce acceleration greater than the gravity (Nishiyama et al., 2020). This hypothesis 798 is also consistent with the fact that the CSFD for the eastern hemisphere does not show the 799 transition of the isochron if constructed with the data from SCI crater-search campaign, 800 801 whereas the CSFD from the global observation campaign does. This difference can be interpreted that the SCI crater-search area is far from the Urashima crater and its resurfacing 802 did not affect this area. 803

Figure 8. (a) Number density of craters larger than 10 m as a function of circular distance from the Urashima crater (crater radius  $R_c$ ). The numbers of craters in each bin (*n*) are also shown. Note that the area of  $R_c = 5-6$  includes both polar regions, where few craters are found. (b) Distribution of craters around Urashima.

810

Finally, we found that the CSFD for the Tokoyo and Horai fossae coincides with that 811 812 for the western bulge (Figure7b). This result is important because no clear stratigraphic relationships were found among the fossae and other units. Although the statistics are poor 813 because the number of craters is only three, this agreement strongly suggests that the fossae 814 were formed in association with the formation of western bulge 2 Myr (late decoupling model) 815 - 9 Myr (early decoupling model) ago. It is still unclear why the fossae are much bluer than the 816 western bulge, because the degree of space weathering should be comparable to each other. 817 One hypothesis is that the trough is even younger than the western bulge and occurred after 818 surface reddening process during Ryugu's orbital excursion 0.2-8 Myr ago (Morota et al., 819 2020). If this is the case, the resurfacing on the trough could be a geologically very recent, 820

potentially ongoing process. As described in the previous paragraph, the two fossae outlining the western bulge are likely to have formed associated with a reshaping process of the western bulge. The significantly different crater ages between the eastern hemisphere and western bulge speak against the simple two-body merge scenario as the origin of the dichotomy: the two hemispheres underwent different geologic histories. Furthermore, the poorly preserved morphology of the putative crater at 15°N, 45°E (Matsumoto et al., 2020) does not seem to support the impact origin of the recently formed western bulge.

828

### 829 4.4. History of Ryugu revealed by cratering record

In this section, we summarize Ryugu's history from the top-shape formation to the present based on the crater population data. Because the age when Ryugu was decoupled from the main belt is sometime between 7 and 0.2 Myr ago, both early- and late-decoupling cases are described (Figure 9).

The precursor top shape (i.e., the equatorial ridge) developed by 23-30 Myr ago after 834 the catastrophic disruption of Ryugu's immediate parent body (Figure 10). The crater record 835 does not provide the time of the catastrophic disruption that formed Ryugu. If we assume that 836 837 Ryugu's parent body is Eulalia or Polana, which experienced breakups 1500-3000 Myr ago (Bottke et al., 2015; Sugita et al., 2019), then Ryugu's current shape has to be formed in the 838 last 1% of that time. This time scale suggests that Ryugu is likely multiple generations younger 839 840 than, rather than is an immediate daughter asteroid of, these potential parent bodies. The age of the disruption will be revealed by radiometric dating of returned samples. As mentioned 841 earlier, the spin period may have been as fast as 3.5 hr at this time to form and enhance the 842 843 equatorial ridge (Watanabe et al., 2019; Hirabayashi et al., 2019), suggesting the long-term rotational evolution over the life of this asteroid. Because the age of 23-30 Myr is comparable 844 to the dynamical lifetime of Ryugu, the top shape might have been a direct result of disruption 845 (Michel et al. 2020). 846

While Ryugu was in the main belt, it experienced continuous impact cratering. The current topography of the eastern hemisphere formed 11-18 Myr ago. Statistically, the formation of the eastern hemisphere, as well as the original western hemisphere before the dichotomy formation, can be contemporary with the equatorial ridge (Figure 9). Nevertheless, one hypothesis to account for the apparent age gap between the ridge and the entire eastern hemisphere is that the craters at the high latitudes were erased as materials passed through the region. Another possible reason for the ~12-Myr younger eastern hemisphere, which includes the areas at higher latitudes, is that craters did not occur at the high latitudes as much as on the equator possibly because of armoring effects or different cohesion, making the eastern hemisphere appear younger compared to the equatorial ridge.

The eastern hemisphere was resurfaced 5-12 Myr ago. This 10-m thick, hemispherical resurfacing event could have been caused by the formation of the largest crater Urashima, which would have obliterated preexisting craters on a part of the eastern hemisphere via ejecta blanketing and/or seismic shaking.

2-9 Myr ago, the western bulge formed presumably with the fossae. The bulge could have been formed by the relaxation of stress in the asteroid that causes a hemispherical mass movement. This event might have modified the equatorial ridge in a way that erases craters at an insignificant level as well (Figure 7a). This resurfacing event occurred >20 Myr after the original ridge formation (Figure 7a). After this event Ryugu's spin rate slowed down to the current value of 7.6 hr likely due to the YORP effect.

Between 0.2 and 7 Myr ago, Ryugu was decoupled from the main belt to the near-Earth orbit. This age is reasonable because it is substantially younger than the typical dynamical lifetime of 40 Myr that an asteroid spends in the near-Earth orbit (Michel and Delbo, 2010). The contrast of colors of some craters on Ryugu suggests that Ryugu's orbit once was much closer to the Sun than it is now, where the asteroid would have experienced surface reddening (Morota et al., 2020). Then, Ryugu changed its orbit to the current one.

873

- Figure 9. Ages of geologic events on Ryugu. Two scenarios are illustrated: (a) Ryugu was
  decoupled from the main belt 7 Myr ago and became a near-Earth object (NEA chronology
  model); (b) Ryugu was decoupled from the main belt 0.2 Myr ago (MBA chronology model).
  Error bars show the uncertainty of the absolute model ages.
- 879
- 880

**Figure 10**. Evolution of Ryugu as revealed by this study. This study revealed the geologic history from the formation of the top-shape, to the migration from the main belt to the near-Earth orbit. Parent-body processes were discussed by Sugita et al. (2019); orbital excursion and surface reddening are after Morota et al. (2020).

886

The most recent, potentially ongoing geologic activities on Ryugu include turnover of regolith or pebbles. The residence time of individual grains shallower than ~1 m can be

estimated from the intersect of crater distribution and model isochrons at a crater diameter of 889 10 m (Sugita et al., 2019). Figure 11 shows the CSFDs of Ryugu and isochrons for the MBA 890 and NEA models. The expected age of the top 1-m layer differs between the models. Thus, the 891 galactic cosmic-ray exposure ages of returned samples, which would record the irradiation 892 history of ~1 m beneath the surface (Nagao et al., 2011), can be used for discriminating the 893 models and reconstructing the geologic history of Ryugu. The cosmic-ray exposure age of 894 returned samples would be 10-100 ka for the late-decoupling case. In contrast, the exposure 895 age would be  $\sim 1$  Ma for the early-decoupling model, because Ryugu spent  $\sim 7$  Ma in the NEO, 896 897 where much fewer meteoritic impacts take place.

898

Figure 11. Crater size-frequency distribution and model isochrons with (a) main-belt asteroid model and (b) near-Earth asteroid model. The MBA and NEA models correspond to late and early decoupling, in which Ryugu was decoupled from the main belt 0.2 Myr ago and 7 Myr ago, respectively (Figure 6). The intersects of CSFDs and model isochrons yields approximate residence time at the depth of crater excavation and could be compared with the cosmic-ray exposure age of returned sample. Horizontal line shows the empirical saturation level.

906

### 907

### 4.5 Implications for spin-state evolution

Our crater chronology data can also be used for determining the timescale of the spin-908 state evolution on Ryugu because its spin period must have been 3.5 hr (Watanabe et al., 2019; 909 Hirabayashi et al., 2019) when the western bulge formed as a result of the asymmetric 910 deformation. The spin rate could be altered by the YORP effect and impact cratering processes. 911 Mass ejection was also considered to be another contributor, but recent study showed that it 912 might be negligible for Bennu (Scheeres et al., 2020). If the western bulge of Ryugu developed 913 914 2 or 9 Myr ago (Figure 7b) when the spin period was 3.5 hr, the average YORP deceleration rate is  $1.8 \times 10^{-6}$  or  $4.1 \times 10^{-7}$  deg day<sup>-2</sup>, respectively. These values are consistent with the current 915 deceleration rate derived from the shape model of Ryugu (1.3×10<sup>-6</sup> deg day<sup>-2</sup>, Kanamaru, 2020). 916 For Bennu, light curve observations showed that the spin acceleration driven by the YORP 917 effect is  $(2.64 \pm 1.05) \times 10^{-6}$  deg day<sup>-2</sup> (Nolan et al., 2019). The magnitude of the YORP effect 918 strongly depends on the local topography of individual asteroids (Statler, 2009). We can 919 nevertheless estimate the timescale of the YORP effect on Ryugu by that of Bennu, with a 920 simple conversion of the asteroid dimensions. The timescale of angular velocity ( $\omega$ ) change 921 922 due to the YORP effect is  $\dot{\omega} = \tau/I \sim 1/A^2$ , where  $\tau$  is the torque induced by the YORP effect, I is the moment of inertia, and A is the diameter of an asteroid. Here,  $I \propto A^5$  and  $\tau \propto A^3$ . 923 Considering that the bulk density and the shape are similar for both Ryugu and Bennu, the 924 equivalent diameters of Bennu (~535 m) and Ryugu (870 m) give the YORP timescale of 925 Ryugu ~0.38 times that of Bennu, or  $(1.0 \pm 0.4) \times 10^{-6} \text{ deg day}^{-2}$ . The magnitude of this value, 926 which is converted from Bennu's observed spin-up rate, is consistent with the spin-down rate 927 obtained from crater chronology for Ryugu within a factor of 3. Despite the strong local-928 topography dependence, the agreement of these YORP rates indicates that the magnitude of 929 the YORP effect observed for Bennu is sufficient to account for the spin rate change of Ryugu. 930 In addition, the agreement of the YORP timescales in turn suggests that western bulge was 931 resurfaced 0.2-7 Myr ago when Ryugu was spinning approximately twice as fast as it is now. 932

### 934 **5 Conclusions**

In this study, we reported the morphology of craters on Ryugu and used the crater 935 population to decipher the geologic history of this C-type, rubble-pile asteroid. We used the 936 high-resolution images obtained by the telescopic optical navigation camera on board the 937 Hayabusa2 spacecraft. Our observations revealed that the abundant boulders on/under the 938 surface of Ryugu affect crater morphology. For example, the craters exhibit relatively simple 939 circular depressions, which was not the case for the rubble-pile asteroid Itokawa. The craters 940 941 on the equatorial ridge show saddle-shaped floors due to the original, pre-impact topography. The craters are typically outlined by the circular pattern of boulders remaining on the rim. 942 943 Large craters (diameter >100 m) host abundant and sometimes unproportionally large boulders 944 on their floors. In contrast, small craters (<20 m) are characterized by much smoother circular 945 floors in the middle of the boulder-rich surface of Ryugu. Such small craters also tend to have 946 dark centers, of unclear origin. The correlation between crater size and boulder number density, which was also observed on Bennu, suggests the presence of processes that sort the boulders 947 948 by size in the shallow (a few m) subsurface.

Furthermore, the crater size-frequency distributions (CSFDs) of different regions on 949 Ryugu revealed the complex geologic history on this only 1-km asteroid (Figure 10). Our crater 950 counting analyses and the crater chronology model for Ryugu indicate that Ryugu was 951 transferred to a near-Earth orbit and decoupled from the main belt 0.2-7 Myr ago. The galactic 952 cosmic-ray exposure ages of returned samples would be used for constraining the time when 953 Ryugu was decoupled from the main belt: the ages should be  $\sim 1$  Ma for the early-decoupling 954 model (Ryugu spent 7 Myr in NEO), while they should be 10-100 ka for the late-decoupling 955 956 scenario (Ryugu spent 0.2 Myr in NEO). Taking the period Ryugu spent in the near-Earth orbit into account, the equatorial ridge is the oldest structure of Ryugu and formed 23-30 Myr ago. 957 958 Ryugu was then partially resurfaced possibly by the impact that formed Urashima at 5-12 Ma, followed by a hemispherical resurfacing event that formed the western bulge at 2-9 Ma. The 959 crater number density on the trough was comparable to that on the western bulge, suggesting 960 that Tokoyo and Horai fossae were formed associated with the resurfacing of the western bulge 961 2-9 Myr ago. Deformation analyses conducted by previous studies suggest that such a 962 hemispherical resurfacing could have been caused by the relaxation of stress in the asteroid, 963 964 providing a mechanism that accounts for the east-west dichotomy of Ryugu. The spin rate of Ryugu was then slowed down plausibly due to the YORP effect, because the size-corrected 965

timescale for the spin-down of Ryugu is comparable to the YORP spin-up timescale measured
 for Bennu. This observation further supports the late hemispherical resurfacing on this asteroid.

### 968 Acknowledgments and Data

The authors thank Dr. Lillian R. Ostrach and an anonymous reviewer for their extensive 969 and insightful reviews of the manuscript. We thank the Hayabusa2 team for data acquisition 970 and spacecraft operation. This study was supported by the JSPS Core-to-Core program 971 "International Planetary Network", JSPS Grant-in-Aid KAKENHI (grant numbers 972 JP19K14778, JP20H04607, JP20H00194, JP19H00727, JP17KK0097, JP17H06459, 973 974 JP19H01951), the Astrobiology Center Program of National Institutes of Natural Sciences (NINS) (grant number AB311012), and the NASA Hayabusa2 Participating Scientist program 975 (grant number NNX17AB36G to CME).
