### Abstract

Many current research efforts undertake the solar flare classification task using the Space-weather HMI Active Region Patch (SHARP) parameters as the predictors. The SHARP parameters are scalar quantities based on spatial average or integration of physical quantities derived from the vector magnetic field, which loses information of the two-dimensional spatial distribution of the field and related quantities. In this paper, we construct two new sets of spatial features to expand the feature set used for the flare classification task. The first set uses the idea of topological data analysis to summarize the geometric information of the distributions of various SHARP parameters. The second set utilizes tools coming from spatial statistics to analyze the vertical magnetic field component Br and summarize its spatial variations and clustering patterns. All features are constructed within regions near the polarity inversion lines (PILs) and classification performances using the new features are compared against the SHARP parameters (also along PIL). We found that using the new features can improve the skill of the flare classification model and new features tend to have higher feature importance, especially the spatial statistics features. This potentially suggests that even using a single channel Br, instead of all SHARP parameters, one can still derive strongly predictive features for flare classification.

# Improved and Interpretable Solar Flare Predictions with Spatial & Topological Features of the Polarity-Inversion-Line Masked Magnetograms

# Key Points:

- We adopt a polarity inversion line (PIL) detecting algorithm to obtain PIL masks for the B<sub>r</sub> channel and several SHARP parameter maps.
  We construct two sets of spatial statistics features and a collection of topological features based on the PIL masks.
  - Our newly constructed features, by itself or joint with topological features, can significantly improve flare predictions than using SHARP parameters only.

# Plain Language Summary:

Our research is targeted at improving the accuracy of solar flare classification by 15 training machine learning models with new interpretable features beyond well-known physics-16 based predictors. We count the number of closed loops and calculate multiple summary 17 statistics of the spatial distribution of high-resolution magnetic field images of solar ac-18 tive regions to boost the classification result of strong and weak flares. Our results re-19 veal that the spatial distribution of local physical quantities derived from the magnetic 20 field images, beyond those commonly adopted, aggregated quantities, can be helpful to 21 improve flare predictability. 22

#### 23 Abstract

Many current research efforts undertake the solar flare classification task using the Space-24 weather HMI Active Region Patch (SHARP) parameters as the predictors. The SHARP 25 parameters are scalar quantities based on spatial average or integration of physical quan-26 tities derived from the vector magnetic field, which loses information of the two-dimensional 27 spatial distribution of the field and related quantities. In this paper, we construct two 28 new sets of spatial features to expand the feature set used for the flare classification task. 29 The first set uses the idea of topological data analysis to summarize the geometric in-30 formation of the distributions of various SHARP parameters. The second set utilizes tools 31 coming from spatial statistics to analyze the vertical magnetic field component  $B_r$  and 32 summarize its spatial variations and clustering patterns. All features are constructed within 33 regions near the polarity inversion lines (PILs) and classification performances using the 34 new features are compared against the SHARP parameters (also along PIL). We found 35 that using the new features can improve the skill of the flare classification model and new 36 features tend to have higher feature importance, especially the spatial statistics features. 37 This potentially suggests that even using a single channel  $B_r$ , instead of all SHARP pa-38 rameters, one can still derive strongly predictive features for flare classification. 39

# 40 1 Introduction

Solar flares occur in magnetic regions of concentrated free energy, which is suscep-41 42 tible to spontaneous reconnection that rapidly heats the plasma producing flare emission. At the photosphere these fields typically take the form of active regions that are 43 characterized by strong horizontal field gradients, long, well defined polarity-inversion 44 lines (PILs), and complex flux distributions (Barnes, Leka, Schumer, & Della-Rose, 2007; 45 Falconer, Moore, & Gary, 2002, 2003, 2006). Vector magnetogram observations reveal 46 the the magnetic field runs nearly parallel to the PIL, where the field is in a configura-47 tion that possesses significant free energy to drive flares. In addition to the free energy 48 content, the other critical feature related to flare onset is the magnetic field complex-49 ity represented by the intermixing of opposing magnetic flux. At the simplest level, such 50 complexity is found in strong gradients along the PIL (Falconer et al., 2003; Schrijver, 51 2007) and in more extreme cases from flare production from delta-spot active regions, 52 which contain both polarities within single penumbra of uniform polarity. A well known 53 example is AR 10486, which produced a series of X-class flares in the fall of 2003. 54

The question naturally arises as to whether there are unique features which may 55 serve as strong discriminators or predictors of flares. Schrijver (2007) found that the amount 56 of unsigned flux within a distance of 15 Mm of the PIL was such a discriminator. Phe-57 nomenological studies have revealed a number of physical discriminators for flare pro-58 duction based solely on the observed line-of-sight component of the field (e.g. Barnes et 59 al., 2007; Falconer, 2001; Falconer et al., 2002, 2006; Leka & Barnes, 2003a, 2003b). These 60 works describe scalar quantities that are measures of the unsigned flux and the length 61 of the PIL, which have proven useful for flare prediction. In the case of Falconer (2002), 62 four measures of magnetic free energy were derived based on 3-component vector mag-63 netograms: the length of the PIL exhibiting strong shear, vertical electric current, to-64 tal unsigned flux, and the current helicity. These works were followed by more elaborate 65 flare prediction studies employing more than 20 scalar quantities derived from Space Weather 66 HMI Active Region Patches (SHARPs). These SHARP variables are derived from largely-67 uninterrupted high-resolution high-cadence full disk vector magnetograms, which pro-68 vide sufficient data for successful application of machine learning for flare prediction (e.g. 69 (Bobra & Couvidat, 2015; Bobra et al., 2014; Y. Chen et al., 2019; Florios et al., 2018; 70 Jiao et al., 2020; Liu, Deng, Wang, & Wang, 2017; Nishizuka, Sugiura, Kubo, Den, & 71 Ishii, 2018; Wang et al., 2020)). 72

Statistical analysis typically strives to determine discriminant functions which may 73 be linear or nonlinear functions of variables constructed from the observed vector mag-74 netic field, which are related to distributions of free energy in the system. Flares follow 75 from two processes, first the buildup of free magnetic energy and second the release of 76 that energy by magnetic reconnection. For the first component there are meaningful mea-77 sures of buildup of energy necessary flares such as the AR size as denoted by unsigned 78 magnetic flux and total electric current, current helicity or total free energy itself. Nu-79 merous studies illustrate the predictive power of these quantities (e.g. Y. Chen et al., 2019). 80 However, whether it is sufficient to produce a flare involves much more subtlety as it re-81 lates to the complexity of the magnetic field which ties into the formation of current sheets, 82 which initiates the flare energy release. Because of this complexity of the reconnection 83 process, there can be a wide range of free energy densities found in flaring ARs, which 84 emphasizes the challenging aspect of predicting flares. 85

In recent years, data driven flare forecasting has caught a lot of attention in the 86 field of space sciences. Many machine learning algorithms have been adopted for solar 87 flare prediction, either with or without operational forecasting in mind (Barnes et al., 88 2007). Bobra et al. (2014) introduced the Space-weather HMI Active Region Patch (SHARP) 89 parameters, which are derived from the magnetograms of the HMI/SDO images and have 90 been used by many solar flare prediction models in recent years (e.g. Barnes et al., 2016; 91 Bobra & Couvidat, 2015; Camporeale, 2019; Y. Chen et al., 2019; Florios et al., 2018; 92 Jiao et al., 2020; Leka & Barnes, 2018; Leka et al., 2019a, 2019b; Liu, Liu, Wang, & Wang, 93 2019; Muranushi et al., 2016; Nishizuka, Kubo, Sugiura, Den, & Ishii, 2021; Nishizuka 94 et al., 2018). The success of using the SHARP parameters in solar flare forecasting show-95 cases the importance of the SHARP parameters in triggering solar eruptions. Despite 96 this, researchers suspect that the SHARP parameters may not capture the full informa-97 tion that the HMI/SDO magnetogram images contain which are relevant for flare fore-98 casting. There are efforts of using the deep neural network methods which directly takes qq the HMI/SDO magnetogram images directly to predict solar eruptions (e.g. the Long 100 Short Term Memory network adopted by Y. Chen et al. (2019) and Liu et al. (2019)). 101 The neural network models, however, suffer from poor interpretability and it is hard to 102 learn new insights on the underlying physics/mechanism of flare eruptions from those 103 models. In an effort to obtain interpretable solar flare forecasting model, while at the 104 same time pushing the frontiers of discovering new physics of solar eruptions, we present 105 our new results and findings on constructing spatial and topological features that are im-106 portant for solar flare predictions, from the magnetograms of HMI/SDO. 107

In Y. Chen et al. (2019), it is shown that the derived features from using deep neu-108 ral network (autoencoder) give similar performance as compared to the SHARP param-109 eters when adopted to solar flare predictions. This result, however, does not conclude 110 that the SHARP parameters already contain all useful information from magnetograms 111 for flare predictions, due to the fact that general-purpose image/video feature reduction 112 techniques typically result in high-dimensional, highly correlated features, many of which 113 are redundant for flare predictions. Despite that efficient dimension reduction and fea-114 ture selection techniques are adopted in Y. Chen et al. (2019) to alleviate this issue, the 115 amount of random noises brought in with this high-dimensional feature construction with 116 limited amount of training data still makes the performance not ideal. Meanwhile, it is 117 important to realize that even in this unfavorable situation of directly extracting features 118 from magnetogram, we can achieve similar flare prediction performance as when using 119 only the SHARP parameters. This possibility makes it promising to further investigate 120 alternative feature construction methods that result in information complimentary to 121 those contained already in the SHARP parameters. More recently, some promising re-122 sults are already shown along this direction: in Deshmukh, Berger, Meiss, and Bradley 123 (2020), topological features are derived for the  $B_r$  channel, which are shown to improve 124 the performance of solar flare predictions. Here, we extend this approach by combining 125 both spatial and topological features of the polarity inversion line masked magnetograms 126

(HMI/SDO active regions) with the SHARP parameters for solar flare predictions. We show that the results of the prediction models are better when we use all three sets of features, and that the spatial statistics features are of key importance. Furthermore, we point out the interpretations of the spatial statistics features and relate it back to the underlying mechanism of flare formation, thus using these features to inform the discovery of new physics.

The remainder of this paper is organized as follows. In Section 2, we first give a motivating example to show the potential of extracting shape information from HMI images for flare classification, then we describe the methodology and details of constructing topological features and spatial statistics features out of HMI/SHARP images. In Section 3, we present the data used for empirical study and the prediction results based on newly constructed features and corresponding interpretations. Section 4 concludes.

# <sup>139</sup> 2 Feature Construction

The SHARP parameters, as introduced in (Bobra et al., 2014), contain several es-140 sential physical quantities. They are calculated from the three-component two-dimensional 141 HMI magnetic field data of an active region. It is important to note that all the SHARP 142 parameters are scalar values summarizing physical quantities of the *whole* active region, 143 which are calculated based on spatial averages (e.g. the MEANGAM) or spatial inte-144 gration (e.g. the TOTUSJH). As a result, the SHARP parameters do not contain any 145 information regarding the spatial distribution of the physical quantities. A refined ver-146 sion of the SHARP parameters taking into account of some information of the spatial 147 distribution is the SHARP parameters weighted by the polarity inversion line (PIL) mask, 148 as given by Wang et al. (2020). The PIL mask is a weighted mask which puts high weight 149 on the region where the vertical component of the magnetic field is zero  $(B_r = 0)$  be-150 tween regions of strong opposite polarity. Empirically, it is not practical to accurately 151 pinpoint all pixels with  $B_r = 0$ , so adjacent regions are also given small weights and 152 overall the PIL mask is giving high weights to regions around the PIL and near-zero weight 153 to other regions. However localized, the PIL-weighted SHARP parameters still cannot 154 reflect the spatial characteristics of the magnetic field. In this section, we introduce two 155 sets of features constructed with the aim of augmenting the SHARP parameters to con-156 sider local and global spatial distribution of the magnetic field components around the 157 polarity inversion line: one based on persistence homology in topology and the other based 158 on concepts from the field of spatial statistics. We will apply these newly constructed 159 features to flare classification and prediction and develop their utility in context of ex-160 isting literature on related topics, e.g. the weighted SHARP parameters by Wang et al. 161 (2020) and the topological data analysis enabled feature construction by Deshmukh, Berger, 162 Bradley, and Meiss (2020). 163

164

#### 2.1 Motivating Example & PIL Mask Construction

To motivate our feature construction machinery, we illustrate the SHARP param-165 eters with a concrete example: comparing a strong and a weak flare that occurred in HARP 166 region 377. In Figure 1, we show two series of HMI magnetograms and some derived im-167 ages of HARP region 377, one for an M class flare (top row) and the other for a B class 168 flare (bottom row), all images are collected 1 hour prior to the moment of peak flare in-169 tensity. Focusing on (a) and (d) first, one can see that before the M flare, the high mag-170 netic flux pixels of opposing polarities are more clustered and concentrated in close prox-171 imity to one another. This distribution coincides with the formation of a well-defined 172 polarity inversion line (PIL) (where  $B_r = 0$ ) that separates the regions of opposing po-173 larity. The PIL is picked up by the corresponding polarity inversion line mask shown in 174 (b) and (e). PILs are the epicenter of flare activity and have been used as a discrimina-175 tor of flare regions in prior studies (Falconer et al., 2006; Wang et al., 2019). Similarly, 176

we concentrate on the PIL regions by calculating the PIL in order to distinguish strong and weak flares.

We derive the PIL mask based on the method given in Schrijver (2007), which fol-179 lows three steps. First, we produce two bitmaps, one for the positive field where pixels 180 with  $B_r > 200$ G are set to 1 and 0 otherwise, one for the negative field where pixels 181 with  $B_r < -200$ G are set to -1 and 0 otherwise. Second, we need to derive the posi-182 tive and negative masks using a density-based clustering algorithm (Ester, Kriegel, Sander, 183 & Xu, 1996). Finally, we need to multiply the two masks after convolving each mask with 184 185 a Gaussian kernel with a bandwidth of 10 pixels. Details of the derivations can also be found in Wang et al. (2019). 186

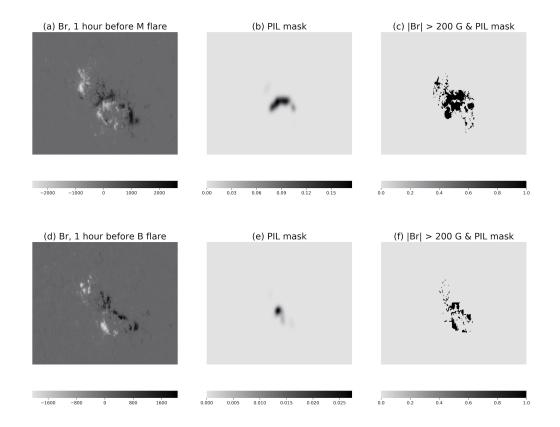

Figure 1. Two HMI magnetograms (vertical component) and derived images of HARP 377. The two rows consist of 3 related images: (left) the Br channel, (middle) the PIL weight mask, (right) bitmap labeling pixels with absolute flux over 200 G and locate in the PIL region. The top row is collected 1 hour before the M-class flare peaked at 2011.02.13 17:38:00 while the bottom row is collected 1 hour before the B-class flare peaked at 2011.02.13 00:42:00. Note the more energetic flare occurs at a later time when more flux has emerged and the PIL is significantly longer. Different scales are used to bring out structure in  $B_r$  and the PIL mask.

If one only compares the SHARP parameters, such as the total unsigned flux, the difference between the M flare and B flare is not necessarily significant because both flares have regions with relatively high flux values. But if one focuses on the spatial distributions of the high flux regions, such as how clustered these regions are and what geometric shapes they form jointly and individually, then extra discriminating power for telling the flares apart would emerge. In the following two sub-sections, we will focus on the HMI magnetograms (the  $B_r$  component in particular) restricted in the PIL region (non-zero PIL weight region), for which we derive topological and spatial features. We concentrate
 on the PIL region since it removes many irrelevant regions outside of the flaring region (Wang
 et al., 2020), which can create potential noises on the derived features.

Besides the  $B_r$  channel, we also derive eight additional 2D SHARP related parameter maps as follows. Here, we calculate the SHARP intensive physical quantities for every pixel, but instead of taking the averages or spatially integrating them to form the scalar SHARP parameters, we retain the 2D distribution of each of these maps and multiply it by the same  $B_r$  PIL mask. Table 1 gives a summary of all nine SHARP parameter masks we collect/construct.

Channel	Formula	Unit
Br	$\mathbf{B}_{z}$	G
GAM	$\arctan\left(rac{\mathbf{B}_{h}}{\mathbf{B}_{z}} ight)$	Degree
GBT	$\sqrt{\left(rac{\partial \mathbf{B}}{\partial x} ight)^2 + \left(rac{\partial \mathbf{B}}{\partial y} ight)^2}$	$\rm G \times \ Mm^{-1}$
GBH	$\sqrt{\left(rac{\partial \mathbf{B}_h}{\partial x} ight)^2 + \left(rac{\partial \mathbf{B}_h}{\partial y} ight)^2}$	$\rm G \times \ Mm^{-1}$
GBZ	$\sqrt{\left(rac{\partial \mathbf{B}_z}{\partial x} ight)^2 + \left(rac{\partial \mathbf{B}_z}{\partial y} ight)^2}$	$\rm G \times  Mm^{-1}$
USJZ	$ \left(rac{\partial \mathbf{B}_y}{\partial x} - rac{\partial \mathbf{B}_x}{\partial y} ight) $	А
USJH	$ oldsymbol{J}_z imes \mathbf{B}_z $	${ m G}^2$ m $^{-1}$
РОТ	$\left( (\mathbf{B}_x - \mathbf{B}_x^{POT})^2 + (\mathbf{B}_y - \mathbf{B}_y^{POT})^2  ight)$	$\rm erg~cm^{-3}$
SHR	$\arccos\left(\frac{\mathbf{B}_{x}^{POT}\times\mathbf{B}_{x}+\mathbf{B}_{y}^{POT}\times\mathbf{B}_{y}+\mathbf{B}_{z}^{2}}{\sqrt{\mathbf{B}_{x}^{POT^{2}}+\mathbf{B}_{y}^{POT^{2}}+\mathbf{B}_{z}^{2}}\sqrt{\mathbf{B}_{x}^{2}+\mathbf{B}_{y}^{2}+\mathbf{B}_{z}^{2}}\right)$	Degree

**Table 1.** SHARP parameter masks, where the formulas in the middle column are applied to every pixel of the HMI magnetogram. Here,  $\mathbf{B}_x, \mathbf{B}_y, \mathbf{B}_z$  are the x, y, z components of the magnetic field and  $\mathbf{B}_x^{POT}, \mathbf{B}_y^{POT}$  the potential field components respectively. Detailed definition of the SHARP parameters can be found in Table 3 of Bobra et al. (2014).

The same feature construction procedure is then applied to all nine SHARP pa-203 rameter maps, which are created by multiplying by the 2-D SHARP distributions by the 204  $B_r$  mask. For the topological features alone, our work using all nine PIL maps can be 205 seen as an extension to the topological data analysis in Deshmukh, Berger, Bradley, and 206 Meiss (2020), which mainly focused on the original  $B_r$  component when constructing topo-207 logical features. For spatial statistics features, which have not yet been adopted by oth-208 ers in literature as far as we are aware of, we only focus on the  $B_r$  component for the 209 ease of interpretation. All of the features, both topological and spatial statistics features, 210 are derived only for the PIL region. As a comparison, we use the SHARP parameters 211 weighted by the PIL mask as a benchmark feature set, which has been shown to improve 212 flare predictions as compared to unweighted SHARP parameters (Wang et al., 2020). 213

#### 214 2.2 Topological Features

222

223

The derivation of our topological features is based on the TDA analysis in Deshmukh, Berger, Bradley, and Meiss (2020), Deshmukh, Berger, Meiss, and Bradley (2020), but we have these extensions:

- we expand the image set to be analyzed from just the  $B_r$  mask to multiple other SHARP parameters masks,
- we restrict our TDA application to the PIL region only to remove noises in feature construction,
  - we adopt the topological features for strong (M/X) versus weak (B) flare classification purpose.

In this subsection, we briefly review the methodology first and then highlight the differences of our data pipeline compared to existing literature.

Topological data analysis, a.k.a. TDA, (see Wasserman (2018) for a brief review) 226 is a field investigating the mathematical shape of a point cloud or a function. It estab-227 lishes the concept of topological invariance between objects that share the same topo-228 logical property, such as a ball and cube, or a cup and a donut. TDA can be applied to 229 analyze the 2D SHARP parameter maps since all SHARP parameters can be viewed as 230 a 2D function with each pixel's x and y coordinate being the functional input. It is not 231 practical to summarize all shape information of a function or a point cloud, and a very 232 simple summary statistics in TDA about the topology property is the Betti number (Munch, 233 2017). Betti numbers, typically denoted as  $\beta_0, \beta_1, \beta_2, \ldots$ , counts the number of holes of 234  $0, 1, 2, \ldots$  dimension. In 2D,  $\beta_0, \beta_1$  represents the number of connected components and 235 loops. In our analysis, we just focus on the  $\beta_1$  Betti number, counting the number of loops 236 within the 2D SHARP masks. 237

Because every 2D SHARP parameter map is a digitized image, it is not a continuous but a discretized surface. Therefore, we need a proper definition of loop in these 240 2D images. Take the  $B_r$  mask as an example, if one thresholds the  $B_r$  image at various 241 levels and only keeps pixels below the threshold and within the PIL region, forcing all 242 other pixels as 0, one obtains distributions as found in Figure 2 shown below.

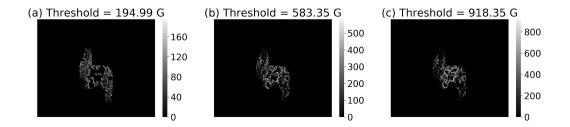

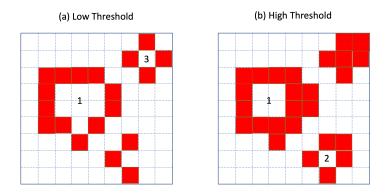

Figure 2.  $B_r$  mask of HARP 377, 2011.02.13 17:38:00. (a), (b), (c) only keep pixels whose  $|B_r|$  value is below the threshold (194.99G, 583.35G, 918.35G) and within the PIL region.

One can notice that around the center of each image, there are several closed loops 243 coming into existence when one increases the threshold from 194.99G to 583.35G; and 244 that some of the loops disappear while others remain but shrink in size when the thresh-245 old level is further increased to 918.35G. Intuitively, these loops are regions of high  $|B_r|$ 246 values within the PIL region, or in other words, they represent the peaks/valleys of the 247 spatial distribution of  $B_r$ . This sequence of thresholded images forms a *filtration*, where 248 the set of all nonzero pixels of one image is a subset of the nonzero pixels of the next im-249 age with a higher threshold. 250

To give these kinds of loops in a digitized image a rigorous definition, we invoke the concept of *cubical complex*, as suggested by Deshmukh, Berger, Bradley, and Meiss (2020). For every image with threshold  $\tau$  as shown in Figure 2, we generate a corresponding bitmap. Each bitmap sets all pixels that are: 1) below the threshold  $\tau$ , 2) within the PIL region, as 1, and 0 otherwise. The loops are then defined for these bitmaps.

As a schematic example, in Figure 3 we show two bitmaps with red pixels being 256 1 and white pixels being 0. Subfigures (a) and (b) show two bitmaps generated from a 257 low and a high threshold value, respectively. In a cubical complex, two pixels are con-258 259 nected if they share an edge or vertex and a loop is a closed, hollow area surrounded by a series of connected pixels. In (a) we have two loops, labeled as 1 and 3. As we increase 260 the threshold, those pixels above the low threshold but under the high threshold become 261 red and some new loops are formed (loop 2 in (b)), some remain but shrink in size (loop 262 1 in both (a) and (b)) and some disappear (loop 3 in (a)). 263

**Figure 3.** Example of loops formed by cubical complexes. In a cubical complex, two pixels are connected if they share a vertex or an edge. (a) at a low threshold, there are two loops formed, labeled as 1 and 3. (b) at a higher threshold, more pixels are selected (marked red), and loop 3 is closed, loop 2 comes into existence and loop 1 remains alive.

Every loop in this cubical complex has its own life-cycle. Each has a birth time and 264 a death time, represented by the threshold values at which the loop emerges and disap-265 pears. A graph showing the birth-death pair of all loops is called the *persistence diagram* (Munch, 266 2017). When a loop has its death time much larger than the birth time, this loop indi-267 cates a strong peak/valley in the 2D distribution of a SHARP parameter map. Such loops 268 appear as scattered points away from the 45 degree line in the persistence diagram. In 269 Figure 4, we show the persistence diagrams for all loops of the  $B_r$  mask of 3 flares com-270 ing from HARP region 377. One can see that compared to the two M flares, the persis-271 tence diagram of the B flare has less loops that are way off the 45 degree line, indicat-272 ing that there are fewer high flux regions prior to the B flare. 273

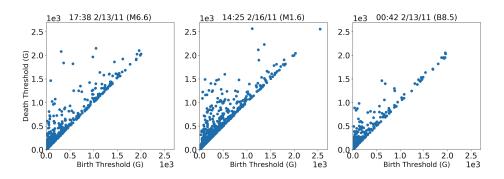

Figure 4. Examples of persistence diagrams for two M flares and a B flare of HARP region 377. Every subplot has the flare peak time, flare class and flare intensity in the title. One can see that compared to M flares, B flare has less loops that are persistent, indicating that there are fewer high flux regions in the PIL region. All  $B_r$  masks analyzed are collected 1 hour prior to the flare time. Both axes in each plot have the unit Gauss.

In order to extract features, namely Betti number  $\beta_1$ , from such diagrams, we do 274 the following. For every SHARP parameter map in Table 1, we first calculate the pixel-275 level percentiles at 5%, 10%, ..., 90%, 95% across all pixels of our dataset. For the  $B_r$ , 276 these percentiles are: 19.4G, 42.8G, ..., 918.3G, 1165.8G. Other SHARP parameters have 277 their corresponding percentiles. Then we derive the persistence diagram for every SHARP 278 parameter map using the procedure above. Finally, we count, at each percentile, how 279 many loops are still alive. Because we have 19 percentiles, we have 19 Betti number fea-280 tures, and since we have 9 SHARP maps, in total we obtain  $19 \times 9 = 171$  topological 281 features for a single flare. 282

#### 2.3 Spatial Statistics Features

In the previous subsection, we reviewed the TDA analysis on SHARP parameter 284 maps, which is able to summarise the shape information of the spatial distribution of 285 corresponding SHARP parameter maps. Using the Betti number  $\beta_1$  as a summary statis-286 tics, we can locate the peaks/valleys of a spatial distribution of any SHARP parameter. 287 However, there are other aspects of the spatial distribution, such as the density of high 288 flux pixels and the spatial variation of a SHARP parameter, that cannot be summarised by the TDA. Spatial statistics techniques (see Gelfand, Diggle, Guttorp, and Fuentes (2010) 290 and references therein), on the other hand, provides natural tools to extract these infor-291 mation from spatial distributions. In our spatial statistics analysis, we focus on the  $B_r$ 292 maps only for the sake of interpretability. The two relevant spatial statistics tools that 293 we adopt here are the Ripley's K function (Ripley, 1976) and the variogram (Cressie & 294 Hawkins, 1980; Oliver & Webster, 2015). 295

296

283

# 2.3.1 Ripley's K Function

We briefly review the definition and interpretation of the Ripley's K function here. Interested readers can refer to Ripley (1976) for more details. The Ripley's K function is a functional summary of the density of a point cloud at various scales. Consider a set of points with coordinates  $\{(x_i, y_i)\}_{i=1}^n$ , which are all located within an area of size A. The Ripley's K function is a function of the scale parameter d, defined as

$$L(d) = \sqrt{\frac{A\sum_{i=1}^{n}\sum_{j=1, j\neq i}^{n}k_{i,j}}{\pi n(n-1)}},$$
(1)

where  $k_{i,j} = 1$  if point  $(x_i, y_i)$  and point  $(x_j, y_j)$  are within Euclidean distance d. Intuitively, the Ripley's K function calculates the proportion of pairs of points that are within distance d. Since d can take on any arbitrary value, the Ripley's K function reflects the clustering and dispersion properties of the points in the point cloud.

The area size A is an important parameter in the calculation. In Figure 5 (a) and 301 (b) we show two identical point clouds, generated from a 2D uniform distribution, lo-302 cated in areas of different sizes. In (a), the red bounding box shows the area considered 303 when calculating the Ripley's K function for the point cloud. In (b), the area is the whole 304 305 region  $[0, 20] \times [0, 20]$ . With the same point cloud, one can see that their Ripley's K function, plotted in (d), are very different. The Ripley's K function for pattern A and B are 306 relatively straight, meaning that points are nearly uniformly randomly distributed in the 307 area. Since when all points are fully randomly distributed, the proportion of points within 308 radius d grows linearly with the size the circle  $\pi d^2$ , so  $L(d) \sim O(d)$  and the slope is re-309 lated to  $\sqrt{A}$ . In Figure 5 (c), we show another point pattern coming from a Gaussian mix-310 ture distribution. Its corresponding Ripley's K function are plotted in (d) in green. With 311 a relatively small d, the Ripley's K function is concave and indicates a clustering pat-312 tern of points. As d becomes larger, the function becomes convex and indicates that at 313 relatively large scale, distribution of points are dispersed (scattered in five clusters). 314

We need to define two key elements in order to calculate the Ripley's K function 315 that contains the spatial information we desire from the SHARP parameter maps: an 316 area and a point cloud within the area. In our implementation, we take the PIL region, 317 as the area, and the number of pixels of the PIL region as the size A. Within the PIL 318 region, we select all pixels with unsigned flux  $|B_r|$  above a threshold  $\tau$ . In some active 319 regions, there are many pixels with extremely large  $|B_r|$  values, leading to many pixels 320 being selected above the threshold  $\tau$ . Based on the formula of Ripley's K function, one 321 can see that it involves the pairwise distance matrix of all points. Empirically, we found 322 that having over 500 points in the point cloud would make the computation of Ripley's 323 K very time consuming. Therefore, if there are more than 500 such pixels, we randomly 324 select only 500 of them where the probability of each pixel getting selected is propor-325 tional to its unsigned flux value (per unit area defined by the pixel)  $|B_r|$ . When there 326 are fewer than 500 pixels before the sub-sampling, we also sample with replacement to 327 make the final point clouds having 500 points. The pixels selected are the point clouds 328 and their (x, y) coordinates in the  $B_r$  mask specify their locations. The distance between 329 any two pixels is the Euclidean distance between their coordinates. Since we are using 330 the Cylindrical Equal Area (CEA) version of the  $B_r$  magnetogram, each pixel has the 331 same physical size, so it makes sense to use the pixel coordinate instead of the true lat-332 itude and longitude as the pixel location. 333

In Figure 6, we show the point clouds generated with threshold being 400G, 1000G 334 and 1600G (on the left, middle, right columns) for the  $B_r$  map collected 1 hour prior to 335 an M flare of HARP 377, without any sub-sampling for comparison purpose. The bot-336 tom row gives the corresponding Ripley's K functions for all pixel distances within the 337 range [0, 100]. As we increase the threshold value  $\tau$ , the point clouds are more and more 338 clustered into several small clusters, and the Ripley's K function is getting more devi-339 ated from a straight line (which corresponds to a random distribution pattern) towards 340 the line pattern indicating a clustering pattern of points at various scales. This is ex-341 emplified also in the top row of Figure 6. 342

Similar to the topological features, the Ripley's K function also locates the clusters of high flux pixels. What sets it apart from the topological features is that it indicates at which scale (in terms of pixel distance) the clusters appear. In other words, the Ripley's K function provides additional information of the size of the loops, whereas topological features only captures the numbers of the loops.

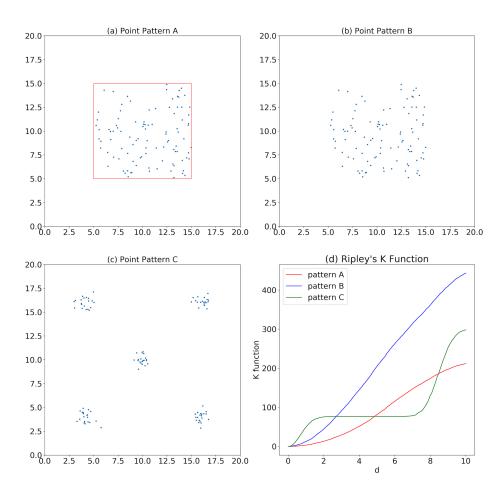

Figure 5. Schematic example of Ripley's K function. (a) a uniformly distributed point cloud in a small area. (b) same point cloud but in a larger area, looking more like clustered in the middle. (c) a non-uniform point cloud. (d) Ripley's K function for all three point patterns. The function is nearly a straight line for both pattern A and B, indicating that points are uniformly randomly distributed in the area. But the different area sizes drastically scale the level of the function. Concave function indicates that points are more clustered than random while convex function indicates that points are more dispersed than random.

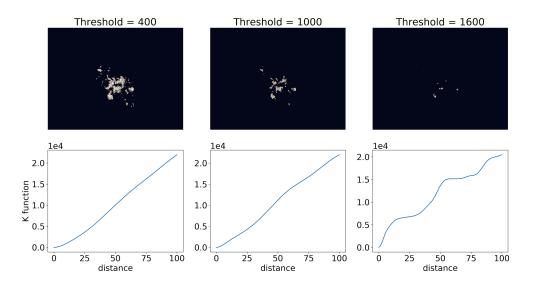

Figure 6. Point cloud and the corresponding Ripley's K function for the  $B_r$  mask collected from HARP 377, 1 hour before the M flare peaked at 2011.02.13 17:38. The top row includes 3 point clouds generated by 3 thresholds at 400G, 1000G, 1600G. The bottom row shows the 3 corresponding Ripley's K functions.

In practice, we implement the Ripley's K function calculations for the  $B_r$  map as 348 follows. For every  $B_r$  map, we use 11 thresholds at 0G, 200G, 400G, 600G, 800G, 1000G, 349 1200G, 1400G, 1600G, 1800G, 2000G, for generating the point clouds. We choose these 350 thresholds because they can filter high  $|B_r|$  value pixels at various magnitudes and there 351 are some considerable differences among the point clouds selected based on these thresh-352 olds so that different Ripley's K functions do not have too much overlapping informa-353 tion. For every point cloud, we calculate the Ripley's K function and evaluate the func-354 tion on the distance grid  $\{1, 2, \ldots, 99, 100\}$ . We restrict the upper bound of the distance 355 scale below 100 (pixel scale) to guarantee that it works for all  $B_r$  images. Additionally, 356 most PIL regions do not exceed 25,000 pixels, so by analyzing the a neighborhood of ra-357 dius 100 pixels of every pixel covers sub-region that is large enough within the PIL re-358 gion while at the same time still remains localized. Thus in total we have 11 Ripley's 359 K functions and each function has 100 functional values, leading to 1,100 raw features 360 per  $B_r$  map. When constructing the final feature, we divide all Ripley's K function 361 by the number of PIL pixels, namely A, so finally the level of Ripley's K function 362 is inversely proportional to  $\sqrt{A}$ . 363

#### 2.3.2 Variogram

364

Both the topological features and the Ripley's K function on the  $B_r$  maps are aimed at analyzing the clustering patterns of high flux pixels. Here we introduce another spatial statistics quantity, called the variogram, which is a description of the spatial continuity of the data. The variogram of the  $B_r$  map is a functional summary of the spatial variation of flux values at various scales. Again, we briefly introduce the definition and interpretations here, and interested readers shall refer to Omre (1984) for details. For any point cloud  $(x_i, y_i)_{i=1}^n$ , denote their  $B_r$  values as  $z(x_i, y_i)$ . At (Euclidean) distance d, the variogram is defined as

$$\gamma(d) = \gamma(\boldsymbol{s}_i, \boldsymbol{s}_j) = \frac{1}{2} \operatorname{Var}[z(\boldsymbol{s}_i) - z(\boldsymbol{s}_j)], \qquad (2)$$

where  $\mathbf{s}_i = (x_i, y_i), \mathbf{s}_j = (x_j, y_j)$  are two arbitrary points in the point cloud that has a Euclidean distance d in-between, and Var denotes the variance of a random variable.

The variogram measures the variance of the differences of  $B_r$  values between any 367 two arbitrary pixels that have a distance d in between. The variogram is similar to the 368 structure function, which has been applied to active regions to measure the fragmented 369 nature of the magnetic network and its relationship to flares Uritsky and Davila (2012). 370 In the  $B_r$  map, typically one would expect that when two pixels are close, their  $B_r$  val-371 ues should be more similar. When two pixels are getting more distant, their  $B_r$  values 372 373 can be more different as well. The relationship of local similarity and correlation of  $B_r$ and the scale d is captured by the variogram, which can provide extra spatial informa-374 tion on top of the topological features and the Ripley's K function. 375

In practice, it is hard to find a large number of pairs of pixels that are separated exactly by distance *d*. To estimate the empirical variogram, one would set a few disjoint bins of distance, and any pair of pixels would fall into one of the bins, depending on their distance. The variance is then calculated for all pairs of pixels belonging to the same bin. In our implementation, we use the same point cloud for Ripley's K function calculation for the calculation of variogram. In Figure 7, we show the corresponding variogram for the 3 point clouds shown in 6.

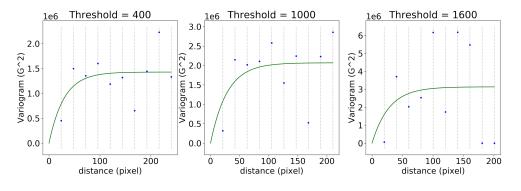

Figure 7. Variogram estimates for point clouds in Figure 6. Vertical dashed line show the center of each distance interval, and the scatter points are the semi-variance (see equation 2) of  $B_r$  values for all pairs of pixels separated by the distance within the interval. The blue line is the fitted curve for the variogram estimates. Note that the scales of x,y axes are different across the three graphs with distint thresholds.

In each variogram, there are multiple distance bins whose centers are indicated by the vertical dashed line. In each bin, there are many pairs of pixels whose distance lies in the distance bin. The scatter points are the variogram estimates based on all pairs of pixels in the same bin. The blue line is the fitted curve of the scatter points using an exponential parametric model:

$$\gamma(d|C_0, a) = C_0 \left(1 - e^{-\frac{d}{a}}\right) \tag{3}$$

Since different point clouds may have all sorts of pairs of pixels whose distance may vary in a wide range. Different variograms can have different distance bins, making it hard to vectorize the variogram as a fixed-length feature vector. As a partial solution, we use the fitted curve parameter  $C_0$ , *a* for each variogram as its features. The two parameters  $C_0$ , *a* are termed as the sill and range parameter of the variogram. Since we have <sup>393</sup> 11 point clouds per  $B_r$  map, and each variogram has 2 parameters, we have 22 variogram <sup>394</sup> features for a single  $B_r$  map.

#### 2.4 Feature Set Summary

395

In our feature construction, we use tools from TDA and Spatial Statistics to an-396 alyze the spatial distribution of SHARP parameters. For every flare, we first derive its 397 nine SHARP parameter maps (Table 1). For each magnetogram, we detect the active 398 region polarity inversion line (PIL) region and focus only on the PIL region for feature 399 construction. Topology features are derived for all nine SHARP parameter maps, and 400 each map has 19 Betti numbers counting the numbers of loops in the 19 bitmaps. Rip-401 ley's K function is applied to the  $B_r$  map only and every  $B_r$  map has 11 Ripley's K func-402 tions out of 11 thresholds, and every function is evaluated on a 100-point grid, leading 403 to 1100 Ripley's K features. Variogram is also applied to the  $B_r$  map and 11 variograms 404 are calculated based on 11 thresholds, where each variogram only retains its sill and range 405 parameter as features. In addition to all these features, there are some extra features which 406 do not belong to any of the categories above, so we group all of them, including the width 407 and height of the  $B_r$  maps, the size of the PIL region and the sum of PIL weights, as 408 the auxiliary features. Table 2 gives a brief summary of all the features used later for 409 flare classification. 410

Feature Category	Shorthand	Description	# of feature
SHARP	S	SHARP parameter in the PIL region	12
Topology	Т	Betti Number for 9 SHARP masks	171
Spatial (SP)	Ripley_K	Ripley's K Function for $B_r$	1100
	V-gram	variogram sill and range parameter for $B_r$	22
Auxiliary Features	Α	area of PIL, height/width of the masks, sum of PIL weights	4

Table 2. A brief overview of the feature sets considered for flare classification. We choose US-FLUX, MEANGAM, MEANGBT, MEANGBH, MEANGBZ, TOTUSJZ, TOTUSJH, SAVNCPP, MEANSHR, MEANPOT, MEANALP, MEANJZD as the SHARP parameter features. The auxiliary features include the area of PIL (# pixels of PIL region), sum of PIL weights and height/width of PIL mask (same as the SHARP parameter masks). In the result section, we introduce a dimension reduction on the topology features and the Ripley's K function features, and denote the dimension-reduced version of the features, in shorthand, as T\_PC, Ripley\_K\_PC. And the spatial statistics feature category including the Ripley\_K\_PC and the variogram features as SP\_PC.

#### **3** Data Description and Prediction Results

In this section, we first introduce the dataset used for feature construction. Then we elaborate the model we use for flare classification and the data pre-processing steps for dimension reductions on the feature sets. Finally, we demonstrate the prediction performances of different combinations of features and show the extra prediction gains of using topological and spatial statistics features on flare classification.

# 417 **3.1 Description of Data**

430

We use the Geostationary Operational Environmental Satellites (GOES) flare list 418 spanning 2010/12 - 2018/06 for collecting flare events. There are originally 11,348 flares 419 within this time range. For the purpose of flare classification, we only keep all B (weak), 420 and M/X (strong) class flares. For each flare, we collect its corresponding high-resolution 421 HMI magnetogram data from the JSOC at 4 time points: 1, 6, 12, 24 hours prior to the 422 peak flux. These 4 time points lead to 4 datasets, and we perform feature construction 423 and flare classifications separately for each of the 4 datasets. Some of the flares do not 424 have available data for all 4 time points, especially for 12-hour and 24-hour data due to 425 the lack of records at exactly 12 or 24 hours before the flare peak time, and we drop them 426 to make sure that every flare appears in all four datasets, for sake of fair comparison across 427 the four datasets. Finally, we have 399 M/X class flares and 1,972 B class flares com-428 ing from 487 HARP regions in each of the 4 datasets. 429

# 3.2 Data Pre-processing & Model Training

The prediction task is to classify strong (M/X) from weak (B) flares. For binary classification, we use the XGBoost model (T. Chen & Guestrin, 2016), which is an efficient gradient boosting (Friedman, 2002) method with a decision tree (Safavian & Landgrebe, 1991) base learner. We train the model with several different combinations of features from the feature set detailed in Table 2.

For topological features (**T**) and the Ripley's K function features (**Ripley\_K**), we 436 have very high dimensional feature spaces. To efficiently compress the information, we 437 conduct dimension reduction on both sets of features. Specifically, for the 19 topology 438 features of every SHARP map, we do a principal component analysis (PCA) and keep 439 top 5 PCs in place of the original 19 features. For every Ripley's K function, which is 440 itself 100-dimensional, we carry out a functional principal component analysis (FPCA, 441 Hall, Müller, and Wang (2006)) and keep top 5 PCs in place of the original 100 features. 442 After both steps, we reduce the topological features from 171 to 45 dimensions, and the 443 Ripley's K function features from 1100 to 55 dimensions. We denote these dimension re-444 duced features as  $\mathbf{T}_{-}\mathbf{PC}$  (for topological features) and  $\mathbf{Ripley}_{-}\mathbf{K}_{-}\mathbf{PC}$ , and the spatial 445 statistics feature category as **SP\_PC**, which includes the Ripley's K principal compo-446 nents and the original variogram parameter estimates. 447

To construct train and test sets for training and validating the classification model, 448 we split the entire flare list according to their HARP regions. As a result, a flare from 449 any HARP region appears in either train or test set only. On average, 70% of the HARP 450 regions are assigned to the train set and the rest 30% go to the test set. The dimension 451 reduction of topological and the Ripley's K features are performed using the train set 452 only and the test set PCs are predicted using the PCA and FPCA results from the train 453 set. Other features are standardized based on the mean and standard deviation of the 454 train set only to avoid information leaking. 455

There is randomness in the process of deriving the topological and spatial statis-456 tics features because we always randomly pick a point cloud with 500 points from all can-457 didate pixels. To guarantee the robustness of the features derived, we re-run the deriva-458 tion of all these features 10 times and take the average as the final features. To make 459 the feature comparison more robust to different train/test split, we re-run the model train-460 ing/testing procedure 20 times, each time with a different train-test split, and then take 461 the average performance for feature comparison. The model is trained separately for the 462 4 datasets, but the flares in the train/test set, in each iteration, is the same for all 4 datasets. 463

#### **3.3** Model Evaluation and Discussion

To compare the discriminating power of different sets of features in the flare classification task, we define the M/X flares as the positive class and the B flares as the negative class. We use the test set True Skill Score (TSS), as the benchmark defined as follows:

$$TSS = \frac{TP}{TP + FN} - \frac{FP}{FP + TN},$$

where TP, TN are the positive (M/X), negative (B) samples that are classified correctly, and FP, FN are the negative (B), positive (M/X) samples that are classified wrongly as being positive and negative, respectively. The range of TSS is from -1 to 1, and it is designed such that a random classifier or an unskilled classifier (always predicting the majority class) has TSS 0. In Table 3, we show the mean test-set TSS for different feature sets across 20 iterations.

Feature Combination	1	6	12	24
S	0.496	0.487	0.455	0.390
Т	0.487	0.521	0.507	0.473
$\operatorname{SP}$	0.473	0.482	0.467	0.459
S+T	0.520	0.507	0.495	0.491
S+SP	0.507	0.508	0.472	0.451
S+T+SP	0.539	0.528	0.515	0.505
S+T_PC+SP_PC	0.505	0.502	0.483	0.457
S+T+SP+A	0.544	0.540	0.515	0.505
S+T_PC+SP_PC+A	0.510	0.505	0.487	0.453

Table 3. Average True Skill Score (TSS), based on 20 train-test split, for classifying strong (M/X) vs. weak (B) flares using different sets of features. Feature shorthand represents: SHARP parameter (S); Topology feature (T); Spatial Statistics feature (SP); Auxiliary feature (A); Topology feature principal component score (T\_PC); Spatial statistics with functional principal component score for Ripley's K function (SP\_PC). Boldface numbers indicate that the TSS is significantly higher than the benchmark model (S), which is fitted only with SHARP parameters in the PIL region, across the 20 iterations. The column names labeled by 1,6,12,24 stands for the 4 datasets collected at 1,6,12,24 hours before the flare peak time.

We define the model fitted with SHARP parameters as the benchmark model, and compare all other feature combinations against it. We show the average TSS differences between some combinations of features against the benchmark. To formally test whether such TSS differences are significant, we apply a one-sided paired Student's t-test to test
the null hypothesis that a certain feature combination has the same TSS as the benchmark for any arbitrary train-test split. In Table 3, we highlight the TSS in boldface when
the TSS of a certain feature combination is significantly higher than the benchmark, i.e.
we reject the null hypothesis with 95% confidence.

As one can see that when using the topological and spatial statistics features, we can improve the TSS of flare classification 12-24 hours before the flare peak time, and further improves when it is getting close to the flare peak time (i.e. 1,6 hours before). When combining all features together, we can do significantly better than only using the SHARP parameters across all 4 datasets. When we reduce the dimension of the topological and spatial statistics features, we can still maintain a margin of skill improvement in the 12 and 24 hour lead time scenario.

The performance improvement introduced by the new features is marginal but significant based on our significance testing results. Besides measuring the contribution of all new features using the TSS, we also calculate the individual feature importance using the Fisher score (F-score (Stork, Duda, Hart, & Stork, 2001), as adopted by Bobra et al. (2014); Deshmukh, Berger, Bradley, and Meiss (2020)). The Fisher score measures the individual feature's discriminating power in a binary classification setting. For any feature,  $x_i$ , the Fisher score is calculated as

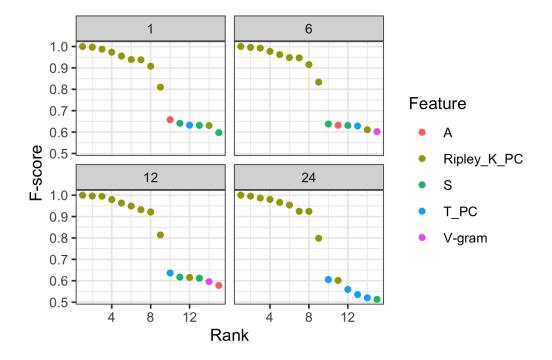

$$F(i) = \frac{(\bar{x}_i^+ - \bar{x}_i)^2 + (\bar{x}_i^- - \bar{x}_i)^2}{\frac{1}{n^+ - 1} \sum_{k=1}^{n^+} (x_{k,i}^+ - \bar{x}_i)^2 + \frac{1}{n^- - 1} \sum_{k=1}^{n^-} (x_{k,i}^- - \bar{x}_i)^2},$$

where  $\bar{x}_i^+, \bar{x}_i^-$  are the subgroup mean of  $x_i$  for all positive, negative samples;  $n^+, n^-$ 497 are the numbers of positive, negative samples; and  $x_{k,i}^+, x_{k,i}^-$  are the k-th observation of 498 the positive, negative class. The Fisher score is the ratio of between-class variation and 499 within-class variation. A high Fisher score indicates that the feature shows high sepa-500 rability for the two classes. We rank all features including the SHARP parameters  $(\mathbf{S})$ . 501 topological feature PCs (**T\_PC**), Ripley's K PCs (**Ripley\_K\_PC**), variogram (**V-gram**) 502 and auxiliary features (A) based on their F-score, for the 4 datasets separately. In Fig-503 ure 8, we show the top 15 features in their order of F-score (normalized to range [0, 1]). 504 and color them based on their feature categories. 505

The feature ranking shows that the newly constructed features have equally good or even better individual discriminating power than the SHARP parameters. Among all new features, the Ripley's K function stands out as the features with the highest discriminating power. Specifically, the top features are the 1st PC score of Ripley's K function generated based on different threshold values.

To visualize the discriminating power of Ripley's K function and variogram parameters, we choose two representative cases, one for B flare and one for M flare, and show their  $B_r$ , PIL mask, sampled point cloud at threshold 2000G and the corresponding Ripley's K function (divided by the number of PIL pixels) in Figure 9 and Figure 10.

The fundamental difference between the derived Ripley's K function, as one can 515 see by comparing the two plots, is the level of the function value. There are two factors 516 that create the level difference: PIL area size and concentration of high-flux pixels. Since 517 we divide each function by the number of PIL pixels, the function value tends to be small 518 when the PIL area is large. The B flare example has a larger PIL region, as suggested 519 by the PIL mask, but only have small scattered pieces of high-flux regions along the PIL. 520 Both of these facts would lead to a low functional value. The M flare, on the contrary, 521 has a smaller PIL area, but the high-flux regions are close to each other and clustered 522 into relatively bigger chunks. Both of these lead to higher functional values. 523

**Figure 8.** Normalized Fisher Score for selected features. Four panels correspond to the 1,6,12,24 hour dataset. In each panel, top 15 features in terms of F-score are plotted. Among all 4 datasets, the top features are always the Ripley's K function's principal component score. Some features from other categories also rank among top 15 features. The F-score ranking indicates that the spatial statistics features, especially the Ripley's K function, have greater individual discriminating power compared to SHARP parameters.

Apart from the differences of the level of the functions, one may also notice that 524 the shape of the functions differ. The B flare has two jumps in the function while the 525 M flare has a constantly increasing trend prior to the plateau. This exactly corresponds 526 to the two pairs of high-flux regions shown in the lower left panel of the B flare exam-527 ple, suggesting that there are a few pairs of small clusters of high-flux pixels. The func-528 tion for the M flare has an increasing trend overall, suggesting that there is a region full 529 of high-flux pixels (i.e. there are such pairs of high-flux pixels separated by an arbitrary 530 distance within range  $0 \sim 80$ ). 531

The variogram effective range parameters also differ significantly between the B and M flare. The variogram of the B flare has range parameter at 1.96 while the M flare has it at 75.95. This suggests that most of the  $B_r$  value spatial variations are observed within ~ 2 pixel distances for the B flare point cloud and ~ 76 pixel distances for the M flare point cloud. This further consolidates our argument that the B flare has small, scattered clusters of pixels with high unsigned flux but the M flare has larger concentrations of such pixels.

In conclusion, the spatial statistics features we derived tend to predict an onset of a strong flare when observing the following  $B_r$  pattern: 1) small PIL area; 2) big clusters of high-flux pixels not locating far from each other; 3) has large  $B_r$  value variation between clusters (e.g. between clusters of strongly positive and strongly negative flux). Such pattern is not exhaustive for all strong flares, but it covers the majority of the cases and lead to features with high discriminating power.

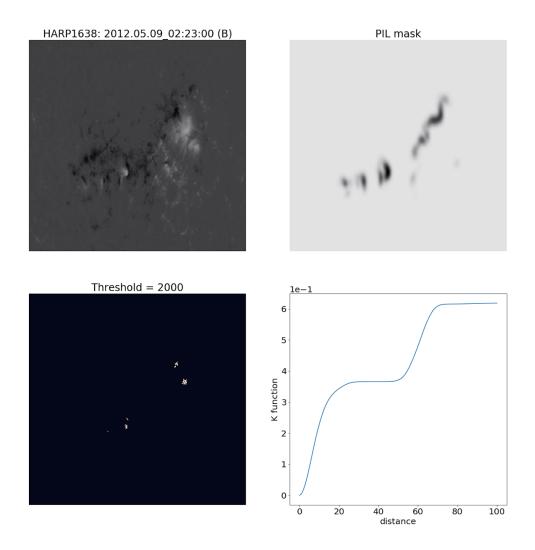

Figure 9. B5.3 flare for HARP 1638 peaked at 02:23, May 09, 2012. Top row shows the  $B_r$  and PIL mask, bottom row shows the sampled point cloud at threshold 2000G, and the Ripley's K function. All three subplots, except the Ripley's K function, are of size 559  $\times$  1002. The variogram range parameter is 1.96 and sill parameter is 0.138.

# 545 4 Conclusion

In this paper, we investigate new features, on top of the SHARP parameters, for 546 flare classification task. The first set of features is derived from persistence homology in 547 topological data analysis, following the idea in Deshmukh, Berger, Meiss, and Bradley 548 (2020). We extend the scope of HMI images from just the  $B_r$  channel to multiple SHARP 549 maps when conducting the analysis, and pay specific attention to the polarity inversion 550 line region (PIL). The second set of features come from spatial statistics concepts. The 551 Ripley's K function analyzes the spatial clustering/dispersion patterns of pixels with strong 552 flux. The Variogram analyzes the spatial variation of the flux at various distance scales. 553 Both sets of features summarize some information regarding the spatial distribution of 554 SHARP parameters, which adds additional information to the feature set that SHARP 555 parameters themselves cannot provide. We demonstrate how the new features can im-556 prove skills of the prediction model and also show that new features, especially the Rip-557 ley's K functions, have great discriminating power. 558

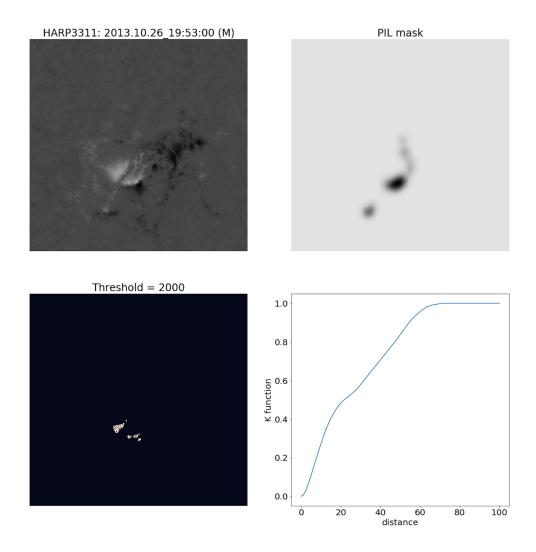

Figure 10. M1.0 flare for HARP 3311 peaked at 19:53, Oct 26, 2013. Top row shows the  $B_r$  and PIL mask, bottom row shows the sampled point cloud at threshold 2000G, and the Ripley's K function. All three subplots, except the Ripley's K function, are of size 411  $\times$  546. The variogram range parameter is 75.95 and sill parameter is 0.143.

One major finding, besides the prediction performance gains, is that by focusing 559 on the  $B_r$  channel only, one can still derive topological and spatial features that has equal 560 or superior predictive power than the SHARP parameters. We find that the top features 561 for discrimination are the Ripley's K functions based on  $B_r$  channel and topological fea-562 tures of the  $B_r$  channel. This result suggests that the spatial and shape information we 563 derived from the  $B_r$  channel alone is a more powerful discriminant than the SHARP quan-564 tities derived from other SHARP maps. One of our future research goal is to analyze the 565 spatial correlations of the  $B_r$  channel and the other SHARP quantities and check if there 566 are systematic differences across different classes of solar flares. 567

We note that out findings of a strong correlation between the  $B_r$  spatial distribution and the flare productivity shows an inherent connection between the free energy buildup and release in solar flares that is related to the clustering and proximity of flux to the PIL. Such a connection has been established earlier by Falconer et al. (2003) and Schrijver (2007); Schrijver, De Rosa, Title, and Metcalf (2005) who respectively found the gradient of and proximity of the magnetic flux (line-of-sight component) with respect to the
PIL to be strongly correlated with flares and coronal mass ejections. Our work goes much
further in establishing this relationship to such a degree that it has greater discriminating power for solar flares than the SHARP parameters derived from the full vector magnetic field.

The analysis of the  $B_r$  channel at multiple flux thresholds and multiple spatial scales 578 can also be found in the thread of research on the fractal dimensions of flaring areas (As-579 chwanden & Aschwanden, 2008; Aschwanden et al., 2016; McAteer, Gallagher, & Ireland, 580 2005). They found that typically M/X flares have higher 2D fractal dimensions, indi-581 cating a larger flaring area with high flux values. The key difference between the spa-582 tial statistics tools we adopted and the fractal dimensions is that, after we choose the 583 high flux areas above a threshold, we measure the spatial clustering pattern of the high 584 flux areas, not the size of the area, since we always randomly sample 500 pixels in the 585 high flux areas for analysis. We do believe that our work complements the researches on 586 fractal dimensions to further quantify the shape complexity of high flux areas at mul-587 tiple scale, and our result suggests that there are more discriminating features out of the 588 shape (i.e. clustering pattern) of the high flux areas, beyond their sizes. 589

From a theoretical perspective, our work suggest that the necessary components 590 for flares, complexity and also free energy are intrinsically related to one another through 591 the photospheric  $B_r$  distribution. The relationship to  $B_r$  and coronal free energy is not 592 immediately obvious. However, we may infer that the energized coronal field may result 593 from the evolution of non-force-free fields in the convection zone that produce signatures 594 in the  $B_r$  distribution detected by our statistical analysis. Such forces may affect the way 595 individual flux tubes find cohesion from magnetic twist or emerge through the convec-596 tion zone. A physical basis for this conjecture is found in simulations of flux emergence 597 of kink-unstable flux ropes that form delta spots, which are highly prone to flaring (Fang 598 & Fan, 2015; Linton, Dahlburg, Fisher, & Longcope, 1998; Toriumi & Hotta, 2019). Sim-599 ulations of flux emergence also show the development of strong shear along forming PILs 600 (Archontis & Török, 2008; Fan, 2001; Fang, Manchester, Abbett, & van der Holst, 2010; 601 Manchester, 2001, 2007; Török et al., 2014), as well as producing eruptive behavior (Manch-602 ester, Gombosi, DeZeeuw, & Fan, 2004). Our spatial and topological analysis suggest 603 a more subtle and universal process may be at work developing the photospheric mag-604 netic field and coronal free energy in a relatable way. 605

With this paper, we also want to popularize the application of spatial statistics tools, 606 which can provide both interpretable and predictive features for various machine learn-607 ing tasks. The biggest advantage of the Ripley's K function and Variogram in our pa-608 per is that they can summarize the spatial patterns of pixels at various scales and give 609 functional summary of the spatial distributions of the physical quantities. Focusing on 610 various spatial scales can potentially uncover the multi-level patterns that are relevant 611 for the initiation of flares. In the future, we want to apply the same or similar tools to 612 analyze not just snapshots of HARP regions, but videos of HARP regions to see if there 613 are temporal trends of such spatial information that can further benefit the flare pre-614 diction. 615
