## Abstract

A better understanding of Earth’s core-mantle boundary (CMB) region is required to address major questions about our planet’s internal dynamics, magnetic field, and thermal evolution. Valuable constraints have come from observations of (CMB-) Stoneley modes, a class of seismic free oscillation whose displacement decreases away from the solid-fluid boundary. The high-frequency modes that are most sensitive to the CMB region are too localized there to be observed at Earth’s surface. Here we clarify why some higher-frequency Stoneley modes can be detected: via ‘mixing’ with surface-localized Rayleigh-type modes of similar frequency. We examine the concept of mixed Rayleigh-Stoneley modes analytically and with a finite-element method. Our calculations show that mixed modes are a sensitive probe of radial and lateral variations in material properties near the CMB. More generally, ‘seismic waveguide coupling’ could help to characterize systems ranging from cell membranes to Pluto’s lithosphere.

## Abstract

A better understanding of Earth’s core-mantle boundary (CMB) region is required to address major questions about our planet’s internal dynamics, magnetic field, and thermal evolution. Valuable constraints have come from observations of (CMB-) Stoneley modes, a class of seismic free oscillation whose displacement decreases away from the solid-fluid boundary. The high-frequency modes that are most sensitive to the CMB region are too localized there to be observed at Earth’s surface. Here we demonstrate that waveguide coupling of Rayleigh and CMB Stoneley modes allows some higher-frequency ‘mixed’ Stoneley modes to be observed. We examine the concept of mixed Rayleigh-Stoneley modes analytically and with a finite-element method. Our calculations show that mixed modes are a sensitive probe of radial and lateral variations in material properties near the CMB. More generally, ‘seismic waveguide coupling’ could help to characterize systems ranging from cell membranes to Pluto’s lithosphere.

## Plain-language summary

After a large earthquake, Earth ‘rings like a bell’ for days due to constructive interference of seismic waves. The frequencies of these ‘normal mode’ oscillations provide information about Earth’s internal structure, including some of the best constraints on density variations. Observations of ‘Stoneley modes’, whose motion is largest near the core-mantle boundary, help to assess various hypotheses in solid-Earth geophysics. However, only low-frequency Stoneley modes are observable at the surface, limiting the resolution of models of the CMB region. We show that these limitations can be overcome at certain frequencies where the Stoneley modes ‘mix’ with ‘Rayleigh modes’, whose motion is largest at Earth’s surface. In these special cases, relatively high-frequency Stoneley modes can be excited by earthquakes, detected by seismometers, and used to study the lower mantle. Additionally, such coupling between seismic ‘waveguides’ is expected in many other settings, from cells to ice sheets.

## 1 Introduction

Improvements in models of the density field near Earth’s core-mantle boundary (CMB) would enhance our understanding of Earth’s history, mantle dynamics, and outer-core stratification. Key constraints come from studies of seismic normal modes. One of the major conclusions of such studies has been that the lower mantle’s so-called large low-

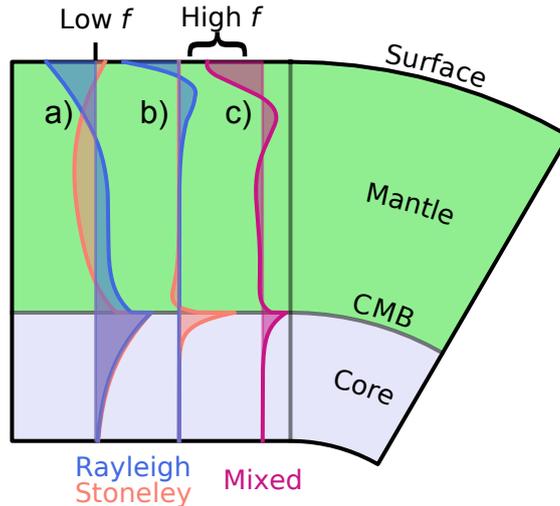

51 shear-velocity provinces (LLSVPs) are also high-density provinces (Ishii & Tromp, 1999;  
52 Trampert et al., 2004; Mosca et al., 2012; Moulik & Ekström, 2016), in agreement with  
53 geodynamical arguments regarding their stability (e.g. Kellogg et al., 1999) and recent  
54 work using ‘tidal tomography’ (Lau et al., 2017).

55 However, some have questioned the conclusions based on normal-mode observations.  
56 Only low-frequency modes (below around 5 mHz) show significant sensitivity to density,  
57 because they have non-negligible self-gravitation (Kennett, 1998). These low-frequency  
58 modes tend to have significant displacement throughout the mantle, leading to poor ra-  
59 dial resolution and trade-offs between parameters in different parts of the Earth (Resovsky  
60 & Ritzwoller, 1999). It seems difficult to resolve these trade-offs without prior assump-  
61 tions (Resovsky & Ritzwoller, 1999; Romanowicz, 2001).

62 Recently, normal-mode researchers have attempted to overcome the trade-offs by  
63 including modes which are localized near the CMB, known as Stoneley modes (Koelemeijer  
64 et al., 2013, 2015, illustrated in Fig. 1a,b). These modes are quite sensitive to density,  
65 due to self-gravitation caused by the large CMB density contrast. Koelemeijer et al. (2017)  
66 fitted these observations (as part of a mode catalog) and proposed that the LLSVPs are  
67 lighter-than-average anomalies, in contrast with previous workers.

68 However, even Stoneley modes have substantial displacement throughout the man-  
69 tle at lower frequencies (Fig. 1a), so they still suffer from significant trade-offs. Ideally,  
70 one would use the sharply-localized higher-frequency Stoneley modes, but these are not  
71 usually observable at the surface (Fig. 1b). In this paper, we explore how some higher-  
72 frequency Stoneley modes have been observed at the surface, not in a pure form, but through  
73 ‘mixing’ (or ‘hybridizing’) with surface-localized Rayleigh modes at certain frequencies  
74 (Fig. 1c).

75 This understanding, combined with more comprehensive observations of these mixed  
76 Rayleigh-Stoneley modes, could tighten constraints on structures in the lowermost man-  
77 tle. Such constraints are crucial for understanding geodynamics (see review by Tackley,  
78 2012), including the role of post-perovskite (Koelemeijer et al., 2018), Earth’s formation  
79 and thermal history (e.g. Zhang & Zhong, 2011) and the heat budget for the geodynamo  
80 (Buffett, 2002; Aubert et al., 2008; Lay et al., 2008). It might also be possible to con-  
81 strain the radial stratification of the outer core (see review by Hirose et al., 2013), al-  
82 though the sensitivity of Stoneley modes to the highly inhomogeneous lower mantle makes  
83 this difficult (Irving et al., 2018).

**Figure 1.** Illustration of typical mode displacement patterns, showing differences between high- and low-frequency modes, and between Rayleigh and Stoneley modes, and the unique mixed modes. Spherical and planar systems are shown side-by-side, and the displacement patterns shown are qualitatively the same for both systems.

84 All of these interpretations of seismic data require a way of solving the forward prob-  
 85 lem. The normal-mode method is well-suited to low-frequency applications and has the  
 86 advantage that once the modes are computed, changing the source in simulations can  
 87 be accomplished at very low cost, unlike, for example, with a spectral-element method  
 88 (Komatitsch & Tromp, 2002). Unfortunately, the standard numerical-integration method  
 89 for calculating the modes of a spherically-symmetric planet cannot be easily generalised  
 90 to three dimensions. Instead, the 3-D problem is approached using the 1-D solution as  
 91 a basis, as in conventional perturbation theory (Dahlen & Tromp, 1998) and the direct-  
 92 solution method (Al-Attar et al., 2012). These approaches work well at low frequencies,  
 93 but the accuracy of the perturbation assumption has not been tested. In this study, we  
 94 demonstrate a normal-mode technique which works in one and three dimensions, and  
 95 does not require any perturbation assumption.

96 Another advantage of the normal-mode approach is that modes provide physical  
 97 insight (e.g. Lau et al., 2016), as we discuss in this study. Related to this, the normal-  
 98 mode formalism is well-suited to the inverse problem, because it leads directly to the req-  
 99 uisite frequency and sensitivity information. In some situations, especially the burgeon-  
 100 ing field of planetary seismology, data coverage may be limited and amplitude informa-

101 tion may not be available; in this case it is helpful that normal-mode centre frequencies  
102 are almost independent of the source term.

## 103 **2 Methods**

### 104 **2.1 Calculation of the modes of a spherically-symmetric planet**

105 We first calculated the spheroidal (P–SV-polarized) modes of a spherically-symmetric  
106 non-rotating Earth model using the *Ouroboros* code (Ye, 2018; Shi et al., 2019, [https://](https://github.com/harrymd/Ouroboros)  
107 [github.com/harrymd/Ouroboros](https://github.com/harrymd/Ouroboros)). We included the effect of gravity but neglected per-  
108 turbations to the gravitational potential. We used the isotropic mean of the PREM Earth  
109 model (Dziewonski & Anderson, 1981), at a period of 1 s, with no attenuation. The first  
110 layer (water) was replaced by a solid layer matching the second layer.

### 111 **2.2 Analysis and calculation of surface waves in a half-space**

112 To understand the behavior of the mixed Rayleigh-Stoneley modes, we sought high-  
113 frequency solutions to the equations of motion for interface waves propagating horizon-  
114 tally through a solid, stratified layer overlying a fluid half-space, as described in detail  
115 by Ye (2018). First, we separated the P-SV from the SH equations. We then rewrote the  
116 P-SV equations in terms of the P and SV eigenfunctions, and solved them in the high-  
117 frequency (‘asymptotic’) limit by following the approach of Woodhouse (1978). Finally,  
118 we used the WKB approximation to find expressions for the  $P$  and  $SV$  wavefunctions.  
119 In this step, we followed the approach of Alenitsyn (1998), who considered a stratified  
120 fluid layer over a solid half-space. We combined this asymptotic solution with the bound-  
121 ary conditions to yield an analytical dispersion equation.

122 To verify the applicability the high-frequency analysis to the modes of our spher-  
123 ical Earth model, we calculated Rayleigh and Stoneley dispersion curves for ‘flattened’  
124 equivalent of the modified PREM model. For this we used the *Computer Programs in*  
125 *Seismology* software package (CPS; Herrmann, 2013) which implements the Haskell-Thomson  
126 propagator matrix technique (Haskell, 1964; C. Y. Wang & Herrmann, 1980). In this code  
127 the Earth-flattening transform is based on the work of Biswas and Knopoff (1970), Biswas  
128 (1972) and Chapman (1973).

### 129 **2.3 Calculation of the modes of a laterally-heterogeneous planet**

130 Finally, we calculated the modes of a 3-D Earth model containing a hypothetical  
 131 LLSVP using the same technique as in the spherically-symmetric case. In three dimen-  
 132 sions this is implemented as the *NormalModes* code (Shi et al., 2018, 2019). Starting  
 133 from our spherically-symmetric modified PREM model, we built a 3-D mesh consisting  
 134 of around 2.5 million second-order tetrahedral finite elements. We then added a repre-  
 135 sentative LLSVP to the base of the mantle.

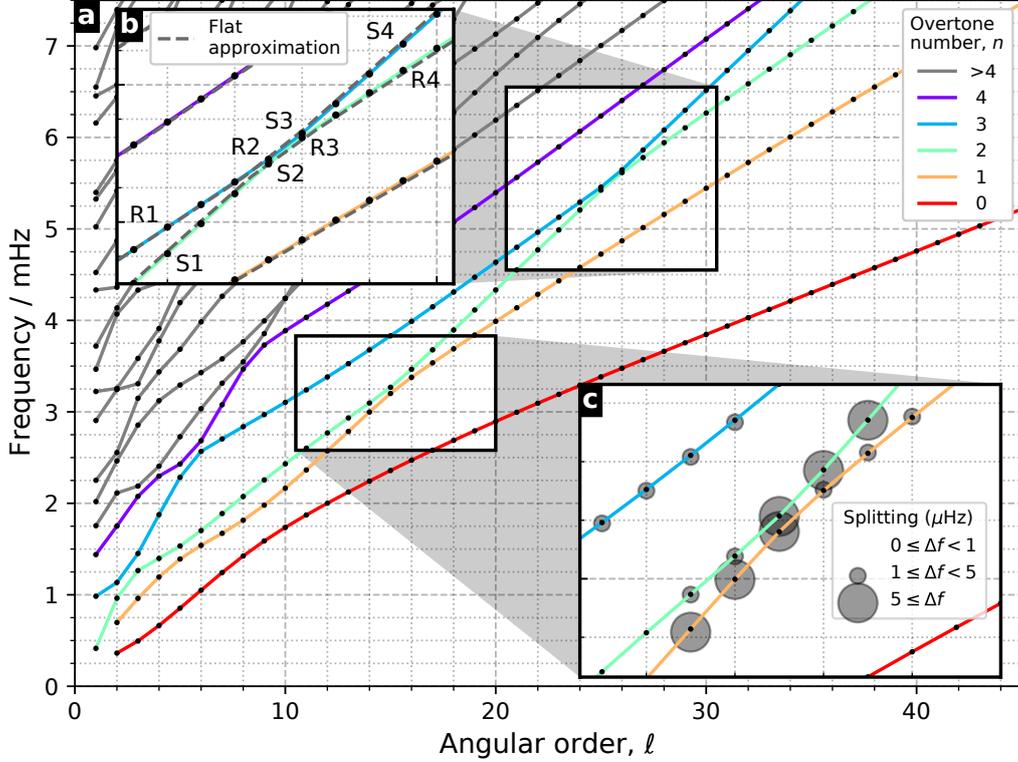

136 Significant uncertainty exists regarding the material properties of LLSVPs, as well  
 137 as their composition, temperature and geometry (see review by Lay, 2015). For the il-  
 138 lustration of the concepts introduced here, we chose properties of the model LLSVP within  
 139 the published range of observations. Specifically, the LLSVP extends from the CMB up  
 140 to a uniform thickness of 400 km, based on the lower bound in the study of Y. Wang and  
 141 Wen (2007). We use the outline of the African LLSVP at 2700 km depth from the con-  
 142 sensus study of Cottaar and Lekić (2016). We used an S-wave-speed anomaly of  $-4\%$ .  
 143 Using the ratio of S- and P-wave-speed anomalies from Tkalčić and Romanowicz (2002)  
 144 of 2.5, we then chose the P-wave-speed anomaly to be  $-1.6\%$ . We took a density anomaly  
 145 of  $+1\%$  (Ishii & Tromp, 1999; Moulik & Ekström, 2016), although others, such as Romanowicz  
 146 (2001), argue that the density anomaly could be positively correlated to the S-wave-speed  
 147 anomaly.

## 148 **3 Results**

### 149 **3.1 Mixed modes of a spherical Earth**

150 The calculated frequencies of the spheroidal modes are plotted on a ‘dispersion di-  
 151 agram’ (relating frequency and wavelength) in Fig. 2a. The Stoneley modes form a line  
 152 which has a steeper slope than the Rayleigh-mode overtone, indicative of a higher group  
 153 velocity, so that there are a series of ‘quasi-intersections’ or ‘avoided crossings’, the first  
 154 two of which are outlined by boxes. We focus first on the modes of the second quasi-intersection  
 155 (Fig. 2b).

156 The vertical-component displacement eigenfunctions of these modes (as a function  
 157 of radius) are shown in Fig. 3a,b. These two panels show the upper and lower branches,  
 158 respectively, and each shows a progression of four modes along the branch, as labeled  
 159 in Fig. 2b, from lowest to highest frequency. The lower branch (Fig. 3a) shows a tran-

**Figure 2.** Dispersion diagrams of Earth’s low-frequency spheroidal modes (black dots), relating angular order ( $\ell$ ) and frequency, with lines connecting branches of constant overtone number ( $n$ ). (The angular order of a mode controls the total number of nodal planes in the displacement pattern. For a given value of  $\ell$ , modes are assigned a value of  $n$  in order of increasing frequency. A spheroidal mode with these two numbers is denoted  ${}_nS_\ell$ . For surface-wave equivalent modes with large  $\ell$  and small  $n$ , the angular order is related to the wavelength ( $\lambda$ ) by  $\ell \approx 2\pi R/\lambda$  where  $R$  is the radius of the planet.) a) Overview. b) The second-quasi intersection, overlaid with the half-space approximation. The labeled Rayleigh (R1, . . . , R4) and Stoneley (S1, . . . , S4) modes have their radial displacement patterns plotted in Fig. 3a,b. c) The first quasi-intersection, showing the splitting of each mode due to lowermost-mantle heterogeneity, as detailed in Fig. 4.

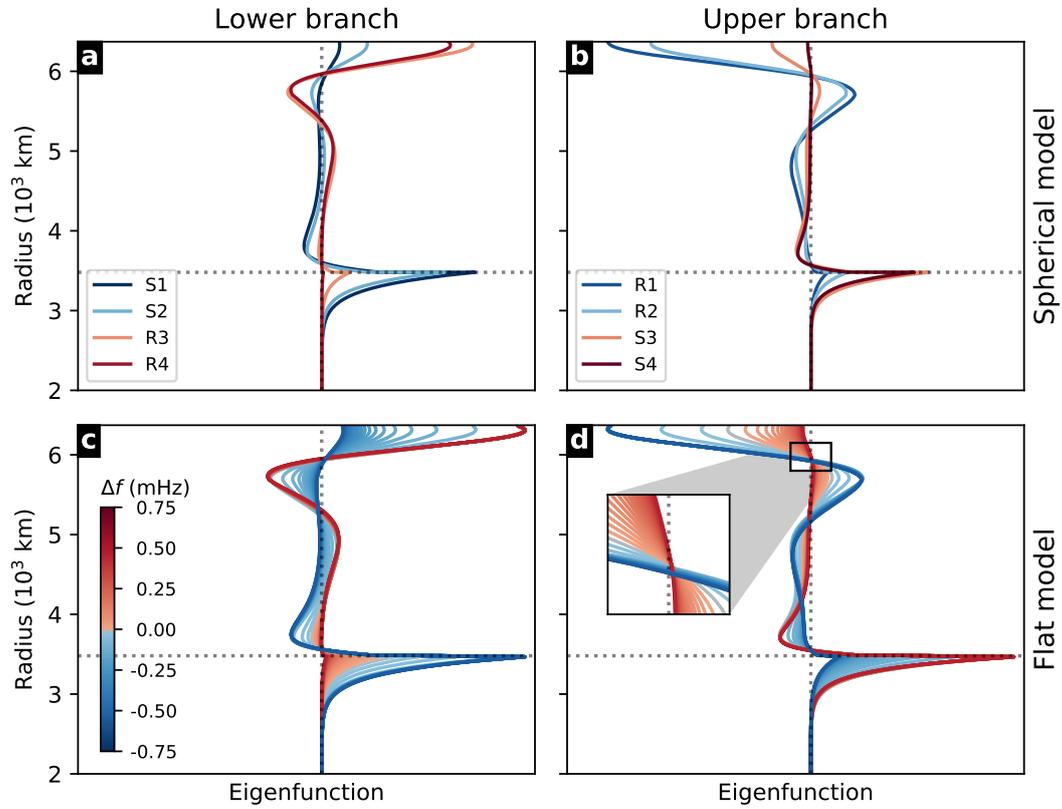

160 sition from a pure Stoneley mode (S1), with much larger displacement near the core-mantle  
 161 boundary, to a pure Rayleigh mode (R4) with much larger displacement near the sur-  
 162 face. The intermediate modes (S2 and R3) have significant displacement at both inter-  
 163 faces. We identify these as ‘mixed Stoneley-Rayleigh modes’. The same behavior is seen  
 164 in the upper branch (Fig. 3b), except that the transition is from a Rayleigh mode (R1)  
 165 to a Stoneley mode (S4). Note that the mixed modes pairs (e.g. S2 and R2) are not the  
 166 result of ‘coupling’ in the usual mode-seismology sense, where ‘coupling’ is attributed  
 167 to aspherical structure, but arise from the interaction of wave phenomena at separate  
 168 (parallel) interfaces, even a spherically-symmetrical medium with no lateral heterogene-  
 169 ity.

170 The displacement patterns have zero crossings, which, like all evanescent waves,  
 171 shift away from an interface when the frequency decreases, and vice versa. This effect  
 172 is shown in the inset in Fig. 3d. The small shifts demonstrate that the dramatic change  
 173 in mode character, from Rayleigh to Stoneley, occurs over a small frequency range.

174 A gallery of additional examples (Supplement S5; includes tangential component)  
 175 shows that mixing occurs near other Stoneley-Rayleigh quasi-intersections, although mix-  
 176 ing becomes weaker and narrower at higher frequencies. At the lowest frequencies, all  
 177 the modes of the CMB Stoneley branch could be described as mixed Stoneley-Rayleigh  
 178 modes (recall Fig. 1a). The distinction between Rayleigh, Stoneley, and mixed modes  
 179 gradually becomes clearer beyond the first intersection, with the second intersection be-  
 180 ing perhaps the best example (Fig. 3a,b). By the fourth quasi-intersection (around 11.5 mHz),  
 181 only a single pair of modes is affected, and the mixing is negligible.

182 Some mixed Stoneley-Rayleigh modes have been previously observed in real data,  
 183 where they are referred to simply as Stoneley modes (see the Discussion, section 4.1).  
 184 We note that pure Stoneley modes cannot be excited by earthquakes, as earthquakes do  
 185 not occur below depths of around 700 km. Even if a pure Stoneley mode were excited,  
 186 it would not be detectable at the Earth’s surface. In contrast, mixed modes can be ex-  
 187 cited by earthquakes and they can be detected at the surface. Their sensitivity is con-  
 188 centrated near the surface and CMB with little sensitivity to the mid-mantle.

189 Calculation of Stoneley modes is challenging for the commonly-used numerical in-  
 190 tegration approach (Dahlen & Tromp, 1998, page 312), for example as implemented in  
 191 the *Mineos* library (Masters et al., 2011). The difficulty is that the boundary conditions  
 192 must be applied at points of zero displacement. Mixed modes are doubly challenging be-

**Figure 3.** Profiles of vertical-component displacement as a function of radial coordinate, for modes along the quasi-intersecting mode branches shown in Fig. 2b, illustrating mode mixing and the correspondence between an infinite, flat system and a spherical one. Each profile is colored according to the frequency of the mode relative to the intersection frequency. Panels a) and b): Selected eigenfunctions calculated for a spherical Earth, as labeled in Fig. 2b. The displacement is multiplied by the radial coordinate, to allow proper comparison of particle displacements at each depth. Panels c) and d): The eigenfunctions of a half-space model, which vary smoothly as a function of frequency. The ‘radius’ here refers to the coordinate before flattening takes place. The relative amplitudes of different eigenfunctions have no physical meaning; only their shape is important.

193 cause it is hard to guarantee orthogonality in the case of the near-identical frequencies  
 194 (‘accidental degeneracy’). Our finite-element technique does not encounter these diffi-  
 195 culties. However, we find that the frequencies, eigenfunctions (and therefore sensitivity  
 196 kernels) are indistinguishable between the *Ouroboros* and *Mineos* codes when the start-  
 197 ing model has an appropriate reference frequency.

198 In conclusion, the calculated mode displacement patterns (Fig. 3a,b) thus show that  
 199 Stoneley and Rayleigh modes mix when they are close in frequency, creating mixed Stoneley-  
 200 Rayleigh modes, which should be excitable, observable and sensitive to the deep man-  
 201 tle.

### 202 3.2 Coupled waveguides in a flat system

203 Our high-frequency analytical solution (Methods, section 2.2) separates in most cases  
 204 to Rayleigh waves at the solid-vacuum interface (Strutt, 1885) and Stoneley waves at the  
 205 solid-fluid interface (Stoneley, 1924; Scholte, 1942), with the allowed combinations of fre-  
 206 quency and wavelength governed by two dispersion curves. (Dispersion curves are the  
 207 continuous analog of the discrete dispersion diagram shown in Fig. 2.) However, near  
 208 the quasi-intersection point, the two solutions cannot be separated, and the dispersion  
 209 equation has two roots, one either side of the intersection point. This explains why there  
 210 is a quasi-intersection instead of a true intersection. This behavior was previously pointed  
 211 out by Zhao and Dahlen (1993), who noted from Arnold (1978, pages 425–437) that ‘such  
 212 avoided crossings are characteristic of weakly-coupled spectra in all physical systems’.

213 One of the pair of solutions has maximum displacement at the solid-fluid interface,  
 214 but also non-negligible displacement at the free surface; we call this a ‘mixed Stoneley-  
 215 Rayleigh mode’. Conversely, the other root has maximum displacement at the free sur-  
 216 face but non-negligible displacement at the fluid-solid interface; we call this a ‘mixed Rayleigh-  
 217 Stoneley mode’ (although we use both terms loosely to refer to both kinds). If we con-  
 218 sider the other side of the intersection, the two kinds of mode are interchanged. We also  
 219 find that the portion of the dispersion diagram affected by the quasi-intersection becomes  
 220 smaller as the frequency increases.

221 To relate this analysis to the spherical case, we calculated the dispersion curves and  
 222 displacement patterns of an equivalent flattened Earth model (Methods, section 2.2), as  
 223 shown in Fig. 2c and Fig. 3c,d. The fundamental difference between the flat and spher-  
 224 ical systems is that the flat system has continuous solution curves (derivatives are shown

225 in Supplement S1) instead of discrete solution points. Apart from this, the flat model  
 226 appears to be a good approximation of the spherical case. We do not expect perfect agree-  
 227 ment, because of the approximations of the Earth-flattening calculations, and also be-  
 228 cause gravity is neglected. Nonetheless, their similarity suggests that, at these ‘high’ fre-  
 229 quencies, qualitative insights from our analysis are also applicable to the spherical case,  
 230 consistent with Woodhouse (1978), whose analysis we followed.

231 These results show that Stoneley-Rayleigh mixing occurs in infinite, flat systems,  
 232 and is not a result of the finite size or curvature of planets. It is an example of what we  
 233 identify as ‘seismic waveguide coupling’, which occurs between two waveguides when-  
 234 ever their dispersion curves come close to intersecting, in spite of a large physical sep-  
 235 aration. Our analysis predicts the properties suggested by the spherical calculations: the  
 236 dispersion curves can never intersect (Fig. 2b,c), mode mixing occurs close to quasi-intersection  
 237 points (Fig. 3), and the affected intersection region becomes narrower at higher frequen-  
 238 cies (Supplement S5). Having established the existence and properties of Stoneley-Rayleigh  
 239 mixed modes, we now return to a slightly more realistic model of the Earth, to illustrate  
 240 how these modes provide useful constraints on the lower mantle.

### 241 **3.3 Mixed modes of a laterally-inhomogeneous Earth**

242 We calculated the modes of a 3-D Earth model containing an LLSVP (Methods,  
 243 section 2.3). As expected, the lateral heterogeneity splits each spherically-symmetric  $(2\ell + 1)$   
 244 degenerate ‘mode’ (Fig. 2a) into a ‘multiplet’ with a range of frequencies, allowing a foren-  
 245 sic analysis of the structure causing the splitting. The frequency splitting near the first  
 246 quasi-intersection is shown in Fig. 2c, as the difference between the minimum and max-  
 247 imum frequencies of each multiplet. We see that the Stoneley modes and mixed Stoneley-  
 248 Rayleigh modes are more severely split by the anomaly, confirming that they are unusu-  
 249 ally sensitive to the lowermost mantle. This illustrates how observations of the splitting  
 250 of these modes provides tighter constraints on lower-mantle structures than observations  
 251 of other modes.

252 A detailed view of the splitting is shown in Fig. 4a for the four modes nearest the  
 253 quasi-intersection. The severity of the splitting varies between multiplets (as was already  
 254 seen in Fig. 2c). This is because some of the multiplets are more sensitive to the CMB  
 255 (for example, compare the sensitivity kernels for modes  ${}_1S_{16}$  and  ${}_2S_{16}$  in the gallery, Sup-  
 256 plement S5). The  $2\ell+1$  modes in each multiplet (31 or 33 for these four modes) show

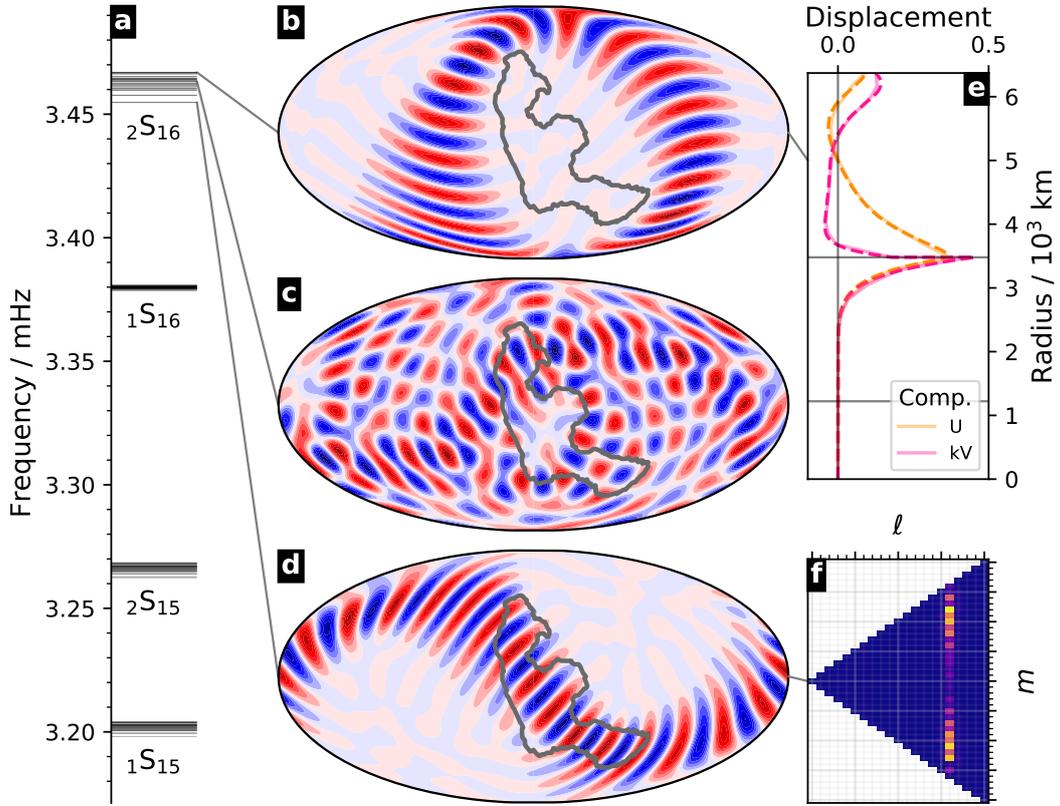

257 irregular changes in frequency. We can understand how this splitting pattern arises by  
 258 looking at the displacement patterns of some of the modes (Fig. 4b,c,d) of the most severely  
 259 split multiplet ( ${}_2S_{16}$ ).

260 The displacement patterns are shown for three of the 33 modes from the  ${}_2S_{16}$  mul-  
 261 tiplet. We have chosen the modes with the highest, middle, and lowest frequencies, as  
 262 indicated by the lines from panel a. For simplicity, we only show one component of the  
 263 displacement (the radial component), and this component is only plotted at the CMB,  
 264 where the displacement is at a maximum. The full displacement pattern for each mode  
 265 (not shown here) is a three-dimensional vector field with both radial and tangential com-  
 266 ponents.

267 The first observation of the displacement patterns is that the shape of the anomaly  
 268 (indicated by a gray outline), along with the requirement that the modes are orthogo-  
 269 nal, controls the ‘shape’ of the modes. Thus the modes form a series from high to low  
 270 frequency. For our choice of material parameters, this sequence starts from the mode most  
 271 concentrated within the anomaly (Fig. 4b) and ends with the mode least concentrated  
 272 within the anomaly (Fig. 4d). This can be interpreted simply in terms of interfering waves  
 273 traveling more slowly through the anomaly. In real observations, the individual singlets  
 274 are usually blurred together, but a seismometer situated directly above the LLSVP would  
 275 observe a lower frequency for mode  ${}_2S_{16}$ . The geographic and frequency variations across  
 276 a mode multiplet are commonly summarized using a ‘splitting function’ map.

277 We note that displacement patterns at other depths (not shown here) are almost  
 278 identical, except that they vary in amplitude. This is consistent with the unperturbed  
 279 case, in which the normal modes can be separated into a product of a function of an-  
 280 gular location and a function of radius. This latter function, the variation in displace-  
 281 ment with radius, is shown for one mode in Fig. 4e. (More precisely, we plot the radial  
 282 and consoidal spherical harmonic components with  $m = 3$ , the dominant value of  $m$ ,  
 283 but all values of  $m$  show the same pattern.) As shown by the dotted line, the perturbed  
 284 result closely matches the result for the spherical Earth. This suggests that perturbed  
 285 modes are predominantly a linear combination of modes within the same unperturbed  
 286 multiplet (which have the same radial profiles), consistent with the ‘isolated multiplet’  
 287 approximation commonly used in perturbation theory.

288 We can confirm this more directly by projecting the perturbed modes into the ba-  
 289 sis formed by the unperturbed modes, as shown in Fig. 4f for the lowest-frequency mode

**Figure 4.** Modes of the first quasi-intersection in an Earth model containing an LLSVP. a) The splitting of the multiplets of the first quasi-intersection (see Fig. 2c) into non-degenerate modes. b, c, d) Radial component of the displacement pattern of three of modes from the  ${}_2S_{16}$  multiplet, as indicated by the gray lines from panel a), sampled at the CMB. The three modes are the highest-, middle-, and lowest-frequency modes of the multiplet. The gray outline shows the edge of the LLSVP. e) The magnitude of the displacement as a function of radius for the mode shown in panel b). Both radial ( $U$ ) and consoidal ( $kV$ ) components are shown; the perturbed model also has a small toroidal component, but it is negligible and so it is not shown here. The dashed line shows the profile expected for the unperturbed model; the perturbed and unperturbed lines are almost identical. f) Projection of the displacement of the mode shown in d) into the basis defined by the unperturbed modes. All coefficients are close to zero (blue) except in the  $\ell = 16$  band.

290 of the  ${}_2S_{16}$  multiplet. We see the dominant coefficients all come from the same parent  
 291 multiplet with  $n = 2$  and  $\ell = 16$ . Other small coefficients indicate minor deviation  
 292 from the isolated multiplet approximation; in other words, coupling with other multi-  
 293 plets (here ‘coupling’ has the usual mode-seismology meaning). Coupling with other modes  
 294 is very small, but can be seen with a logarithmic color scale (Supplement S2).

295 In a more realistic Earth model, the mode coupling, frequency splitting and ‘shape’  
 296 of the modes will also be affected by other lateral heterogeneity and by the planet’s ro-  
 297 tation. We investigated the effect of rotation (Supplement S3) and find that splitting in-  
 298 creases for all modes, but the mixed modes remain markedly more strongly split due to  
 299 the LLSVP anomaly. The intuitive interpretation of the ‘LLSVP-dominated’ splitting  
 300 (Fig. 4) remains valid, but the rotation adds a new group of ‘oblateness-dominated’ modes.

301 In summary, these calculations show that mixed modes arise in a realistic Earth  
 302 model and are unusually sensitive to CMB structures (Fig. 2c and 4e). This sensitivity  
 303 can be exploited via geographical measurements of the modes’ frequency splitting (Fig. 4b,c,d).

## 304 4 Discussion

### 305 4.1 Previous studies of Stoneley modes

306 Measurements of splitting of higher-frequency mixed Rayleigh-Stoneley modes are  
 307 given by Koelemeijer et al. (2013) and Koelemeijer et al. (2015), where they are referred  
 308 to as Stoneley modes. A systematic search yielded only those modes that were near the  
 309 first quasi-intersection (the  $\ell = 1$  modes  ${}_1S_{13}$  to  ${}_1S_{16}$ , and the  $\ell = 2$  modes  ${}_2S_{13}$  to  
 310  ${}_2S_{17}$ ), the second quasi-intersection (modes  ${}_2S_{25}$ ,  ${}_3S_{25}$  and  ${}_3S_{26}$ ), and some lower-frequency  
 311 Stoneley modes which sample the whole mantle. This can be explained by the mode-mixing  
 312 phenomenon described here: Stoneley modes far from the branch intersections have no  
 313 surface (Rayleigh) component, and so are not excitable or observable.

### 314 4.2 Perturbation theory

315 The conventional approach to calculating the modes of a laterally-heterogeneous  
 316 Earth is to use perturbation theory. We have presented the first calculations of mixed  
 317 modes using a direct (non-perturbative) approach. The results are qualitatively simi-  
 318 lar, but in future work we aim to quantify the errors introduced by standard perturbation-  
 319 theory approaches. These errors may contribute to the misfit of relatively high-frequency

320 mode data (Deuss & Woodhouse, 2001), especially the effect of CMB topography (Al-  
321 Attar et al., 2012), but also lateral heterogeneity and rotation. This may be more im-  
322 portant for stronger deviations from spherical symmetry found in other planetary bod-  
323 ies.

### 324 **4.3 New ways to study Earth’s CMB region**

325 Beyond refinement of results from known modes, it may be possible to expand or  
326 better constrain the catalog of mixed modes, thanks to new deployments, instrumenta-  
327 tion, earthquakes, inverse theory, and signal-processing techniques. In particular, some  
328 of the CMB-sensitive modes further from the the quasi-intersections (e.g. modes  ${}_2S_{23}$   
329 and  ${}_3S_{23}$ ; see the gallery) might be detectable, perhaps using depth-based stacking (see  
330 Lekić et al., 2009), array-based gradiometry (see Schmelzbach et al., 2018), or horizontal-  
331 component data (see Schneider & Deuss, 2020), given that Stoneley-mode particle-motion  
332 polarization is distinct from that of overlapping Rayleigh modes (compare with Boaga  
333 et al., 2013).

334 We also investigated numerically the possibility of a ‘mixed Stoneley-Rayleigh wave’  
335 propagating along the parallel waveguides of the outer surface and the CMB, by using  
336 mode summation. Our findings are detailed in Supplement S4 and summarized here. For  
337 the sum of modes to resemble a traveling wave instead of a standing wave, the mixing  
338 must affect enough modes near the intersection. We found that the waveguide coupling  
339 is strong enough for an earthquake to generate a Stoneley wave on the CMB, whose wavepacket  
340 is quite dispersive, spanning the range of group velocities from the two mode branches.  
341 At the Earth’s surface, however, the wavefield is dominated by an ordinary Rayleigh wave,  
342 with no indication that it is influenced by waveguide coupling. Therefore, although the  
343 CMB Stoneley wave is of theoretical interest, we do not expect that mode mixing could  
344 be observed in a traveling wave at the surface.

### 345 **4.4 Modes and waveguide coupling in other settings**

346 Waveguide coupling has been recognized in many non-seismic systems, such as pho-  
347 tonic waveguides (Marcuse, 1971; Bertolotti et al., 2017, section 3.4), oceanic gravity waves  
348 (Miropol’sky, 2001, section 2.2) and acoustic gravity waves in the atmosphere (Harkrider,  
349 1964). Seismic waveguide coupling is an important example, and we expect it to occur  
350 in many settings outside of the solid Earth, such as in ocean basins (Alenitsyn, 1998),

351 cells with vesicles (Vorselen et al., 2017), solid-state acoustic circuits (see Hess, 2002),  
352 floating ice sheets, magma chambers, and planetary bodies containing internal oceans,  
353 such as Europa (Anderson et al., 1998) and (perhaps) Pluto (Denton et al., 2020). More  
354 generally, the non-perturbation-based approach which we showcase here will allow us  
355 study the seismic modes of planets, stars, and asteroids which are far from spherically  
356 symmetrical, such as the irregularly-shaped asteroid Apophis.

## 357 5 Conclusions

358 We show that two exponentially-localized seismic waves, propagating along par-  
359 allel solid-vacuum and solid-fluid interfaces, can couple to form a pair of waves, both of  
360 which have a non-zero displacement component near both interfaces. Even if the sep-  
361 aration between the two interfaces is large, coupling will occur at frequencies where the  
362 two dispersion curves almost intersect. This is an example of the waveguide coupling phe-  
363 nomena found in many branches of physics.

364 Earth’s normal modes also display waveguide coupling. Most dramatically, we show  
365 that there is coupling between the free surface and core-mantle boundary, which results  
366 in mixed Stoneley-Rayleigh modes. Some of these modes are excitable by earthquakes  
367 and are expected to be detectable at the Earth’s surface. This clarifies why previous work-  
368 ers have been able to observe higher-frequency Stoneley-like modes, which, in the ab-  
369 sence of mode mixing, are exclusively focused at the core-mantle boundary.

370 We use a new finite-element technique for both spherically-symmetric and laterally-  
371 inhomogeneous models to show that mixed-mode frequencies and splitting are unusu-  
372 ally sensitive to anomalies in the lower mantle. The concept of mode mixing, and the  
373 new tools demonstrated here, may guide future observational studies of mixed Rayleigh-  
374 Stoneley modes. Such observations are key to important debates about the lowermost  
375 mantle, including the density of LLSVPs and the spatial distribution of post-perovskite.  
376 Moreover, mixed modes may be a useful probe for other bodies with strong internal wave-  
377 guides, for example cells with vesicles, and planetary bodies such as Europa and Pluto.  
378 In the coming decades, an abundance of seismic data will be gathered from bodies be-  
379 yond Earth, which are in many cases far from spherically symmetric. The non-perturbation-  
380 based forward modeling demonstrated here will help to understand the interiors of those  
381 strange new worlds.

## Code availability

The 3-D code, *NormalModes*, is available at <https://github.com/js1019/NormalModes>. The 1-D code, *Ouroboros*, will be made public on GitHub and the FAIR-compliant repository Zenodo at the time of publication. In the meantime, the source code is included as ‘Data Set SI - Supplemental Code’. Please do not distribute this code.

## Author contribution statement

RDvdH and MVdH conceived the idea of mixed Rayleigh-Stoneley modes. Under the supervision of MVdH: 1. JY carried out semiclassical analysis; 2. JY and JS developed the weak form and implemented a finite-element radial solution; 3. JY first calculated mixed modes; 3. JS implemented a finite-element 3D solution including eigensolver; 4. JH improved the radial code and translated it into Python. Under the supervision of both RDvdH and MVdH: 1. HMD tested semiclassical analysis numerically; 2. HMD calculated modes of 3D LLSVP model; 3. HMD wrote the first draft of paper and prepared figures. RDvdH, MVdH and HMD revised the manuscript, and all authors provided comments on the final draft.

## Acknowledgments

MvdH is supported by the Simons Foundation Math + X program, National Science Foundation grant DMS-1815143, and XSEDE allocation EAR170019. HMD is grateful to R. Herrmann, P. Koelemeijer and H. Lau for helpful discussions. For spherical harmonic analysis, we used packages *SHTns* (Schaeffer, 2013) and *SHTools* (Wieczorek & Meschede, 2018). For plotting, we used *Matplotlib* (Hunter, 2007), including *Cartopy* for maps (Met Office, 2015).

26 **S1 Group velocity**

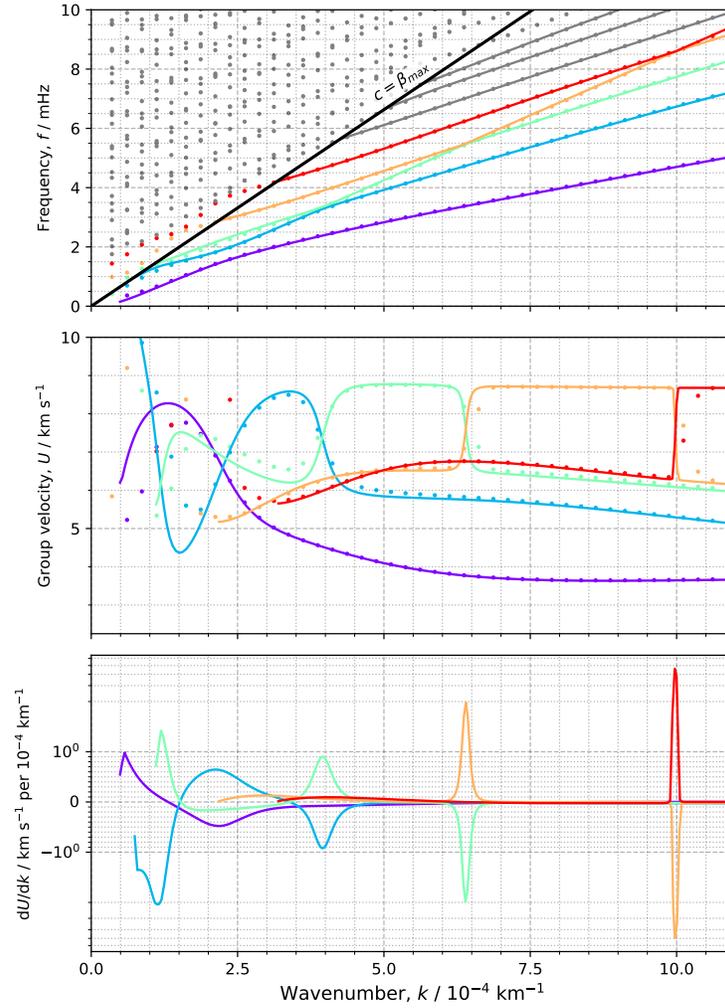

Figure S1: a) Dispersion diagram for modes, shown as points, and the half-space approximation, shown as solid lines. b) Group velocity, calculated from the dispersion diagram, for the first five branches. c) The (continuous) first derivative of the group velocity, illustrating that the group velocity is a smooth function of wavenumber. Note the change from a linear y-axis (between -1 and 1) to a logarithmic one.

## 27 **S2** Projection of perturbed modes into basis of 28 unperturbed modes

29 The modes of the spherically-symmetric reference model form a complete basis  
30 within the sphere. The perturbed modes can be projected into this basis, as  
31 shown here (Supp. Fig. S2) for the lowest-frequency mode of the  ${}_2S_{16}$  multiplet  
32 (see Fig. 4d,f in the main text). The basis functions are normalized using the  
33 *Mineos* normalization.

34 The unperturbed mode basis is used in the perturbation-theory approach  
35 to calculate the modes and frequencies of the perturbed model. A common  
36 assumption in this approach is the ‘isolated multiplet’ approximation, where the  
37 modes of a perturbed multiplet are calculated using only the modes of the same  
38 multiplet, before perturbation, as the basis. The coefficients in Supp. Fig. S2  
39 are mostly close to zero, except for the  ${}_2S_{16}^m$  coefficients, indicating that the  
40 isolated multiplet approximation is a good approximation. However, we can  
41 also see weak coupling with  ${}_2S_{15}$ ,  ${}_2S_{17}$ ,  ${}_1S_{15}$ ,  ${}_1S_{16}$ ,  ${}_1S_{17}$ ,  ${}_6S_6$  and  ${}_3T_5$ .

42 The power spectrum of the LLSVP anomaly used in our calculation is shown  
43 in Supp. Fig. S3. It is dominated by the  $\ell = 1$  band.

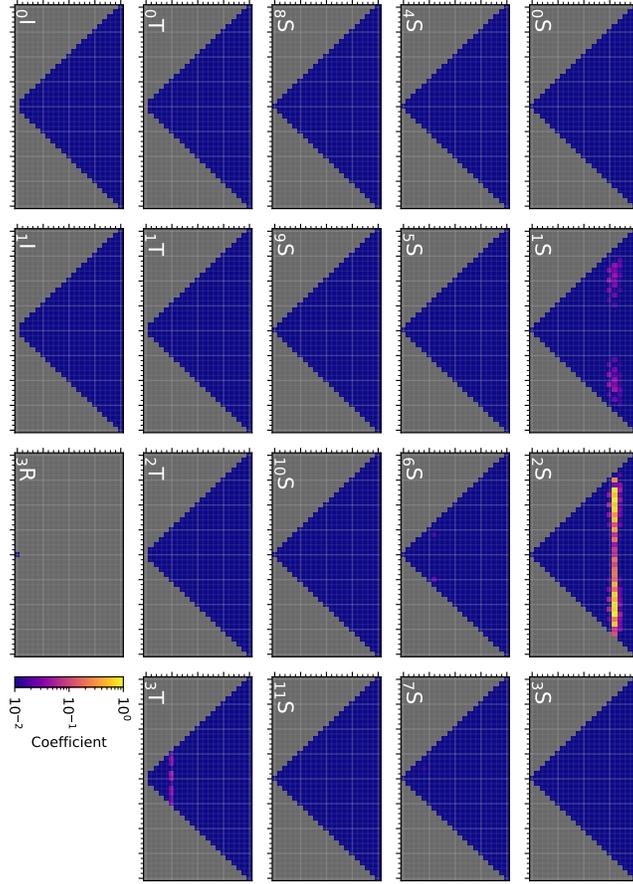

Figure S2: Projection of one of the perturbed modes from the  ${}_2S_{16}$  multiplet into the unperturbed-mode basis. Each panel shows the coefficients  $C_{l,m}$  for a given mode branch  ${}_nX$ . Only branches with modes within 0.5 mHz of the target mode are shown. For each panel, the  $x$ -axis corresponds to the angular degree  $m$  and the  $y$ -axis corresponds to angular order  $l$ .

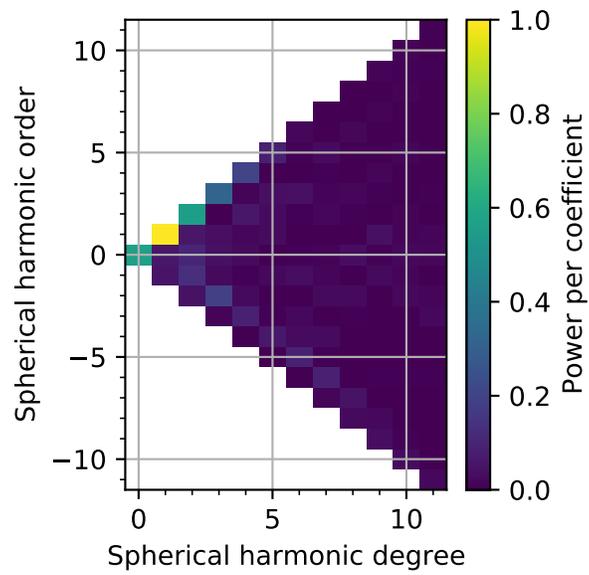

Figure S3: The spherical harmonic power spectrum of the LLSVP anomaly (shown in outline in Fig. 4b,c,d). The power is normalized to the largest coefficient.

### 44 **S3 Effect of Earth’s rotation on the mixed modes**

45 We can make the 3-D mode calculations from the main text (section 3.3) more  
46 realistic by including the effects of Earth’s rotation: oblateness, centripetal  
47 potential, and Coriolis force. Our approach is described in Shi et al. (in review).  
48 We assume a rotation period of 23.9345 hours, and calculate the ellipticity as a  
49 function of radius using Radau’s approximation to Clairault’s equation (Dahlen  
50 and Tromp, 1998, equation 14.20). Once rotation is including, the eigenfunction  
51 vector fields become complex, representing eastward- or westward-propagating  
52 waves. The frequencies and spatial displacement patterns are also altered, as  
53 we discuss below.

54 We first note that rotation increases the ‘splitting’ of each multiplet (which  
55 we define as difference between the highest and lowest singlets within a given  
56 multiplet). This can be seen by comparing the splitting in the rotating case  
57 (Supp. Fig. S4) with the non-rotating case (Fig. 1c); note the change in marker  
58 scaling. Although all modes have greater splitting, the splitting of the mixed  
59 modes is still markedly stronger due to their sensitivity to the LLSVP anomaly.  
60 As an aside, we note that all of the multiplets have a positive shift in their  
61 center frequency (the mean of the singlet frequencies).

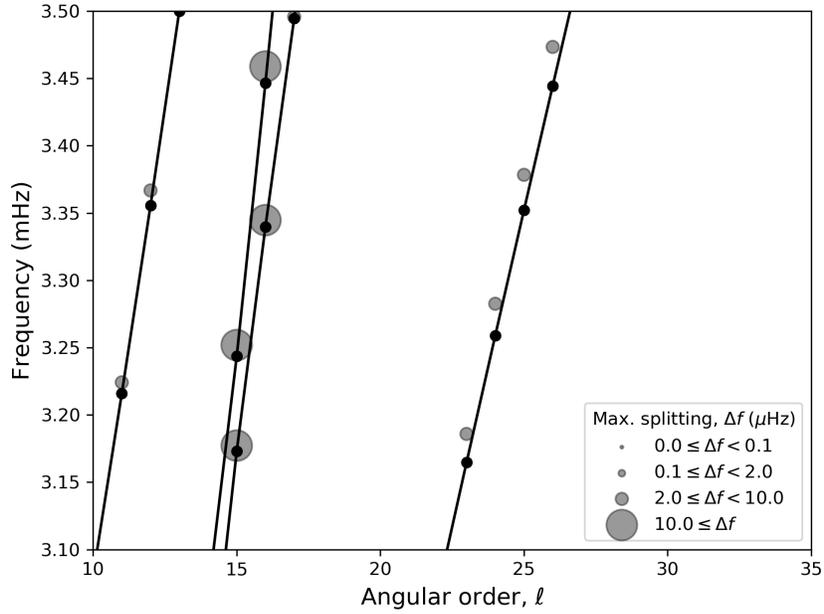

Figure S4: Frequency splitting of each degenerate multiplet in a model with rotation and an LLSVP anomaly. The modes of the spherically-symmetrical reference model are shown as solid lines with opaque dots.

62 This additional splitting can be understood by examining the eigenfunctions,  
 63 for example for the mode  ${}_1S_{15}$  in [Supp. Fig. S5](#). As we saw in the non-rotating  
 64 case (Fig. 4), a range of frequencies arises from modes concentrated inside or out-  
 65 side the LLSVP ('LLSVP-dominated'). This range is augmented by a group of  
 66 modes whose shape is controlled primarily by Earth's oblate shape ('oblateness-  
 67 dominated'). These modes have wider, more regular frequency separation, with  
 68 lower-frequency modes being more concentrated at the equator. Note that the  
 69 number of singlets does not change.

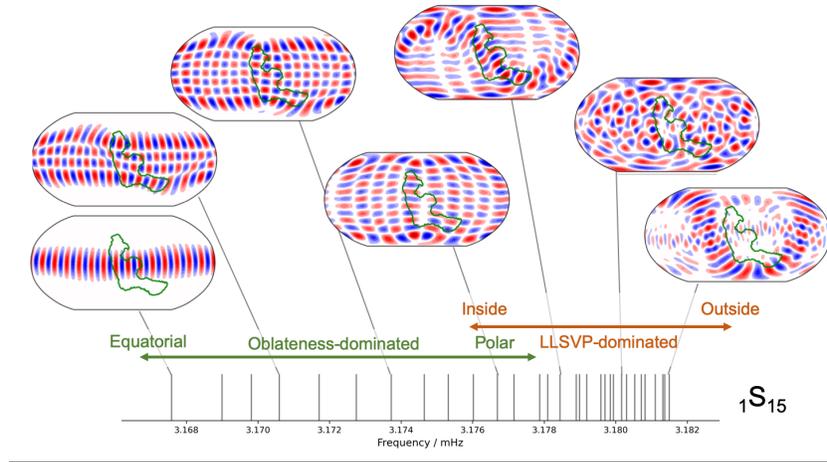

Figure S5: Selected eigenfunctions for multiplet  ${}_1S_{15}$ , showing relationship to frequency splitting. Each map shows the real part of the vertical-component displacement field at Earth's surface for a given mode.

70 This behavior is found in all of the mixed modes and most of the other  
 71 modes which we calculated (not shown here). A complicating factor is mode  
 72 coupling, which becomes stronger when rotation is included. We do not discuss  
 73 mode coupling in detail here, although in future we plan to compare the mode  
 74 coupling in the direct 3-D approach to the predictions of perturbation theory.

## 75 S4 Illustration of traveling-wave behavior

76 It is well-known that summation of normal modes along a branch yields a trav-  
77 eling wave. We investigated whether summation of the modes of the second  
78 quasi-intersection produces any unusual traveling-wave behavior. The modes  
79 used in the summation are shown in [Supp. Fig. S6](#). Each mode marker is  
80 scaled according to the globally-averaged RMS excitation of that mode, given  
81 our choice of source, which was the point CMT approximation of the 2011 To-  
82 hoku earthquake. Note that these calculations were carried out in *Mineos* and  
83 include the effect of attenuation, unlike other mode calculations in this paper.

84 We restricted the summation to modes from the two intersecting branches  
85 ( $n = 2$  and  $n = 3$ ) within a narrow frequency band indicated by the outer pair of  
86 gray horizontal lines. A cosine frequency taper was applied to this band, so that  
87 modes outside the inner pair of gray horizontal lines had reduced amplitude. It  
88 can be seen that the Stoneley branch has low excitation amplitudes, typically  
89 around 100 times weaker than the Rayleigh branch.

90 The contributions of the two branches can be visualized in [Supp. Fig. S7](#).  
91 From the left column, we see that the Rayleigh branch resembles a traveling  
92 wave in the middle and upper mantle, but in the lower mantle it resembles a  
93 standing wave, due to contributions from just a small number of mixed modes  
94 at these depths. The middle column shows that the Stoneley branch resembles  
95 a standing wave throughout the planet, because only a few modes are excited.  
96 The net effect, shown in the right column, appears to have a traveling wave in  
97 the upper mantle and on the CMB.

98 We can understand the results of the full summation by plotting the velocity  
99 field as a seismic section with increasing distance from the source ([Supp. Fig. S8](#)).  
100 The plot also shows the group velocities of the modes (calculated using *Mineos*)  
101 for a selection of modes. The wavefield at the surface is a traveling wave whose  
102 group velocity is well described by the ‘normal’ Rayleigh modes before and after  
103 the quasi-intersection region (e.g. modes  ${}_3S_{22}$  and  ${}_2S_{28}$ ). In other words, the  
104 surface wavefield is dominated by the second Rayleigh overtone.

105 By contrast, if we plot the wavefield just above the core-mantle boundary  
106 (Supp. Fig. S9), a different traveling wave arises. This wavepacket is more  
107 dispersive, with group velocities ranging between the Rayleigh and Stoneley  
108 group velocities found further from the intersection. Note that the amplitude  
109 of this wave is around 10 times smaller than the surface wave.

110 We interpret this CMB wave in the following way: near the quasi-intersection,  
111 the Rayleigh modes have a small Stoneley component at the CMB, and the  
112 Stoneley modes have a small Rayleigh component at the surface. When car-  
113 rying out the normal-mode summation near the quasi-intersection, if all of  
114 these modes are included, the excitation amplitudes are large enough over a  
115 sufficiently wide bandwidth to produce a traveling wave on the CMB. The  
116 wavepacket is broad due to the wide range of group velocities of the contributing  
117 modes. We call this a ‘mixed Stoneley-Rayleigh wave’

118 Unfortunately, if a corresponding ‘mixed Rayleigh-Stoneley wave’ exists and  
119 propagates along the free surface, its amplitude must be very small as it is not  
120 visible in Supp. Fig. S8. Therefore, although it is interesting to know about the  
121 CMB wave, it is not of practical use.

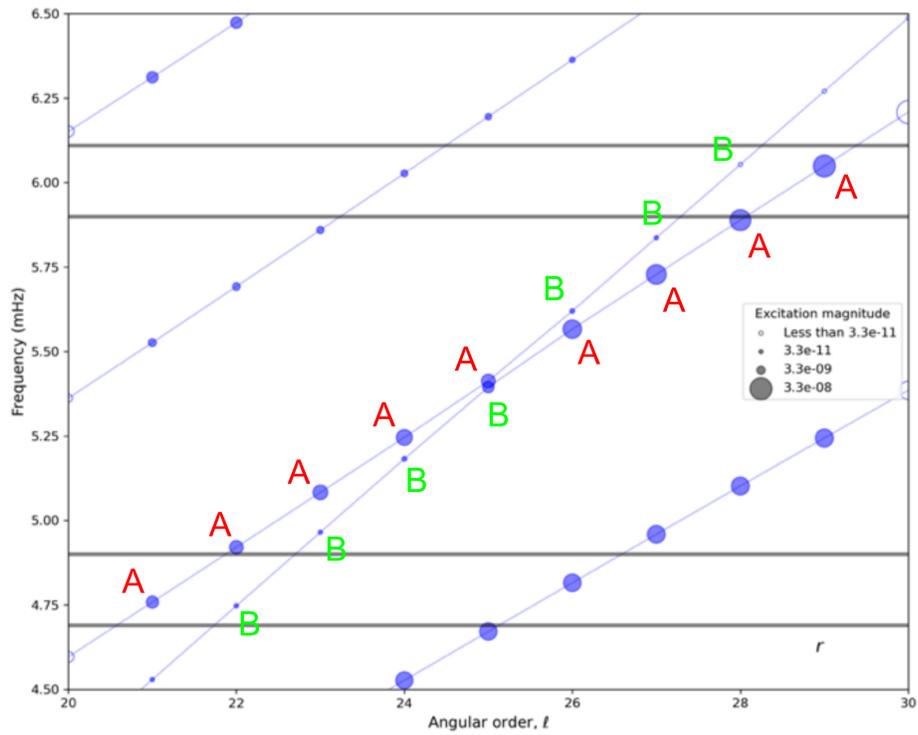

Figure S6: Mode diagram showing detail of the second quasi-intersection. Marker symbols are scaled by the excitation of each mode (in S.I. units). Second-overtone Rayleigh modes are labeled 'A', and Stoneley modes are labeled 'B' (although this distinction is arbitrary in the case of the mixed modes).

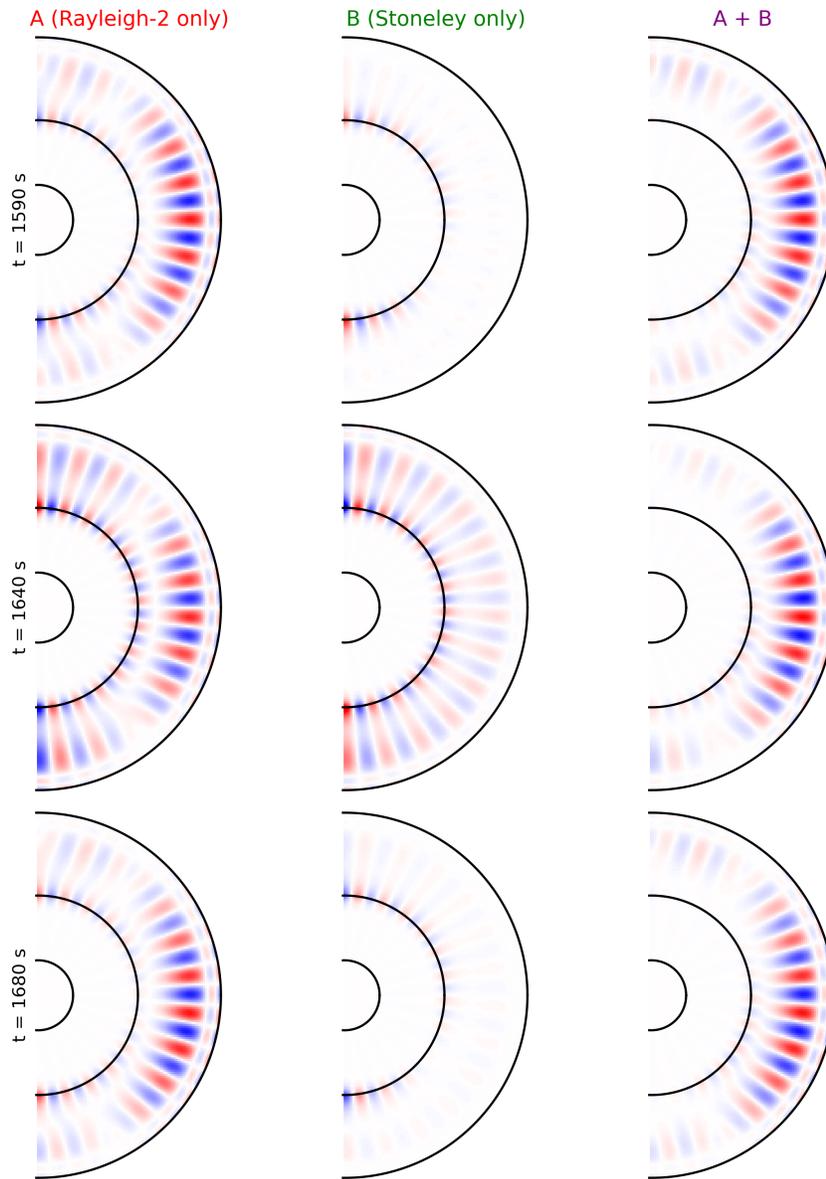

Figure S7: Plots of the vertical velocity field at various times (indicated on the left-hand side) after the earthquake, decomposed into contributions from different mode branches (indicated at the top). The color scale is the same for each panel. The source location is at the top of each panel.

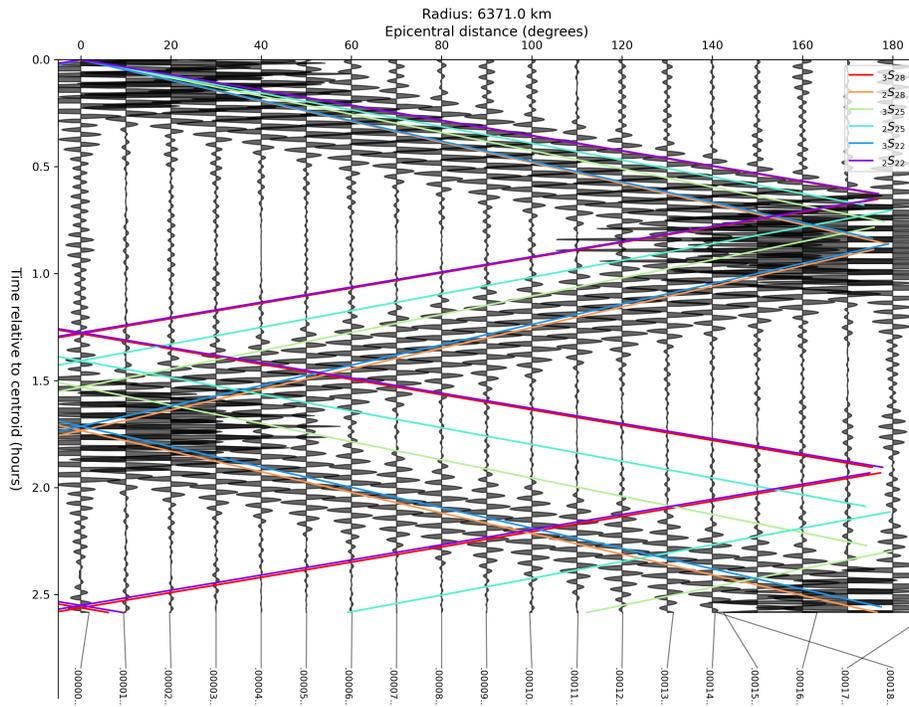

Figure S8: Seismic section observed at the surface. Each trace shows the particle velocity at the specified epicentral distance. Traces are normalized by a common value so that relative amplitudes are preserved. Mode group velocities are indicated by colored lines as shown in the legend.

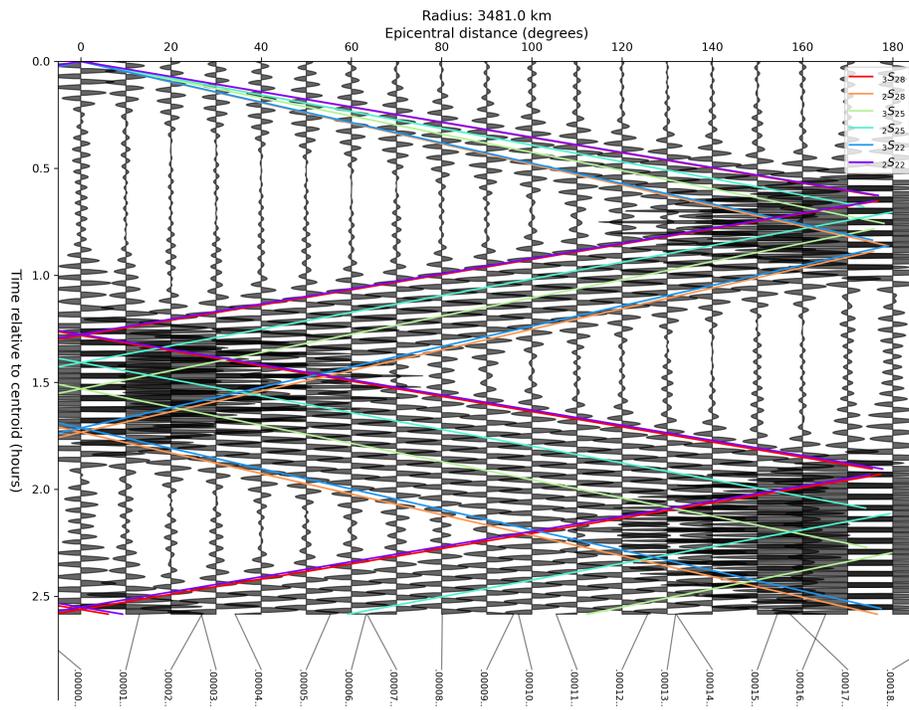

Figure S9: The same as Supp. Fig. S8, except the particle velocity is plotted at the CMB instead of the surface.

## 122 **S5 Gallery of modes near quasi-intersections**

123 Here we show the eigenfunctions for modes in the vicinity of the first, second  
124 and third quasi-intersections, calculated using the *Mineos* code. In contrast  
125 with the main text, we include the effects of attenuation and the perturbation  
126 to the gravitational potential, to make these calculations as realistic as possible.  
127 Nonetheless, given that mode mixing is sensitive to small shifts in mode fre-  
128 quencies, this gallery should not be used to pin-point mode-mixing frequencies  
129 on the real Earth, because we have neglected the effects of anisotropy, rotation,  
130 and three-dimensional structures, including ellipticity and the crust and ocean.

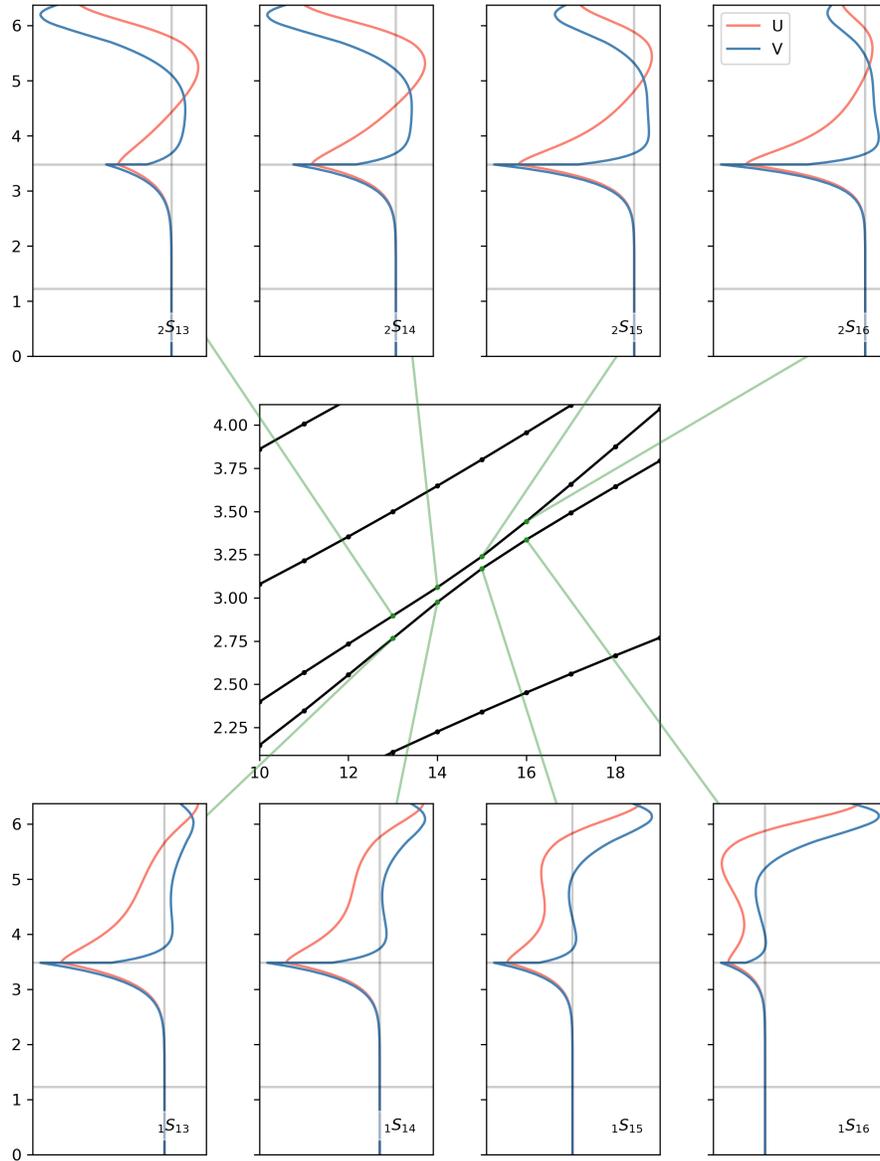

Figure S10: Summary of eigenfunctions of modes near the first quasi-intersection. The central panel shows the location of the modes on the dispersion diagram ( $\ell$  versus frequency in mHz). For each mode, the radial and consoidal components are shown, including the factor of  $k$  omitted in some conventions. The y-axis shows radial coordinate in units of  $10^3$  km and horizontal lines indicate the CMB and ICB discontinuities.

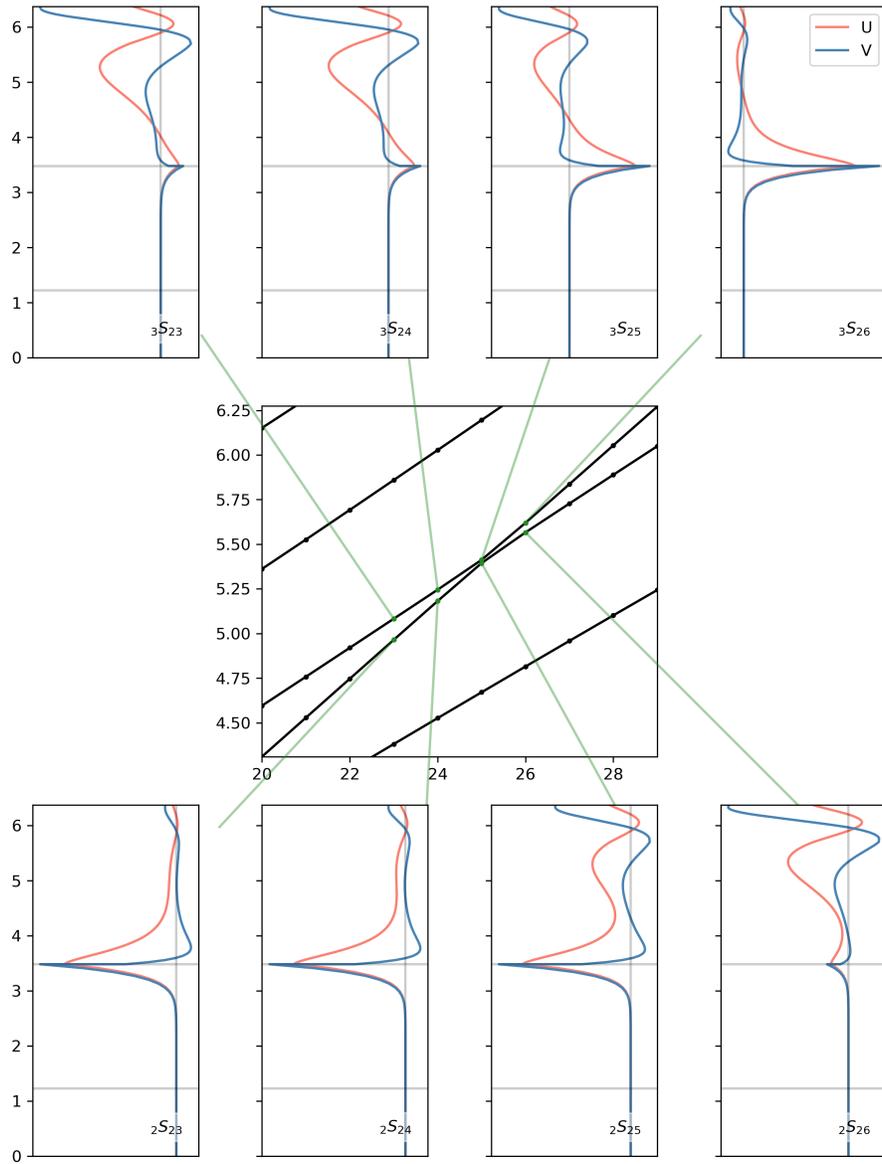

Figure S11: Same as Supp. Fig. S10, but for the second quasi-intersection.

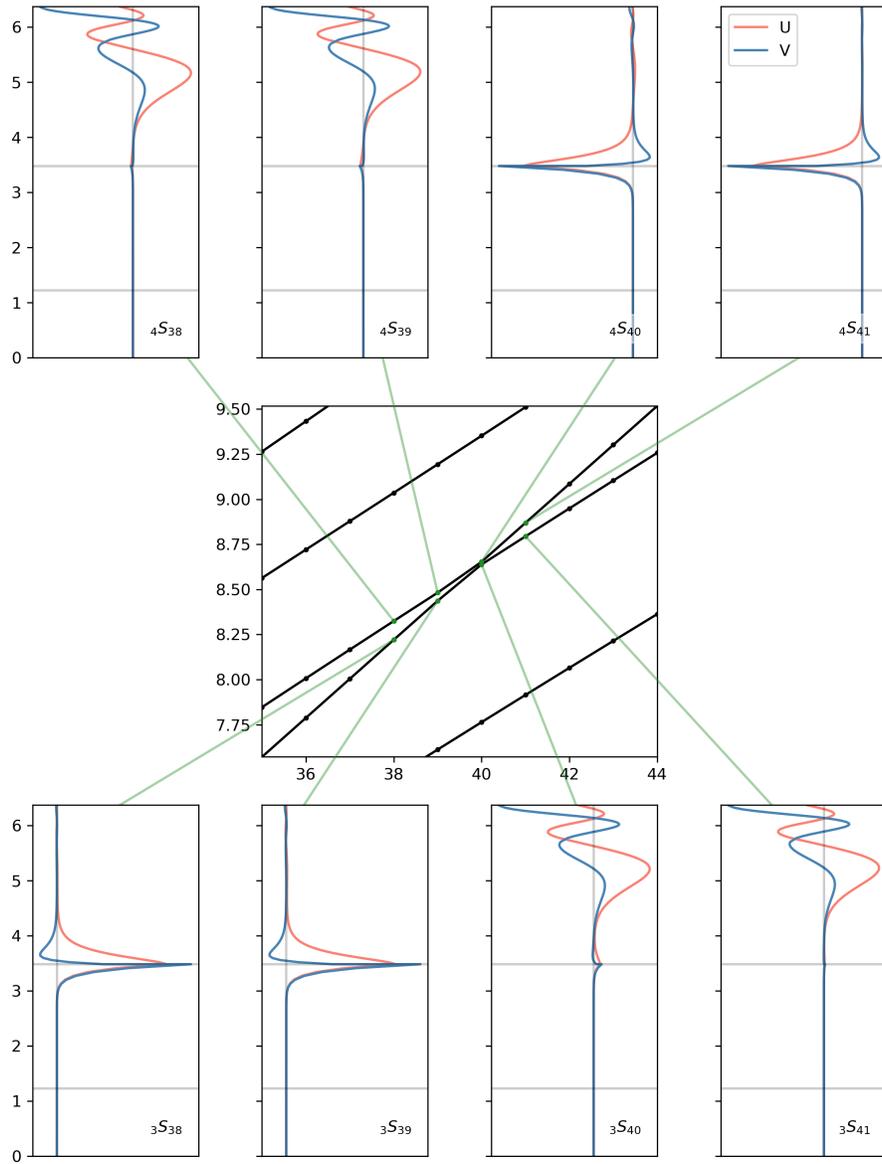

Figure S12: Same as Supp. Fig. S10, but for the third quasi-intersection.
