Abstract

We apply a coarse-grained decomposition of the ocean's surface geostrophic flow derived from satellite and numerical model products. In the extra-tropics we find that roughly 60% of the global surface geostrophic kinetic energy is at scales between 100 km and 500 km, peaking at ~300 km. Our analysis also reveals a clear seasonality in the kinetic energy with a spring peak. We show that traditional mean-fluctuation (or Reynolds) decomposition is unable to robustly disentangle length-scales since the time mean flow consists of a significant contribution (greater than 50%) from scales <500 km. By coarse-graining in both space and time, we find that every length-scale evolves over a wide range of time-scales. Consequently, a running time-average of any duration reduces the energy content of all length-scales, including those larger than 1000 km, and is not effective at removing length-scales smaller than 300 km. By contrasting our spatio-temporal analysis of numerical model and satellite products, we show that the AVISO gridded product suppresses temporal variations less than 10 days for all length-scales, especially between 100 km and 500 km.

A coarse-grained decomposition of surface geostrophic kinetic energy in the global ocean

16 Abstract

We apply a coarse-grained decomposition of the ocean's surface geostrophic flow 17 derived from satellite and numerical model products. In the extra-tropics we find that 18 roughly 60% of the global surface geostrophic kinetic energy is at scales between 100 km 19 and 500 km, peaking at ≈ 300 km. Our analysis also reveals a clear seasonality in the 20 kinetic energy with a spring peak. We show that traditional mean-fluctuation (or Reynolds) 21 decomposition is unable to robustly disentangle length-scales since the time mean flow 22 consists of a significant contribution (greater than 50%) from scales < 500 km. By coarse-23 graining in both space and time, we find that every length-scale evolves over a wide range of time-scales. Consequently, a running time-average of any duration reduces the energy 25 content of all length-scales, including those larger than 1000 km, and is not effective at 26 removing length-scales smaller than 300 km. By contrasting our spatio-temporal anal-27 vsis of numerical model and satellite products, we show that the AVISO gridded prod-28 uct suppresses temporal variations less than 10 days for all length-scales, especially be-29 tween 100 km and 500 km. 30

³¹ Plain Language Summary

Traditionally, 'eddies' are identified as transient features that vary in time relative 32 to a background time mean flow. As such, a 'mean' flow does not necessarily imply a large 33 length-scale flow. For example, standing eddies or stationary meanders due to topographic 34 interactions have little variation in time, but can still have significant energy at small 35 length scales. Similarly, 'eddy', 'time-varying' or 'transient' do not necessarily imply small 36 length-scale, with examples including the large-scale transient motions from Rossby waves 37 or fluctuations of the Kuroshio Current. Hence, the traditional time average approach 38 offers no control over the specific physical length that divides oceanic flow into 'large' 39 and 'small'. That is, the length-scales constituting the large-scale flow cannot be var-40 ied/controlled by time averaging in a manner that is consistent with length-scales resolved 41 in a coarse climate simulation. 42

We consider a coarse-graining method to studying geostrophic ocean currents with this method consistent with our notions of 'mesoscale' as defined by a length scale. Our approach is directly relevant to scale-aware parameterization requirements of coarse-resolution simulations, since we are directly focused on length-scales of the flow fields. To illustrate the coarse-graining method, and to add understanding to the oceanic flows analyzed here, we present the first global characterization of kinetic energy content and its temporal variation as decomposed by coarse-graining according to precisely defined length-scales.

50 1 Introduction

The oceanic circulation emerges from a suite of linear and nonlinear dynamical pro-51 cesses that act over a broad range of space and time scales. The flow field is markedly 52 inhomogeneous and characterized by waves, instabilities, and turbulent eddies, each of 53 which are subject to a variety of energetic sources and sinks. The mesoscale defines a 54 key band of spatial scales where ocean flows are largely geostrophic and where kinetic 55 energy peaks (Wunsch, 2007). Correspondingly, it is widely recognized that flow at the 56 ocean mesoscales, and its response to changes in atmospheric forcing, are fundamental 57 to the large-scale circulation and central for regional and global transport of heat and 58 biogeochemical tracers (Ferrari & Wunsch, 2009). 59

However, significant gaps remain in our understanding of the mesoscale flows and
 their role in ocean circulation and climate. In particular, from a numerical modeling per spective, despite the ever-increasing ability to conduct simulations with mesoscale eddy rich general circulation models (GCMs), accurately resolving these scales in routine climate-

scale (order centuries and longer) simulations remains prohibitively expensive; e.g., (Griffies
 et al., 2015). We are thus confronted with the need for mesoscale eddy parameterizations
 for the foreseeable future (Pearson et al., 2017).

A central question of physical oceanography, and in particular the eddy parame-67 terization problem, concerns a characterization of flow features according to length-scale. 68 This question motivates the goal of this paper, which is to provide a length-scale decom-69 position of the global ocean geostrophic kinetic energy, and to study the seasonal vari-70 ations of this decomposition. This goal has previously been unavailable due to limita-71 72 tions of the commonly used Fourier spectral methods, which are unsuited to global ocean analysis due to the complex geometry of ocean basins. We thus make use of a coarse-73 graining method that does not share the limitations of Fourier analysis. This paper thus 74 serves to detail the use of coarse-graining for the purpose of decomposing ocean kinetic 75 energy, and in so doing we uncover some rather novel features of the ocean surface cir-76 culation as a function of length scale. 77

78

1.1 Limitations of Fourier methods for the ocean

It is common to quantify the spectral distribution of ocean kinetic energy via Fourier 79 transforms computed either along transects or within regions; e.g., Fu and Smith (1996); 80 Chen et al. (2015); Rocha et al. (2016); Khatri et al. (2018); O'Rourke et al. (2018); Cal-81 lies and Wu (2019). This approach has rendered great insights into the length scales of 82 oceanic motion and the cascade of energy through these scales (Scott & Wang, 2005; Scott 83 & Arbic, 2007; Arbic et al., 2012, 2013, 2014). However, it has notable limitations for 84 the ocean where the spatial domain is generally not periodic, thus necessitating adjust-85 ments to the data (e.g., by tapering) before applying Fourier transforms. Methods to pro-86 duce an artifically periodic dataset can introduce spurious gradients, length-scales, and 87 flow features not present in the original data (Sadek & Aluie, 2018). A related limita-88 tion concerns the chosen region size, with this size introducing an artificial upper length 89 scale cutoff. In this manner, no scales are included that are larger than the region size 90 even if larger structures exist in the ocean. Furthermore, the data is typically assumed 91 to lie on a flat tangent plane to enable the use of Cartesian coordinates. However, if the 92 region becomes large enough to sample the earth's curvature, then that puts into ques-93 tion the use of the familiar Cartesian Fourier analysis of sines and cosines. The use of 94 spherical harmonics, common for the atmosphere, is not suitable for the ocean, again since 95 the ocean boundaries are complex. These limitations mean that in practice, Fourier meth-96 ods are only suited for open ocean regions away from boundaries, and over a rather lim-97 ited regional size. 98

99

1.2 Eddy and mean flow decomposition using time averages

A traditional approach to extract the "eddies" from a flow uses time averaging. This 100 approach is relatively simple operationally and it accords with the common practice in 101 atmospheric and oceanic sciences of studying long-term climate means and fluctuations 102 relative to that mean. As part of this decomposition for turbulent flow, we typically uti-103 lize the time averaging operator as a Reynolds averaging (RA) operator, whereby the 104 average of a fluctuating quantity vanishes (Vallis, 2017). This assumption is largely based 105 on practical considerations, with Reynolds averages strictly holding only for ensemble 106 averages that are unavailable for most applications. 107

However, within the traditional decomposition, 'time mean' flow does not necessarily imply a large length-scale flow as we shall discuss in this paper. For example, standing eddies or stationary meanders due to topography (Youngs et al., 2017) have little temporal fluctuations but can have much structure at length-scales $\mathcal{O}(100)$ km or smaller. Similarly, with a temporal decomposition, 'eddy' does not necessarily imply small lengthscale. For example, a time averaging based decomposition would ascribe eddying motion to large-scale Rossby waves (Kessler, 1990) or variations in the Kuroshio Current's
 path (Kawabe, 1995).

Moreover, by construction, an eddy-mean decomposition limits our ability to an-116 alyze temporal variability (from intra-annual to inter-annual, (Bryan et al., 2014; Griffies 117 et al., 2015)) of the multiscale coupling and evolution of different length-scales, includ-118 ing those that need to be resolved/predicted in global climate (coarse-grid) models. There-119 fore, it offers limited guidance for coarse-resolution models and no control over the spe-120 cific physical length which partitions oceanic flow into 'large' and 'small.' In other words, 121 122 the set of length-scales constituting the large-scale flow cannot be varied/controlled to be consistent with those length-scales resolved in a coarse climate simulation. In this sense, 123 the traditional decomposition cannot help with current efforts to develop 'scale-aware' 124 parameterizations (Ringler et al., 2013; Zanna et al., 2017; Pearson et al., 2017; Jansen 125 et al., 2019). 126

1.3 Coarse-graining

127

In order to understand the multiscale nature of oceanic flows, while simultaneously 128 resolving them in space and in time, we use a "coarse-graining" framework that is rel-129 atively new in large-scale physical oceanography (Aluie et al., 2018; Busecke & Abernathey, 130 2019; Srinivasan et al., 2019; Schubert et al., 2020; Rai et al., 2021; Barkan et al., 2021). 131 It is a very general approach to analyzing complex flows, with rigorous foundations ini-132 tially developed to model (Germano, 1992; Meneveau, 1994) and analyze (Eyink, 1995, 133 2005) turbulence. Aluie (2017) provides a theoretical discussion of coarse-graining and 134 its connection to other methods in physics. The approach has been recently generalized 135 to account for the spherical geometry of flow on Earth (Aluie, 2019), and applied to study 136 the nonlinear cascade in the North Atlantic from an eddying simulation (Aluie et al., 2018). 137

The coarse-graining framework is very useful from the standpoint of ocean subgrid 138 scale parameterizations (Fox-Kemper et al., 2011; Zanna et al., 2017; Khani et al., 2019; 139 Jansen et al., 2019; Haigh et al., 2020; Stanley et al., 2020; Grooms et al., 2021). Namely, 140 it provides a theoretical basis for constructing subgrid closures that faithfully reflect the 141 dynamics at unresolved scales. A primary objective in ocean modeling is practical: an 142 accurate subgrid parameterization that is numerically stable. Significant advances have 143 been achieved in this regard in the fluid dynamics and turbulence community (Piomelli 144 et al., 1991; Buzzicotti et al., 2018; Linkmann et al., 2018), and the field of large-eddy 145 simulation (LES) is well-established (Meneveau & Katz, 2000). 146

Our use of coarse-graining supports the needs of parameterization, but our primary 147 objective is to characterize the fundamental dynamics of the flow at *all* length scales. 148 Even within the wider fluid dynamics community, much less work has been done in this 149 regard, i.e. using coarse-graining as a "probe" of the fundamental scale-physics. For ex-150 ample, LES sub-grid parameterization studies are seldom concerned with using coarse-151 graining to probe the energy pathways across the entire range of scales, such as the cas-152 cade (Eyink, 1995; Eyink & Aluie, 2009; Kelley & Ouellette, 2011; Aluie et al., 2012; Rivera 153 et al., 2014; Buzzicotti et al., 2018), forcing (Aluie, 2013; Rai et al., 2021), dissipation 154 (Zhao & Aluie, 2018), or the range of coupling between different scales (Eyink, 2005; Aluie 155 & Eyink, 2009). 156

As an important case in point, despite LES being a well established field in fluid 157 dynamics since the seminal works of Leonard (1974) and Germano (1992), the idea of 158 using coarse-graining in physical space to extract the energy content at different scales; 159 160 i.e., the spectrum, was only recently established and demonstrated by Sadek and Aluie (2018). This method is central to our calculation here of the spectrum for the oceanic 161 general circulation. A main advantage of coarse-graining is that it allows us to decom-162 pose different length scales in a flow, at any geographic location and any instant of time, 163 without relying on assumptions of homogeneity, isotropy or domain periodicity. This gen-164

erality makes it ideally suited for studying oceanic flows with complex continental boundaries over the entire globe or in any particular regions of interest and at any time.

167 1.4 Key results and outline of this paper

In this paper we make use of the coarse-graining method on a satellite sea surface 168 product and a global ocean simulation. To directly compare the two products, we focus 169 on geostrophic components to the horizontal surface velocity as diagnosed from sea level. 170 We here highlight the key novel results from this analysis. First, we show that $\approx 60\%$ 171 of the extra-tropical surface geostrophic kinetic energy, as estimated by satellite sea sur-172 face observations and a global ocean simulation, resides at scales between 100 km and 173 500 km, peaking at \approx 300 km. We also show that these scales exhibit a clear season-174 ality, with kinetic energy peaking in spring. Furthermore, we demonstrate how coarse-175 graining allows us a new way to compare observations with models. In particular, com-176 paring data from a numerical simulation with gridded satellite observations reveals that 177 the satellite analysis misrepresents the evolution of all length-scales over time-scales less 178 than ≈ 10 days, with the mis-representation being more pronounced at scales ≤ 500 km. 179 We show that this misrepresentation is due to the temporal averaging required to con-180 struct the gridded satellite product. 181

The paper is organized as follows. In Section 2 we give details on the coarse-graining 182 and the Reynolds averaging methods used in this work. In Section 3 we present the data 183 products used in our analysis. In Section 4 we discuss the main results from this anal-184 ysis, following the coarse-graining decomposition such as the measurement of the energy 185 spectrum, and the comparison with the traditional Reynolds average decomposition. At 186 the end of Section 4 we introduce the combined spatio-temporal decomposition and com-187 pare satellite and numerical model data. In Section 5 we present our conclusions. Ap-188 pendix A discusses some technical choices used when coarse-graining. 189

¹⁹⁰ 2 Coarse-graining for the ocean

In this section, we discuss the coarse-graining framework and how it is used to partition energy across length scales. We also discuss the traditional approach of temporalbased Reynolds averaging, in which the flow is decomposed into a mean and fluctuating components.

195

198

204

2.1 Basics of coarse-graining on the sphere

For any scalar field, $F(\mathbf{x})$, we can calculate its coarse-grained (or low-pass filtered) version, $\overline{F}_{\ell}(\mathbf{x})$, by convolving $F(\mathbf{x})$ with a normalized filter kernel $G_{\ell}(\mathbf{r})$,

$$\overline{F}_{\ell}(\mathbf{x}) = G_{\ell} * F(\mathbf{x}) \tag{1}$$

where *, in the context of this work, is convolution on the sphere (Aluie, 2019), **x** is geographic location on the globe, and the kernel $G_{\ell}(\mathbf{x})$ can be any non-negative function that is spatially localized (*i.e.* it goes to zero fairly rapidly as $\mathbf{x} \to \pm \infty$). The parameter ℓ is a length-scale related to the kernel's "width." We use the notation $\overline{(\cdots)}_{\ell}$ to denote a coarse-grained field. The kernel is area normalized for all ℓ , so that

$$\int G_{\ell}(\mathbf{x}) \,\mathrm{d}\mathcal{S} = 1,\tag{2}$$

where dS is the area element on the sphere. Correspondingly, the convolution (1) may be interpreted as an average of the function F within a region of diameter ℓ centered at location \mathbf{x} . By construction, at each point in space, \mathbf{x} , the coarse-grained field, $\overline{F}_{\ell}(\mathbf{x})$, contains information about the scale ℓ . The above formalism holds for coarse-graining scalar fields. To coarse-grain a vector field on a sphere generally requires more work (Aluie, 2019). However, since we are concerned only with the surface geostrophic velocity, $\mathbf{u}(\mathbf{x}, t)$, in this work, it greatly simplifies our analysis. We assume the geostrophic velocity is non-divergent on the two-dimensional spherical surface, so that it is related to the geostrophic streamfunction ψ via

$$\mathbf{u} = \hat{\boldsymbol{e}}_r \times \nabla \psi, \tag{3}$$

with $\hat{\boldsymbol{e}}_r$ the radial unit vector in spherical coordinates, $\psi = \eta g/f$, η the free sea surface height (SSH), and the Coriolis parameter, $f = 2\Omega \sin(\phi)$, is a function of latitude ϕ , where Ω is Earth's spin rate.

Aluie (2019) showed that for non-divergent vector fields such as in eq. (3), coarsegraining **u** is equivalent to coarse-graining each of its Cartesian components. We therefore transform the vector from spherical (u_r, u_λ, u_ϕ) to planetary Cartesian coordinates (u_x, u_y, u_z) via:

222
222
223

$$u_{x} = u_{r} \cos(\lambda) \cos(\phi) - u_{\lambda} \sin(\lambda) - u_{\phi} \cos(\lambda) \sin(\phi)$$
223

$$u_{y} = u_{r} \sin(\lambda) \cos(\phi) + u_{\lambda} \cos(\lambda) - u_{\phi} \sin(\lambda) \sin(\phi)$$
(4)

$$u_y = u_r \sin(\lambda) \cos(\phi) + u_\lambda \cos(\lambda) - u_\phi \sin(\lambda) \sin(\phi)$$

$$u_z = u_r \sin(\phi) + u_\phi \cos(\phi)$$

where λ , ϕ are longitude and latitude, respectively, and u_{λ} , u_{ϕ} are the zonal and meridional velocity components, respectively. The radial velocity component, $u_r = 0$ for the geostrophic flow. We apply the spherical convolution operation in eq. (1) to each of u_x , u_y , u_z as scalar fields to obtain the corresponding coarse-grained fields $\overline{u_x}$, $\overline{u_y}$, $\overline{u_z}$, then retrieve the coarse-grained velocity, $\overline{\mathbf{u}}_{\ell}$ in spherical coordinates via

$$\begin{array}{ll} \text{coarse-grained radial flow} = \overline{u_x}\cos(\lambda)\cos(\phi) + \overline{u_y}\sin(\lambda)\cos(\phi) + \overline{u_z}\sin(\phi) = 0\\ \text{coarse-grained zonal flow} = -\overline{u_x}\sin(\lambda) + \overline{u_y}\cos(\lambda) \\ \text{coarse-grained meridional flow} = -\overline{u_x}\cos(\lambda)\sin(\phi) - \overline{u_y}\sin(\lambda)\sin(\phi) + \overline{u_z}\cos(\phi) \end{array}$$
(5)

That the 'coarse-grained radial flow' (i.e. vertical flow, parallel to gravity) vanishes is not obvious and was proved in Aluie (2019) and demonstrated numerically in Teeraratkul and Aluie (2021).

We emphasize that the coarse-graining algorithm we just described is valid only for non-divergent vectors such as **u** in eq. (3). Significant errors can arise for a general flow field (Teeraratkul & Aluie, 2021), where the complete coarse-graining formalism of Aluie (2019) is necessary (e.g. Aluie et al. (2018)).

242

248

214

We use the following coarse-graining kernel

$$G_{\ell}(\mathbf{x}) = \frac{A}{2} \left(1 - \tanh\left(10\left(\frac{\gamma(\mathbf{x})}{\ell/2} - 1\right)\right) \right), \tag{6}$$

as shown in Figure 1. It is essentially a top-hat kernel (Pope, 2001) but with graded edges to avoid numerical artifacts from the non-uniform discrete grid on the sphere. We use geodesic distance, $\gamma(\mathbf{x})$, between any location $\mathbf{x} = (\lambda, \phi)$ on Earth's surface relative to location (λ_0, ϕ_0) where coarse-graining is being performed, which we calculate using

$$\gamma(\mathbf{x}) = R_{\text{Earth}} \arccos \left[\sin(\phi) \sin(\phi_0) + \cos(\phi) \cos(\phi_0) \cos(\lambda - \lambda_0) \right].$$
(7)

with $R_{\text{Earth}} = 6371$ km for Earth's radius. In eq. (6), A is a normalization factor, evaluated numerically, to ensure G_{ℓ} area integrates to unity as per equation (2). In general, we are not restricted to this choice of kernel; however, we use it because of its well-defined characteristic width ℓ . Indeed, a convolution with G_{ℓ} in equation (6) is a spatial analogue to an ℓ -day running time-average.

Figure 1. The coarse-graining kernel from equation (6), which is essentially a top-hat kernel (or moving window) along with graded edges to avoid numerical artifacts from the non-uniform discrete grid on the sphere. Geodesic distance $\gamma(\mathbf{x})$ is relative to location \mathbf{x}_0 where coarsegraining is being applied. This plot is for the un-normalized kernel, $\frac{1}{4}G_{\ell}(\mathbf{x})$, with $\ell = 200$ km. It is a spatial analogue for an ℓ -day window for a running time-average.

2.2 Partitioning the geostrophic kinetic energy

From the coarse-grained horizontal geostrophic velocity field, $\overline{\mathbf{u}}_{\ell}(\mathbf{x},t)$, following equa-255 tion (1) as prescribed in (Aluie, 2019), we partition kinetic energy (KE) into different 256 sets of length-scales: 257

$$\mathcal{E} = \frac{1}{2} |\mathbf{u}(\mathbf{x}, t)|^2 \qquad \text{(bare KE)} \qquad (8)$$

259

258

254

$$\mathcal{E}_{\ell} = \frac{1}{2} |\overline{\mathbf{u}}_{\ell}(\mathbf{x}, t)|^{2} \qquad (\text{coarse KE}) \qquad (9)$$
$$\mathcal{E}_{<\ell} = \frac{1}{2} \left(\overline{|\mathbf{u}(\mathbf{x}, t)|_{\ell}^{2}} - |\overline{\mathbf{u}}_{\ell}(\mathbf{x}, t)|^{2} \right) \qquad (\text{fine KE}). \qquad (10)$$

264

The "bare KE" in equation (8) is the KE per unit mass (m^2/s^2) of the original geostrophic 262 flow that includes all scales; "coarse KE" in equation (9) represents energy of the coarse-263 grained geostrophic flow at length-scales larger than ℓ ; and "fine KE" in equation (10) accounts for geostrophic energy at scales smaller than ℓ , which we discuss more in the 265 following two paragraphs. Partitioning geostrophic energy across scales is not trivial since 266 one needs to ensure that such quantities are physically valid in the sense described by 267 Germano (1992) and Vreman et al. (1994). In particular, it is important to ensure that 268 the partitioned kinetic energy is (i) positive semi-definite (> 0) at every x and every time, 269 and (ii) that summing the partitions yields the total energy. 270

While it is clear that $\mathcal{E}_{\ell} \geq 0$ in equation (9), this property is not obvious for $\mathcal{E}_{<\ell}$ 271 in equation (10). Moreover, it may not be obvious why $\mathcal{E}_{<\ell}$ should represent energy at 272 scales smaller than ℓ . Vreman et al. (1994) showed that $\mathcal{E}_{<\ell} \geq 0$ if $G_{\ell} \geq 0$, whereas 273 $\mathcal{E}_{<\ell}$ can be negative if the coarse-graining kernel G_{ℓ} is not positive semi-definite. A proof 274 using convexity of the $(...)^2$ operation illustrates why the first term $\overline{|\mathbf{u}(\mathbf{x},t)|^2}_{\ell}$ in eq. (10) 275 has an overbar rather than defining fine KE as $(|\mathbf{u}(\mathbf{x},t)|^2 - |\overline{\mathbf{u}}_{\ell}(\mathbf{x},t)|^2)/2$. The proof from 276 Sadek and Aluie (2018) is as follows. When using $G_{\ell} \geq 0$, coarse-graining $\overline{(\ldots)}_{\ell}$ is a 277 local averaging operation. From Jensen's inequality (Lieb & Loss, 2001), we know that 278 $\overline{[\mathcal{F}(\mathbf{u})]}_{\ell} \geq \mathcal{F}(\overline{\mathbf{u}}_{\ell})$ for any convex operation, \mathcal{F} . Since $\mathcal{F}(\mathbf{u}) = |\mathbf{u}|^2$ is convex, we are 279

guaranteed that $\overline{|\mathbf{u}(\mathbf{x},t)|_{\ell}^2} \geq |\overline{\mathbf{u}}_{\ell}(\mathbf{x},t)|^2$ and, therefore, $\mathcal{E}_{<\ell} \geq 0$ if the kernel $G_{\ell}(r) \geq 0$, which is the case for our study (see equation (6)).

Regarding condition (ii) on the sum of energy partitions, Aluie (2019) proved that (for a normalized G_{ℓ}) the coarse-graining operation on the sphere in equation (1) preserves the spatial average of any field, $\{\overline{F}_{\ell}(\mathbf{x})\} = \{F(\mathbf{x})\}$, where $\{\ldots\} = (Area)^{-1} \int d\mathcal{S}(\ldots)$. Therefore, we have $\{\overline{|\mathbf{u}|_{\ell}^2}\} = \{|\mathbf{u}|^2\}$. This property guarantees that the sum of coarse KE and fine KE yields the total kinetic energy after integrating in space and in the absence of land,

$$\{\mathcal{E}\} = \{\mathcal{E}_{\ell}\} + \{\mathcal{E}_{<\ell}\}. \tag{11}$$

Eq. (11) justifies our interpretation of $\mathcal{E}_{<\ell}$ as energy at scales smaller than ℓ , since it is the difference between bare and coarse kinetic energy, on average, while also being positive locally.

292

288

2.3 Treatment of land-sea boundaries

In the above decomposition of energy, a choice has to be made in the presence of land. We here discuss three possibilities along with their pros and cons.

295 Deformed kernel

The "deformed kernel" approach is realized by coarse-graining ocean points near land with a kernel that is deformed or masked to avoid overlapping with land points. Such a deformed kernel must be renormalized to yield an average over just ocean points rather than the whole sphere. The main advantage of this approach is that it treats land as a well-defined boundary that is separate from the ocean regardless of the coarse-graining length-scale. It is also familiar to ocean modelers who routinely mask values over land and do not include such masked values when performing area averages.

However, the deformed kernel has disadvantages that motivate against its use for 303 coarse-graining ocean flows. First, a kernel that is inhomogeneous (*i.e.* changes shape depending on geographic location) does not conserve domain averages, including the ki-305 netic energy of the flow. The reason for this failed conservation is detailed in Appendix 306 A and demonstrated in Figure 2 (blue plot). This figure shows how a kernel that is de-307 formed (via masking) to exclude land does not yield 100% of the total energy, *i.e.*, it does 308 not satisfy equation (11). As a result, it can yield total energy that is either less than 309 100% (e.g., over scales larger than 500 km in Figure 2) or greater than 100% (e.g., be-310 tween 100 km and 400 km in Figure 2). 311

For some purposes, the total energy values in Figure 2 are fairly close to 100% (de-312 viations less than 1%) so one might argue that the deformed kernel is suitable in prac-313 tice. Nonetheless, a more basic reason to avoid deformed kernels is that such inhomo-314 geneous kernels (which also include averaging values at adjacent grid-cells or block-averaging 315 on the sphere) do not commute with spatial derivatives. Consequently, the coarse-grained 316 field resulting from a deformed kernel is not guaranteed to satisfy fundamental flow prop-317 erties exhibited by the unaveraged flow, such as incompressibility, geostrophy, and the 318 vorticity present at various scales. These considerations are further detailed in Aluie et 319 al. (2018) and Aluie (2019). 320

Fixed kernel

321

The "fixed kernel", also shown in Figure 2, is homogeneous so that it preserves its shape at all locations. When coarse-graining ocean points near land such that the kernel overlaps land points, we treat land points in a manner consistent with the boundary conditions between land and ocean. For example, if we are coarse-graining the velocity, we treat land as water with zero velocity, which is consistent with the formulation of OGCMs where land is often treated as a region of zero velocity. Furthermore, we include these zero land values as part of the coarse-graining operation.

This choice may seem unnatural since we are including unphysical values within 329 the coarse-graining operation. However, it is helpful to think of coarse-graining as an op-330 eration analogous to removing one's eyeglasses, rendering an image fuzzy and boundaries 331 less well-defined. When coarse-graining at a scale ℓ , the precise boundary between land 332 and ocean becomes blurred at that scale and its precise location becomes less certain. 333 The coarse-grained velocity, $\overline{\mathbf{u}}_{\ell}$, can be nonzero within a distance $\ell/2$ beyond the con-334 tinental boundary over land. Forfeiting exact spatial localization in order to gain scale 335 information is theoretically inevitable due to the uncertainty principle, which prevents 336 the simultaneous localization of data in physical-space and in scale-space (Stein & Weiss, 337 1971; Sogge, 2008). The main advantage of the "Fixed Kernel" choice is ensuring that 338 coarse-graining and spatial derivatives commute so that it preserves the fundamental phys-339 ical properties of the flow. Further discussion of these issues can be found in Aluie et al. 340 (2018) and Aluie (2019). 341

³⁴² Fixed kernel with or without land

After coarse-graining the velocity field with a fixed kernel, we show in Figure 2 the 343 level of energy conservation if we include or exclude land points from the final tally of 344 kinetic energy. We call these, respectively, the "fixed kernel w/ land" and "fixed kernel 345 w/o land". The latter (orange plot) highlights how coarse-graining smears energy onto 346 land (within $\ell/2$ distance inland) such that if we exclude land from the final tally, we 347 find some leakage of energy onto land, which increases as the coarse-graining scale ℓ in-348 creases. We find energy leakage of the order of 1% at coarse-graining scales < 100 km, 349 $\approx 4\%$ for scales $\lesssim 500$ km, and up to 12% at scales of order 2000 km. However, if we 350 choose to include land in our final tally, we are guaranteed to conserve 100% of the en-351 ergy by satisfying equation (11), thus ensuring that the energy budget is fully closed. Af-352 ter all, in an ocean model on a discrete grid, the land boundary is only expected to be 353 accurate within a Δx distance from any estimate of the truth, where Δx is analogous 354 to our coarse-graining scale ℓ . 355

What we use here

While we have implemented all three approaches to coarse-graining (see Figure A1 357 in Appendix A), unless otherwise stated in this work, we choose the fixed kernel w/ land 358 by including land regions that have non-zero velocity (again, as realized through leak-359 age from nearby ocean values). We have checked that our results in all figures shown are 360 almost indistinguishable from choosing fixed kernel w/o land due to the relatively small percentage of energy leakage involved in Figure 2. We avoid coarse-graining with a de-362 formed kernel to remain consistent with previous work Aluie et al. (2018) and with forth-363 coming studies where we apply coarse-graining to the dynamical equations where com-364 muting with spatial derivatives is essential. 365

366

356

2.4 The filtering spectrum

Sadek and Aluie (2018) showed how coarse-graining can be used to extract the energy content at different length scales. They do so by partitioning the velocity into discrete length scale bands rather than the two sets (coarse KE and fine KE) in equations (9) and (10). The resulting quantity is called the *filtering spectrum*. The filtering spectrum is distinct from the traditional Fourier spectrum, with coarse-graining offering a way to measure energy distributions without relying on a Fourier transform, thus avoiding the limitations noted in Section 1.1.

Figure 2. Percentage of total energy recovered by summing the fine and coarse KE terms in equation (11) obtained by coarse-graining over the full ocean surface as a function of the filter scale, $k_{\ell} = 1/\ell$. The three lines correspond to the three approaches described in section 2.3, namely, filtering with a fixed kernel shape and excluding/including land (orange/green lines) when tallying the total energy. We also coarse-grain with a deformable filter kernel to exclude the filter overlapping land regions (blue line).

The filtering spectrum is obtained by differentiating in scale the coarse KE

$$\overline{E}(k_{\ell}) = \frac{d}{dk_{\ell}} \left\{ \mathcal{E}_{\ell} \right\} = -\ell^2 \frac{d}{d\ell} \left\{ \mathcal{E}_{\ell} \right\}, \qquad (12)$$

where $k_{\ell} = 1/\ell$ is the 'filtering wavenumber.' Sadek and Aluie (2018) showed that $\overline{E}(k_{\ell}, t) \geq$ 376 0 when using certain types of kernels (e.g., concave) of which the top-hat kernel is an 377 example. Moreover, Sadek and Aluie (2018) identified the conditions on G_{ℓ} for $\overline{E}(k_{\ell},t)$ 378 to be meaningful in the sense that its scaling agrees with that of the traditional Fourier 379 spectrum (when a Fourier analysis is possible, such as in periodic domains). Below, we 380 shall sometimes refer to \mathcal{E}_{ℓ} as the "cumulative spectrum" following Sadek and Aluie (2018) 381 since it accounts for all energy at scales larger than ℓ . In contrast, $E(k_{\ell}, t)$, is the spec-382 tral energy *density* at a specific scale ℓ . 383

³⁸⁴ 2.5 Reynolds averaging

We close this section by reviewing basic properties of Reynolds averaging (RA) as realized by time averages.

Basics of Reynolds averaging

Time averaging separates the flow into a time-average/'mean' and a fluctuating/'eddy' as given by (Pope, 2001)

$$\langle \mathbf{u} \rangle(\mathbf{x}) = \frac{1}{T} \int_{t_0}^{t_0+T} \mathbf{u}(\mathbf{x}, t) \mathrm{d}t, \qquad (13)$$

387

390

374

375

$$\mathbf{u}'(\mathbf{x},t) = \mathbf{u}(\mathbf{x},t) - \langle \mathbf{u} \rangle(\mathbf{x}), \tag{14}$$

where $\langle \mathbf{u} \rangle$ is the mean component, \mathbf{u}' the eddy component, and T represents the entire time record and not just a time window. Two key properties of the Reynold's decomposition are

$$\langle \langle \mathbf{u} \rangle \rangle = \langle \mathbf{u} \rangle \quad \text{and} \quad \langle \mathbf{u}' \rangle = 0,$$
 (15)

³⁹³ so that the mean of a mean returns the mean (idempotence property) while the mean ³⁹⁴ of the eddy is zero. The resulting mean and eddy kinetic energy components are respec-³⁹⁵ tively given by

398

$$MKE(\mathbf{x}) = \frac{1}{2} |\langle \mathbf{u} \rangle|^2(\mathbf{x}), \tag{16}$$

$$EKE(\mathbf{x},t) = \frac{1}{2} |\mathbf{u}'|^2(\mathbf{x},t).$$
(17)

Notice that the sum of mean and eddy kinetic energy is not equal to the total kinetic energy. Rather, there is an extra cross term, $\mathbf{u}' \cdot \langle \mathbf{u} \rangle$, needed to close the budget. However, the cross term is not positive definite and it has a zero time average, $\langle \mathbf{u}' \cdot \mathbf{u} \rangle =$ 0. Following a RA decomposition, the total energy can be written as

403

$$\mathcal{E}(\mathbf{x},t) = EKE(\mathbf{x},t) + MKE(\mathbf{x}) + \frac{1}{2} \left(\mathbf{u}' \cdot \langle \mathbf{u} \rangle \right)(\mathbf{x},t).$$
(18)

404

Key differences between Reynolds averaging and coarse-graining

A key difference between coarse-graining and Reynolds-averaging is that within RA,
 applying the averaging operation twice on any field yields the same result whereas that
 property does not hold for coarse-graining with non-projector kernels (Buzzicotti et al.,
 2018)

409

$$\langle\langle F \rangle\rangle = \langle F \rangle$$
 whereas $\overline{\overline{F}} \neq \overline{F}$. (19)

Another important difference is that a Reynolds average does not provide a control to
adjust the partition between the "mean" and "eddy" components. That is, a Reynolds
decomposition is not a length-scale decomposition and this point is illustrated in section
4.5 (see Figure 11). Consequently, the time-mean flow is not synonymous with large-scale
flow, nor does a Reynolds eddy fluctuation directly correspond to a characteristic finescale.

To help understand the above points, we emphasize the distinction between time-416 scale and decorrelation-time for a particular flow feature. While it is generally true that 417 larger (smaller) scales have slower (faster) time-scale dynamics, it is not always true that 418 their decorrelation-time follows this relation. As an example, consider stationary eddies, 419 such as the Mann eddy in the North Atlantic. Such eddies have a small spatial-scale (rel-420 ative to the gyre or basin) but are persistent in time. As a result, even if the timescale 421 $(\sim \ell/u)$ for a structure is small when it is associated with the relatively fast dynamics 422 of eddying flows, it can be highly correlated (or even stationary) in time, so that its con-423 tribution to the MKE is not completely removed by a time-average. We show this be-424 havior in sections 4.5 and 4.6. 425

⁴²⁶ **3** Satellite and numerical model data

We examine the horizontal geostrophic velocity of surface ocean currents from a 427 global numerical model simulation and from an analysis of satellite sea surface altime-428 try, focusing on regions to the north and south of the tropics, $[15^{\circ}N-90^{\circ}N]$ and $[15^{\circ}S-$ 429 90° S], as depicted in Figure 3. We avoid the tropics since our interest is with the geostrophic 430 flows in the higher latitudes, and only the surface geostrophic current is available from 431 satellite altimetry. Details of the two products are given in the following subsections, and 432 both were publicly accessed through the Copernicus Marine Environment Monitoring 433 Service (CMEMS) webpage. 434

435

3.1 AVISO analysis of satellite altimetry

Geostrophic currents are obtained from the AVISO+ analysis of multi-mission satellite altimetry measurements for sea surface height (SSH) (Pujol et al., 2016). We used
the Level 4 (L4) post-processed dataset of daily-averaged geostrophic velocity, gridded

Figure 3. Geographic regions considered in this analysis. The shaded area between $[15^{\circ}S - 15^{\circ}N]$ is the tropical band that is neglected in this work. We instead consider the geostrophic flow in the higher latitudes. Visualization shows a one-year time average of the full kinetic energy from NEMO for illustration.

at a resolution of $0.25^{\circ} \times 0.25^{\circ}$ and spanning from January 2010 to October 2018. Post processing was performed by the Sea Level Thematic Center (SL TAC) data processing system, which processes data from eleven altimeter missions.

The product identifier of the AVISO dataset used in this work is
"SEALEVEL_GLO_PHY_L4_REP_OBSERVATIONS_008_047", and can be downloaded at https://marine.copernicus.eu/services-portfolio/access-to
-products/.

446

3.2 Numerical simulation

We analyze 1-day averaged surface geostrophic currents from the NEMO nu-447 merical modeling framework, which is coupled to the Met Office Unified Model 448 atmosphere component, and the Los Alamos sea ice model (CICE). The NEMO 449 dataset consists of weakly coupled ocean-atmosphere data assimilation and forecast 450 system, which is used to provide 10 days of 3D global ocean forecasts on the same 451 grid of 0.25 degree spacing. We use daily-averaged data that spans three years, from 452 2016 to 2019. More details about the coupled data assimilation system used for 453 the production of the NEMO dataset can be found in (Hewitt et al., 2011; Lea et 454 al., 2015). The specific product identifier of the NEMO dataset used in this work 455 is "GLOBAL_ANALYSISFORECAST_PHY_CPL_001_015", and it can be down-456 loaded from CMEMS at https://marine.copernicus.eu/services-portfolio/ 457 access-to-products/. 458

459 4 Analysis results

In this section we present results of the coarse-graining analysis along with a
 comparison with Reynolds averaging based on time averages. In the second part of
 this section we present results from coarse-graining in both space and in time as a
 means to characterize the time-scales associated with different length-scales.

4.1 Coarse-graining the surface geostrophic flow from AVISO

We split the geostrophic kinetic energy from AVISO into its fine and coarse-465 grained components following equations (9) and (10). For a qualitative appreciation 466 of this decomposition, Figure 4 displays maps of the kinetic energy just over the At-467 lantic using two different filter scales, $\ell = 100$ km in the top row and $\ell = 400$ km in 468 the bottom row. From left to right, panels in Figure 4 show the total kinetic energy, 469 \mathcal{E} , the coarse energy, \mathcal{E}_{ℓ} , and the fine energy, $\mathcal{E}_{<\ell}$. The fine scale kinetic energy, $\mathcal{E}_{<\ell}$, 470 represents kinetic energy at scales less than ℓ , as represented (or projected) on a grid 471 of resolution $\Delta x \sim \ell$. Notably, as seen in Figure 4, $\mathcal{E}_{<\ell}$ does not have small scale 472 features, which results since there is a filter applied to both terms in equation (10)473 defining $\mathcal{E}_{<\ell}$. This definition ensures that $\mathcal{E}_{<\ell}$ is positive semi-definite at each point 474 in space and time. 475

476 Visualization of fine kinetic energy, $\mathcal{E}_{<\ell}$, is still useful to identify the regions 477 where it is dominant in the ocean. Even so, one may wish to view the alternative 478 quantity

$$\mathcal{E} - \mathcal{E}_{\ell} = \frac{1}{2} \left(|\mathbf{u}(\mathbf{x}, t)|^2 - |\overline{\mathbf{u}}_{\ell}(\mathbf{x}, t)|^2 \right),$$
(20)

which is shown in the right-most column of Figure 4. This quantity reveals more fine scale features since only the second term on the right hand side is filtered. However, as discussed in Section 2.1, the energy difference, $\mathcal{E} - \mathcal{E}_{\ell}$, can be negative locally in space, and so it does not serve our purposes for decomposing the energy into non-negative terms.

485

479

464

4.2 Seasonality of the fine scale geostrophic kinetic energy

In Figure 5, we present the seasonality of the fine scale geostrophic kinetic energy in the North (solid lines) and South (dashed lines). We show results just from AVISO, though note that similar results hold for the NEMO output. Figure 5 shows the calculation of fine scale kinetic energy with four different filter scales, $\ell = 77$ km, 129 km, 215 km, and 464 km. We choose these length-scales due to their equal spacing on a logarithmic scale.

The fine scale geostrophic kinetic energy in Figure 5 reveals a clear seasonality 492 across all length scales, generally peaking in the spring and attaining a minimum in 493 the autumn of both hemispheres. The study of Qiu et al. (2014) and Steinberg et 101 al. (2021) arrive at a similar conclusion about seasonality using different methods. 495 The cause for such seasonality is an ongoing topic of research, requiring the anal-496 ysis of various mesoscale sources and sinks. Rai et al. (2021) recently showed that 497 eddy-killing is a significant global mesoscale sink with a seasonal cycle that peaks in 498 winter, thereby offering a potential explanation for mesoscale seasonality. Another 499 possible explanation was put forth by Qiu et al. (2014), who showed evidence for 500 seasonality in the upscale energy cascade in the North Pacific. While it is beyond 501 the scope of this paper, it is worth noting that, in addition to highlighting seasonal 502 variations, the bottom panel of Figure 5 reveals a general increase in mesoscale 503 energy over the plotted timeframe. This long-term increase is present in both the 504 North of Tropics and South of Tropics regions and is consistent with recent analysis 505 by Martínez-Moreno et al. (2021). 506

In the middle panel in Figure 5 we show the fine scale kinetic energy normalized as a percentage of the total energy, $\{\mathcal{E}_{<\ell}\}/\{\mathcal{E}\}(t)$. From this plot we can see that along the full time series, more than 90% of the total geostrophic kinetic energy resides at scales ≤ 500 km and a large percentage ($\approx 60\%$) is contained between ≈ 100 and ≈ 500 km, which can be identified as the bulk of the geostrophic flow.

Figure 4. Maps of the coarse-grained decomposition of kinetic energy performed on a singleday from the AVISO analysis at two different filter scales, $\ell = 100$ km (top row) and $\ell = 400$ km (bottom row). Here the bare KE, $\mathcal{E}(\mathbf{x}, t)$, is compared with coarse KE, $\mathcal{E}_{\ell}(\mathbf{x}, t)$, and fine KE, $\mathcal{E}_{<\ell}(\mathbf{x}, t)$. The right-most column shows the resulting fine scale term defined by equation (20), which can yield values that are negative.

512 4.3 The filtering spectrum

In Figure 6 we show the filtering spectrum for the global ocean surface 513 geostrophic kinetic energy as obtained from equation (12) for both AVISO and 514 NEMO. In the left panel we show the cumulative energy spectra, \mathcal{E}_{ℓ} , as a function 515 of coarse-graining scale, ℓ . These results highlight those from Figure 5, revealing 516 that the overwhelming contribution to geostrophic kinetic resides at length-scales 517 $\ell < 500$ km. Based on prior characterization of ocean energetics (Ferrari & Wunsch, 518 2009), we assume that this length scale is dominated by mesoscale features such as 519 geostrophic turbulence, boundary currents, and fronts. Hence, our analysis provides 520 further compelling evidence for dominance of the ocean surface kinetic energy by 521 mesoscale flows. 522

In the right panel of Figure 6, we show the actual filtering spectrum, which 523 is the derivative (in scale) of the corresponding plot in the left panel. We can see 524 a peak centered at $\ell \approx 300$ km, with the bulk of the geostrophic kinetic energy re-525 siding between scales 100 km and 500 km. From the analysis shown in Figure 6, 526 we find that $60 \pm 0.4\%$ of the kinetic energy in the extra-tropics from the AVISO 527 and NEMO products lies within the 100 km to 500 km scale-band. Again, Figure 6 528 provides compelling evidence that the mesoscales in the extra-tropical latitudes 529 constitute the most energetic component of the oceanic circulation. 530

Figure 5. Top panel: Time-series of fine scale geostrophic kinetic energy, $\mathcal{E}_{<\ell}$, representing energy at scales smaller than ℓ , in the North (solid lines) and South (dashed lines) obtained from the AVISO analysis. Different colors indicate different scales ℓ . Middle panel: The same time-series, but now normalized by the original kinetic energy, \mathcal{E} , to show the % of kinetic energy residing at scales $< \ell$. Bottom panel: deviation of $\mathcal{E}_{<\ell}$ from the time-mean value to emphasize seasonal variability. Vertical grid lines indicate the start of each quarter-year (01Jan, 01Apr, 01Jul, 01Oct). We see that the mesoscales exhibit a seasonal oscillation that generally peaks in the spring, and that they account for a dominant fraction of the total geostrophic kinetic energy. Here, we show only 6.5 years of the 9-year record analyzed with a 4-day sampling, but averages are based on a 1-day sampling.

If we focus on each hemisphere separately, we find that the 100 km to 500 km 531 scale-band comprises $62 \pm 1\%$ of the North's kinetic energy and $58 \pm 1\%$ of the 532 South's kinetic energy. Indeed, one can notice slight differences between the North's 533 and South's spectra in Figure 6 (right panel), where the South has relatively more 534 energy at scales larger than 1000 km. This bias can be attributed to the large-scale 535 contribution from the Antarctic Circumpolar Current. On the other hand, the North 536 has slightly more kinetic at scales within the 100 km to 1000 km range, which can 537 be attributed to boundary currents (Kuroshio and Gulf Stream). In support of our 538 assertion, consider Fig. 7, which shows the zonally-averaged kinetic energy for se-539 lected length-scale bands. Scales larger than 1000km (blue plot in Fig. 7) have a 540 dominant contribution from latitudes $[60^{\circ}S, 40^{\circ}S]$, which roughly corresponds with 541 the Antarctic Circumpolar Current. However, these latitudes are no longer domi-542 nant when considering the band of smaller scales: 215 km $<\ell<1000$ km. These 543 scales (orange plot in Fig. 7) show a distinct signal at latitudes [30°N, 40°N], which 544 roughly aligns with the Gulf Stream and Kuroshio. There is also a weaker signal at 545 latitudes [40°S, 35°S], with roughly aligns with the Agulhas and the Brazil-Malvinas 546 currents. 547

Figure 6. Left panel: Cumulative surface geostrophic kinetic energy spectra, \mathcal{E}_{ℓ} , as a function of scale ℓ , obtained from both the AVISO and NEMO products in the North and South. Right panel: Filtering spectra obtained as a derivative with respect to $k_{\ell} = 1/\ell$ of the corresponding cumulative energy spectra showed in the left panel (see equation (12)). Envelopes show interquartile range (25th to 75th percentiles) of temporal variation. Note that the bulk of surface geostrophic kinetic energy resides at scales within the 100 km to 500 km range.

Figure 7. Time- and zonally-averaged kinetic energy computed from AVISO within selected length-scale bands (see in-set legend) as a function of latitude. We can see that the Antarctic Circumpolar Current has significant energy at scales > 1000 km, while the North has significant energy within $\approx 30^{\circ}$ N-40°N where the Western Boundary Currents are located. Note that the latitude axis is broken to exclude the band [15°S, 15°N].

548

4.4 Reynolds averaging decomposition

In this subsection and the next, we show that the time-mean flow consists of 549 an entire range of length scales with substantial contributions from the mesoscale. 550 Figure 8 shows the mean-fluctuation decomposition following the Reynolds averaging 551 approach. The maps are focused on the Atlantic region to help reveal details and 552 we show just those obtained from AVISO. The time mean is obtained by averaging 553 the velocity over the whole time series available, spanning nine years. From left to 554 right we show the total energy at a single day, the time mean energy, $MKE(\mathbf{x})$, the 555 fluctuating eddy term, $EKE(\mathbf{x}, t)$, and the cross term, $1/2(\mathbf{u}' \cdot \langle \mathbf{u} \rangle)$. 556

Having used a relatively long time series for averaging, the mean energy in Figure 8 is rather depleted away from major current systems, so that the Gulf Stream

Figure 8. Decomposition of geostrophic kinetic energy from AVISO for the Atlantic basin from a time averaging (Reynolds) decomposition. Left panel: total energy, $\mathcal{E}(\mathbf{x}, t)$ at a single day. Left middle panel: 9-year time mean, $MKE(\mathbf{x})$. Right middle panel: fluctuating eddy term, $EKE(\mathbf{x}, t)$. Right panel: the cross term required to recover the total geostrophic energy as defined in equation (18). Note that $MKE(\mathbf{x})$ contains small length-scales and EKE contains a large-scale component of the flow.

and the Antarctic Circumpolar Current are quite pronounced relative to the gyre 559 interiors. We appreciate from this figure that the mean flow retains a substantial 560 contribution from structures with a variety of sizes. In the same way, the 'eddy' (or 561 temporally fluctuating) flow in Figure 8 contains most of the small scale fluctuations 562 but also a substantial contribution from large-scale structures. The cross term shown 563 on the right panel of Figure 8 has strong fluctuations around zero, which make its 564 contribution almost (but not exactly) zero after a spatial-average. The blending 565 of length scales revealed by these figures reflects the inability of time averaging to 566 decompose the kinetic energy according to length-scales. 567

To further investigate the role of the three Reynolds average energy terms, 568 Figure 9 shows their temporal variability in both hemispheres. In the first row, we 569 see that EKE constitutes a substantial portion of the total energy \mathcal{E} (80%) and 570 their temporal evolution is almost indistinguishable. Both EKE and \mathcal{E} tend to peak 571 during the spring-summer. The bottom row of Figure 9 shows MKE, which is inde-572 pendent of time, and the cross term, which has a zero average. These two quantities 573 are much less energetic, with the mean term $\approx 20\%$ of the total and the cross term 574 fluctuates about its zero average without a clear seasonal signal. 575

576

4.5 Spatio-temporal decomposition

In this section we present results from coarse-graining in both space and time to reveal the time-scales of various length-scales, including length-scales present in the 9-year temporal mean. Our analysis demonstrates a new way for comparing data from satellite analysis (AVISO) and numerical models (NEMO).

The approach consists of measuring the filtering spectrum of a temporallysmoothed version of the original velocity field. The latter is obtained from a running

Figure 9. Top panel: Time-series of total geostrophic kinetic energy, $\{\mathcal{E}(t)\}$ (blue), and the fluctuating component, $\{EKE(t)\}$ (orange), in the North (solid line) and South (dashed line) from the AVISO analysis. Vertical grid lines indicate the start of each quarter-year (01Jan, 01Apr, 01Jul, 01Oct). Bottom panel: Time-series of the cross term (blue) and kinetic energy of the 9-year mean, $\{MKE(\mathbf{x})\}$ (orange), in the North (solid line) and South (dashed line). EKE constitutes a substantial portion of the total energy and with an almost indistinguishable temporal variation. Here, we show only 6.5 years of the full 9-year record. Plots shown use a 4-day sampling frequency, but averages are based on a 1-day sampling of the 9-year record.

⁵⁸³ window time-average,

587

591

593

$$\mathbf{u}\rangle_{\tau}(\mathbf{x},t) = \frac{1}{\tau} \int_{t-\tau/2}^{t+\tau/2} \mathbf{u}(\mathbf{x},t') \,\mathrm{d}t', \qquad (21)$$

with τ the size of the time window. Note that a running window time-average in equation (21) is similar to spatial coarse-graining (equation (1)) since

$$\langle \langle F \rangle_{\tau} \rangle_{\tau} \neq \langle F \rangle_{\tau},\tag{22}$$

so that it does not satisfy the Reynolds averaging idempotent property, $\langle\langle F \rangle\rangle = \langle F \rangle$.

⁵⁸⁹ Combining equation (12) with equation (21) allows us to measure the filtered ⁵⁹⁰ energy spectrum of the time smoothed field

$$\overline{E}(k_{\ell},\tau) = \langle \frac{d}{dk_{\ell}} \{ \frac{1}{2} | \langle \overline{\mathbf{u}}_{\ell} \rangle_{\tau} |^2 \} \rangle = \langle \frac{d}{dk_{\ell}} \{ \mathcal{E}_{\ell,\tau} \} \rangle, \qquad (23)$$

592 where we introduced

$$\mathcal{E}_{\ell,\tau}(\mathbf{x},t) = \frac{1}{2} |\langle \overline{\mathbf{u}}_{\ell} \rangle_{\tau}|^2, \qquad (24)$$

which is the cumulative spectrum of the temporally-smoothed field. As indicated, $\mathcal{E}_{\ell,\tau}(\mathbf{x},t)$ is a function of both the size of the time-window, τ , and the inverse coarsegraining scale, $k_{\ell} = \ell^{-1}$.

⁵⁹⁷ We show the time-smoothed energy map, $\mathcal{E}_{\ell=0,\tau}$, in Figure 10 from AVISO. ⁵⁹⁸ Here, the two columns compare results from the North and the South regions, while ⁵⁹⁹ different rows compare results with different time windows, τ . From these maps we

can see that increasing τ from one day to 1093 days reduces the energy down to 600 $\approx 21\%$ ($\approx 25\%$) of the original total energy in the North (South). Hence, averaging 601 over three years brings the energy down to values comparable to those over the full 602 nine years obtained in the previous section by the Reynolds averaging decompo-603 sition, where we found that MKE accounts for $\approx 20\%$ of the total energy in the 604 extra-tropics. This result indicates that temporal averaging converges quickly for 605 the geostropphic kinetic energy, and using longer time records does not significantly 606 alter the partitioning between the temporal mean and fluctuating components of the 607 surface geostrophic ocean flow.

Figure 10. The surface geostrophic kinetic energy from the temporally coarse-grained flow, $\mathcal{E}_{\ell=0,\tau}$, in the North (left column) and South (right column) from AVISO. The top row shows the original 1-day averaged flow. The middle and bottom rows show the kinetic energy from the flow when averaged with a ≈ 6 months time window and a ≈ 3 years time window, respectively, with the kinetic energy decreasing with an increasing time window. Each panel indicates the % of kinetic energy remaining relative to the 1-day top row.

608

In Figure 11 we show the filtering spectra of the temporally-smoothed flow, 609 $\overline{E}(k_{\ell},\tau)$. The top panel shows the filtering spectra $\overline{E}(k_{\ell},\tau)$ as a function of k_{ℓ} for 610 various values of τ . Bottom panel shows the same quantities, but normalized by 611 $\overline{E}(k_{\ell}, \tau = 0)$, which is the spectrum of the flow without temporal coarse-graining. 612 From this analysis, we find that the main effect of the temporal coarse-graining is to 613 make the energy peak around $\ell \approx 300$ km less pronounced, with the consequence of 614 having a spectral energy distribution that is more evenly distributed across length-615 scales than in the original flow. Indeed, we can see from Figure 11 (bottom panel) 616 that time averaging removes energy at all scales. As we increase the time window τ , 617 $\overline{E}(k_{\ell},\tau)$ at scales ≤ 300 km appears to mostly shift downward in equal proportion. 618 This behavior is counter to the notion that smaller scales decorrelate faster in time 619 and are removed more efficiently with time-averaging. 620

From Figure 11, we see that as the time window $\tau \to \infty$, $\overline{E}(k_{\ell}, \tau)$ converges to the time-mean spectrum (dashed plot in Figure 11), which highlights that the 9-year mean flow consists of an entire continuum of length-scales. The spectrum of the 9-year mean flow shows a reduction of $\approx 20\%$ of the total at the largest scales of > 1000 km (bottom panel in Figure 11). Our analysis of Figure 11 (dashed line), allows us to infer that roughly 60% of the kinetic energy in the 9-year time-mean is at

Figure 11. Top panel: Kinetic energy spectra as a function of spatial scale, $k_{\ell} = 1/\ell$, of the temporally smoothed velocity field, $\overline{E}(k_{\ell}, \tau)$, in the North from AVISO. Colours indicate the time-window size τ used in the smoothing procedure, ranging from 1 day (pale yellow colour) up to 1000 days (dark green). Bottom panel: The same spectra but now normalized by $\overline{E}(k_{\ell}, \tau = 0)$, which is the spectrum of the flow without temporal smoothing. In both panels the dashed lines represent the spectra of the mean energy obtained via the Reynolds averaging decomposition, from which we find that 70% of energy in the time-mean flow in the North is at scales < 500 km (55% in the South, not shown).

scales < 500 km outside the $[15^{\circ}S - 15^{\circ}N]$ band, underscoring the poor association between temporal averaging and length-scales.

629

4.6 Spatio-temporal comparison of AVISO and NEMO

We now demonstrate a new method to compare data from satellite analysis 630 (AVISO) and numerical models (NEMO) by using a spatio-temporal coarse-graining 631 to identify inconspicuous flow properties or artifacts, and may complement cur-632 rent efforts to disentangle balanced from unbalanced motions in SSH-derived flows. 633 Figure 12 presents space-time 2-D spectra, $-\langle \frac{d}{d\tau} \frac{d}{dk_{\ell}} \{ \mathcal{E}_{\ell,\tau} \} \rangle$, which decomposes the 634 energy as measured from AVISO and NEMO. In the main panel of Figure 12 we 635 show the isolevels of space-time spectra from AVISO (blue lines), superposed onto 636 those from NEMO (red lines). Here, the color intensity is proportional to the energy 637 as indicated by the colorbar in Figure 12. At the side of the main panel we show 638 the one dimensional energy spectra as a function of time, τ , and scale, ℓ . The most 639 striking difference is that AVISO isolines (blue) are concentric circles with a peak at 640 $\tau \approx 20$ days and $\ell \approx 300$ km, while NEMO isolines (red) resemble horseshoes with a 641 peak that encompasses shorter time-scale $\tau \leq 20$ days and a wider range of length-642 scales. The right panel in Figure 12 plots $-\langle \frac{d}{d\tau} \{ \mathcal{E}_{\ell=0,\tau} \} \rangle$, underscoring the difference 643 between AVISO and NEMO spectra, which disagree significantly over time-scales 644 smaller than ≈ 10 days. Note that the top panel in Figure 12, which compares 645

Figure 12. Combined spatio-temporal coarse-graining shows space-time 2D spectra, $-\partial_{\tau}\partial_{k_{\ell}}\mathcal{E}_{\ell,\tau}$, (central panel) from AVISO (blue isolines) and NEMO (red isolines). Right (top) panel shows energy spectra as a function of time-scale τ (length-scale $k_{\ell} = 1/\ell$). Spatiotemporal spectral isolines from AVISO are concentric circles with a peak around $\tau \approx 20$ days and $\ell \approx 300$ km while those from NEMO (red isolines) are horseshoe-like with a peak encompassing smaller time-scales. AVISO mis-represents time-scales $\lesssim 10$ days over all length-scales.

spectra of spatial scales, shows very good agreement and, without a temporal decomposition, it fails to detect the disagreement in time-scales that exist over a wide range of spatial scales, from $\ell \approx 100$ km to 1000 km (main panel in Figure 12).

Remember that for the entire analysis in this paper, we are using 1-day aver-649 ages of SSH to derive velocity from the NEMO data. While the SSH from AVISO 650 is also available daily, it is effectively averaged over longer periods of time to pro-651 duce gridded SSH maps from along-track altimeter data. We hypothesize that the 652 difference between isocontours from AVISO and NEMO in Figure 12 comes from 653 the optimal interpolation used to produce the gridded AVISO product (Pujol et 654 al., 2016), which is necessary to construct the global maps from satellite altimeters' 655 along-track data. To support this hypothesis, in Figure 13, we show the spectra as a 656 function of τ measured from AVISO and NEMO. In this plot we have repeated the 657 analysis of the NEMO spectra after passing the data through a 7-day running time-658 average (green line), which reproduces the time average over the satellite orbits. We 659 can see that the green curve overlaps the AVISO measurement (blue) very closely, 660 supporting our hypothesis. This is similar to what was done in Arbic et al. (2014); 661 Khatri et al. (2018) who were comparing the cascade from AVISO and model data 662 and determined that AVISO's spectral fluxes can be reproduced from model data 663 after filtering the latter in both space and time. 664

What component of the flow could be yielding the discrepancy between NEMO 665 and AVISO? The most obvious possibility is unbalanced motion present in the 1-day 666 mean SSH fields of NEMO that is absent from AVISO due to the effective weekly 667 averaging required for gridding the satellite measurements. However, unbalanced motion had been believed to be important mostly over length-scales \lesssim 100 km and 669 time-scales \lesssim 2 days (e.g. Richman et al. (2012); Qiu et al. (2018)). If our conjec-670 ture is correct, it would imply that unbalanced motion is present at all scales and is 671 significant even at scales between 200 km to 1000 km, requiring averaging over a few 672 days to be removed. Isolating balanced from unbalanced motions (e.g. Bühler et al. 673 (2014)) is an active research topic that is beyond the scope of this work. 674

Figure 12 shows the importance of performing a combined spatio-temporal 675 decomposition to access all information in the data. Our method is similar to 676 frequency-wavenumber analysis performed within Fourier boxes by several re-677 cent studies: Arbic et al. (2014) were interested in mesoscale-driven intrinsic low-678 frequency variability, while Savage et al. (2017); Qiu et al. (2018); Torres et al. 679 (2018) were primarily motivated by isolating the unbalanced motions from SSH-680 derived velocities. Our Figure 12 is analogous, for example, to Figure 4 in Arbic 681 et al. (2014) and to Figure 3 in Torres et al. (2018). However, as we mentioned in 682 the introduction, the coarse-graining approach gives us access to the *global* energy 683 budget and, moreover, frees us from the limitations of Fourier boxes and the re-684 quired tapering and detrending. As such, the approach here complements previous 685 frequency-wavenumber analysis by allowing us to access much larger length-scales. 686

A common feature between our Figure 12 and those in previous studies is a slight elongation of iso-contours along the diagonal from small to large spatiotemporal scales in the main panel of our Figure 12. Such elongation is most prominent in Figure 3 of Torres et al. (2018), who were probing scales < 100 km and from roughly 3 hours to 40 days. The diagonal elongation of isocontours represents a slight tendency for larger length-scales to have longer time-scales.

However, we emphasize that unlike in Torres et al. (2018), such tendency is 693 only *slight* over the larger scales we analyze here. In fact, an important take-away 694 from Figure 12 is that all length-scales evolve over a wide range of time-scales, con-695 sistent with plots in Figure 11. Consider, for example, $\ell \approx 500$ km in the main panel 696 of Figure 12 at different τ values. We see that the (red) isoline is almost vertical 697 over $\tau \approx 5$ days to $\tau \approx 50$ days, indicating that flow at 500 km has an equal contri-698 bution from all these time-scales. We also see that both AVISO and NEMO isolines 699 get flatter (stretched horizontally) as τ increases, such that at $\tau \approx 300$ days, there is 700 almost equal energy at all scales between $\ell \approx 100$ km and $\ell \approx 1000$ km. 701

702 5 Conclusions

703

5.1 Summary of the main results

In this paper, we have exhibited a suite of analysis insights available from a 704 coarse-graining approach that is relatively new in physical oceanography. As part 705 of our coarse-grained analysis of numerical model and satellite analysis products, 706 we found that the surface geostrophic kinetic energy is dominated by the mesoscale 707 flow, thus supporting our understanding that it is the most energetic component 708 of the general circulation (Ferrari & Wunsch, 2009). More precisely, our use of 709 coarse-graining to measure the global spectrum (Sadek & Aluie, 2018), reveals that 710 $\approx 60\%$ of the surface geostrophic kinetic energy resides at scales between 100 km 711 and 500 km. We also found that the kinetic energy has a clear seasonality, peaking 712 in the spring of both hemispheres, thus supporting analysis using different meth-713 ods by Qiu et al. (2014) and Steinberg et al. (2021). Furthermore, results of the 714

Figure 13. Evidence that the disagreement between AVISO and NEMO over time-scales ≤ 10 days is due to temporal averaging used in generating the gridded AVISO product. Here, we show temporal spectra from AVISO (blue) and NEMO (red) in the North (solid lines) and South (dashed lines), which disagree over $\tau \leq 10$ days as in Figure 12. However, the temporal spectra from NEMO agree with those from AVISO after applying a 7-day temporal smoothing to the original NEMO velocities (green). This result supports our hypothesis that AVISO is missing dynamical information at time-scales less than 10 days due to temporal smoothing over all length-scales.

global energy spectrum from both AVISO satellite analysis and NEMO model areconsistent.

By coarse-graining in both space and time, we have shown that every length-717 scale evolves over a wide range of time-scales. This result makes temporal averaging, 718 which is traditionally used to decompose oceanic flow into a mean and fluctuating 719 components, unable to decompose the flow according to length-scales. Indeed, we 720 showed that temporal averaging reduces the energy at all length-scales and not just 721 the mesoscales. We found that the mean flow from a 9-year average has over 50%722 of its energy residing at length-scales smaller than 500 km. This result makes us 723 appreciate the significance of temporally coherent forcing mechanisms acting on the 724 mesoscales, such as bottom topography and continental boundaries. 725

An important contribution of this work is to demonstrate how a combined 726 spatio-temporal coarse-graining analysis in Section 4.6 is able to expose hidden 727 properties in the data. We did so by showing that the gridded AVISO product 728 misrepresents the SSH-derived velocity over time-scales less than ≈ 10 days at all 729 *length-scales*, including at ≈ 1000 km. The misrepresentation, however, was most 730 severe over scales ≤ 500 km. We showed evidence supporting our hypothesis that 731 this deficiency in AVISO is due to the temporal averaging (optimal interpolation) 732 required for generating a gridded product from altimeter along-track measurements 733 (Pujol et al., 2016). This deficiency is unravelled from a combined spatio-temporal 734 analysis but not by a spatial scale analysis alone. In fact, AVISO has a spatial reso-735 lution (Ballarotta et al., 2019) comparable to that of the NEMO model we analyzed 736 here and their spatial spectra agree well at all resolved spatial scales. We conjecture 737 that the discrepancy between AVISO and NEMO is due to unbalanced motions in 738 NEMO that is absent from AVISO, including at scales larger than 500 km. 739

5.2 Coarse-graining and the filtering spectrum

740

The coupling between different length- and time-scales and also between different geographic regions presents a major difficulty in understanding, modeling, and predicting oceanic circulation and mixing. Indeed, the oceanic kinetic energy budget is estimated to suffer from large uncertainties (Ferrari & Wunsch, 2009). A major reason behind these difficulties is a lack of scale-analysis methods that are appropriate in the *global* ocean.

In this paper, we have demonstrated the versatility of coarse-graining in serv-747 ing as a robust scale-analysis method for the global ocean circulation that comple-748 ments existing methods. The approach is very general, allows for probing the dy-749 namics simultaneously in scale and in space, and is not restricted by assumptions of 750 homogeneity or isotropy commonly required for traditional methods such as Fourier 751 or structure-function analysis. Therefore, coarse-graining offers a way to probe and 752 to quantify the energy budget at different length-scales globally while maintaining 753 local information about the heterogeneous oceanic regions. 754

Here, we have also demonstrated how the recently developed *filtering spectrum* (Sadek & Aluie, 2018), which relies on coarse-graining, can be used to quantify the energy spectrum in the ocean. The method frees us from the limitations of Fourier boxes, and allows us to extract the spectrum globally. We view this work as a necessary step toward constructing a scale-aware global Lorenz Energy Cycle for the ocean circulation.

⁷⁶¹ Appendix A Deforming the kernel around land

As outlined in section 2.1, filtering with a constant kernel while treating land as zero-velocity water and including land cells ("Fixed Kernel w/ Land") in the final tally is guaranteed to conserve 100% of the energy, while excluding land cells and integrating only over water cells ("Fixed Kernel w/o Land") leads to a loss of about 11% of the total kinetic energy at a filter scale of 2000 km (see Figure 2). This result follows since some of the kinetic energy 'smears' onto the land cells, which are then excluded from the spatial integrals.

An alternative approach is to deform the kernel around land ("Deforming Kernel") so that only water cells are incorporated in the filtering operation. This approach has the advantage of not needing to treat land as water, yet we have shown in Figure 2 that this choice still does not conserve 100% of the energy, sometimes even yielding larger values, albeit still within 1% error. Here, we explain why a deforming a kernel cannot be expected to yield 100% of the energy, unlike the "Fixed Kernel w/ Land."

To illustrate how the loss of energy conservation can happen with the Deforming Kernel method, consider a one-dimensional domain with five equally spaced points and a simple kernel that has a weight of 2 at the target point, 1 at neighbouring points, and 0 otherwise.

If the domain were periodic then the filtering operation could be represented as the matrix

$$G := \begin{bmatrix} 1/2 & 1/4 & 0 & 0 & 1/4 \\ 1/4 & 1/2 & 1/4 & 0 & 0 \\ 0 & 1/4 & 1/2 & 1/4 & 0 \\ 0 & 0 & 1/4 & 1/2 & 1/4 \\ 1/4 & 0 & 0 & 1/4 & 1/2 \end{bmatrix}$$

such that $\overline{\text{KE}} = G \cdot \text{KE}$, where KE is a column vector. Note that the sum of each row of G is 1, a result of normalizing the kernel (assuming a grid spacing of 1 for simplicity).

⁷⁸³ Domain integrating in this scenario is simply left-multiplying by the row vector ⁷⁸⁴ S := [1, 1, 1, 1, 1], which is equivalent to taking a column-wise sum. Since $S \cdot G = S$, ⁷⁸⁵ $S \cdot \overline{\text{KE}} = S \cdot G \cdot \text{KE} = S \cdot \text{KE}$, and so the domain integrated kinetic energy is conserved.

However, if the domain is non-periodic (such as if the edges were 'land'), then the resulting filtering kernel according to the Deformed Kernel approach that excludes anything outside the boundaries would be

	$^{2/3}$	$^{1/3}$	0	0	0 -
	$^{1/4}$	$^{1/2}$	$^{1/4}$	0	0
G :=	0	$1/_{4}$	$^{1/2}$	$^{1/4}$	0
	0	0	1/4	1/2	$^{1/4}$
	0	0	0	1/3	$^{2}/_{3}$

In this case, $S \cdot G = [11/12, 13/12, 1, 13/12, 11/13] \neq S$, and so in general $S \cdot \overline{\text{KE}} \neq S \cdot \text{KE}$. Moreover, there is no guarantee that $S \cdot \overline{\text{KE}} \leq S \cdot \text{KE}$, and so it may be that the total filtered kinetic energy exceeds the total unfiltered kinetic energy.

As observed, in general the error arising from deforming the kernel will be 789 much smaller than that of treating land as zero-velocity water and only integrating 790 over true water cells, especially for large filter kernels. However, again, it is worth 791 recognizing that deforming the kernel does not guarantee energy conservation. To 792 fully conserves energy and maintain commutativity with differentiation, we choose 793 the "Fixed Kernel w/ Land" option, which treats land as zero-velocity water and 794 include land cells in spatial integrals to compute total energy. Figure A1 shows the 795 spectra obtained from implementing the three different coarse-graining possibilities. 796
