Abstract

The Community Earth System Model version 2 (CESM2) simulates a high equilibrium climate sensitivity ($ECS > 5$ degC) and a Last Glacial Maximum (LGM) that is substantially colder than proxy temperatures. In this study, we use the LGM global temperature from geological proxies as a benchmark to examine the role of cloud parameterizations in simulating the LGM cooling in CESM2. Through substituting different versions of cloud schemes in the atmosphere model, we attribute the excessive LGM cooling to the new schemes of cloud microphysics and ice nucleation. Further exploration suggests that removing an inappropriate limiter on cloud ice number (NoNimax) and decreasing the time-step size (substepping) in cloud microphysics largely eliminate the excessive LGM cooling. NoNimax produces a more physically consistent treatment of mixed-phase clouds, which leads to more cloud ice content and a weaker shortwave cloud feedback over mid-to-high latitudes and the Southern Hemisphere subtropics. Microphysical substepping further weakens the shortwave cloud feedback. Based on NoNimax and microphysical substepping, we have developed a paleoclimate-calibrated CESM2 (PaleoCalibr), which simulates well the observed 20th century warming and spatial characteristics of key cloud and climate variables. PaleoCalibr has a lower ECS (~ 4 degC) and a 20% weaker aerosol-cloud interaction than CESM2. PaleoCalibr represents a physically and numerically better treatment of cloud microphysics and, we believe, is a more appropriate tool than CESM2 in climate change studies, especially when a large climate forcing is involved. Our study highlights the unique value of paleoclimate constraints in informing the cloud parameterizations and ultimately the future climate projection.

LGM paleoclimate constraints inform cloud parameterizations and equilibrium climate sensitivity in CESM2

Key Points:

- Excessive LGM global cooling in CESM2 is attributed to the simulation of cloud microphysical processes including the ice nucleation
- A new configuration (PaleoCalibr) with a cloud-ice-number limiter removed and microphysical substepping produces realistic LGM temperature
- PaleoCalibr simulates realistic modern climate and clouds with reduced equilibrium climate sensitivity and cloud feedback

Plain Language Summary: The Community Earth System Model version 2 (CESM2) shows a much higher equilibrium climate sensitivity ($ECS > 5^{\circ}\text{C}$) than its predecessor models ($\leq 4^{\circ}\text{C}$), which, if true, implies a greater future warming than previously thought and a more severe challenge for climate adaptation and mitigation. Therefore, it is critical to determine whether the high ECS is realistic and what causes its increase. In a previous study, we suggested that the high ECS is likely unrealistic because CESM2 simulates excessive cooling for an ice age climate—the Last Glacial Maximum (LGM; ~21,000 years ago). In this study, we investigate which aspects of CESM2 are responsible for the extreme LGM cooling and the high ECS. We find that the simulated LGM climate is very sensitive to treatments of cloud microphysical processes, and that removing an inappropriate limiter on cloud ice number and using a smaller time-step size in the microphysics largely eliminate the excessive LGM cooling. With these microphysical modifications, CESM2 simulates a much lower ECS ($\sim 4^{\circ}\text{C}$) and matches present-day observations well. Our study suggests that an $ECS > 5^{\circ}\text{C}$ is likely unrealistic and highlights the importance of using past climates to inform and validate the model development including the treatment of clouds.

Abstract: The Community Earth System Model version 2 (CESM2) simulates a high equilibrium climate sensitivity ($ECS > 5^{\circ}\text{C}$) and a Last Glacial Maximum (LGM) that is substantially colder than proxy temperatures. In this study, we use the LGM global temperature from geological proxies as a benchmark to examine the role of cloud parameterizations in simulating the LGM cooling in CESM2. Through substituting different versions of cloud schemes in the atmosphere model, we attribute the excessive LGM cooling to the new schemes of cloud microphysics and ice nucleation. Further exploration suggests that removing an inappropriate limiter on cloud ice number (NoNimax) and decreasing the time-step size (substepping) in cloud microphysics largely eliminate the excessive LGM cooling. NoNimax produces a more physically consistent treatment of mixed-phase clouds, which leads to more cloud ice content and a weaker shortwave cloud feedback over mid-to-high latitudes and the Southern Hemisphere subtropics. Microphysical substepping further weakens the shortwave cloud feedback. Based on NoNimax and microphysical substepping, we have developed a paleoclimate-calibrated CESM2 (PaleoCalibr), which simulates well the observed 20th century warming and spatial characteristics of key cloud and climate variables. PaleoCalibr has a lower ECS ($\sim 4^{\circ}\text{C}$) and a 20% weaker aerosol-cloud interaction than CESM2. PaleoCalibr represents a physically and numerically better treatment of cloud microphysics and, we believe, is a more appropriate tool than CESM2 in climate change studies, especially when a large climate forcing is involved. Our study highlights the unique value of paleoclimate constraints in informing the cloud parameterizations and ultimately the future climate projection.

1. Introduction

The Community Earth System Model version 2 (CESM2) is the newest and most comprehensive model of the CESM family and is a participant in the Coupled Model Intercomparison Projects phase 6 (CMIP6) (Bacmeister et al., 2020; Danabasoglu et al., 2020; Meehl, Arblaster, et al., 2020). One of the most conspicuous differences between CESM2 and its predecessor models is its high equilibrium climate sensitivity (ECS; Bacmeister et al., 2020; Bitz et al., 2011; Gettelman et al., 2019; Gettelman, Kay, & Shell, 2012; Kiehl, Shields, Hack, & Collins, 2006). In the early versions of CESM (the Climate System Model version 1, the Community Climate System Model versions 2–4, and CESM1), ECS ranges from 2.0 to 4.0 K, increasing with the model version and spanning the likely (66%) range from multiple synthesis reports (Figure 1; Charney et al., 1979; IPCC, 2013; Sherwood et al., 2020). In CESM2, ECS has risen to values higher than 5.0°C and well beyond the likely range in different synthesis reports including the Sixth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC, 2021). These increases of ECS with CESM model versions have been attributed to increases of model resolution and improvements of physical parameterizations (Bacmeister et al., 2020; Bitz et al., 2011; Gettelman et al., 2019; Gettelman et al., 2012; Kiehl et al., 2006). Specifically, the higher ECS in CESM2, configured with the Community Atmosphere Model version 6 (CAM6), than that in CESM1 with CAM5 (hereafter CESM1) is attributed to changes in the atmospheric parameterizations of stratiform cloud microphysics, unified turbulence, ice nucleation, and convection, as well as the adjustment of aerosol-cloud interactions to match the 20th century temperature record (Gettelman et al., 2019). A high ECS similar to that of CESM2 has been reported in other CMIP6 models and similarly attributed to the simulation of cloud processes (Zelinka et al., 2020).

Whether the high ECS of CESM2 and many other CMIP6 models is realistic remains uncertain and is difficult to address using evidence from present-day observations. On the one hand, CESM2 reproduces well the magnitude of the 20th century global warming in instrumental records and outperforms CESM1 in many observation-based climate metrics (Danabasoglu et al., 2020). In particular, CESM2 simulates a more realistic cloud phase distribution with more supercooled liquid water over the Southern Ocean, largely correcting a major model deficiency in CESM1 (Bjordal, Storelvmo, Alterskjær, & Carlsen, 2020; Gettelman et al., 2020; Kay et al., 2016; Kay et al., 2012). The higher amount of supercooled liquid water is attributed to the updated ice nucleation and cloud microphysical schemes in the atmosphere model and should lead to less cloud phase transitioning (ice to liquid) in response to warming and a weaker (less negative) cloud-phase feedback than in CESM1 (Gettelman et al., 2020). Thus, the stronger cloud feedback and higher ECS in CESM2 is an expected outcome of model improvements (Bjordal et al., 2020; Frey & Kay, 2018; Tan, Storelvmo, & Zelinka, 2016). On the other hand, process understanding from satellite observations suggests that the high-ECS models including CESM2 overestimate the cloud feedback over tropical shallow cumulus regions (Cesana & Del Genio, 2021; Myers et al., 2021). In addition, recent work shows models (including CESM2) underestimate a negative cloud feedback from cloud lifetime changes (Mülmenstädt et al., 2021). There is no doubt that the representation of cloud feedbacks in climate models remains as a large source of uncertainty in climate model projections. Thus, CESM2's successful simulation of the 20th century warming could result from coexisting and compensating model biases due to excessive sensitivities to both aerosol and greenhouse gas (GHG) increases. In this case, the resultant cooling and warming during the historic period offset each other (Kiehl, 2007; Meehl, Senior, et al., 2020; C. Wang, Soden, Yang, & Vecchi, 2021).

Paleoclimate constraints represent a unique and independent way to assess the climate sensitivity of models and consist of performing paleoclimate simulations that incorporate reconstructed climate forcings and assessing them against proxy reconstructions of paleotemperature (e.g. Manabe & Broccoli, 1985). Simulations of the Last Glacial Maximum (LGM; an extreme ice-age climate of ~21,000 years ago) have been performed using many versions of the CESM models and exhibit a close relationship between global cooling and ECS (Figure 1; correlation coefficient = -0.97) (Brady, Otto-Bliesner, Kay, & Rosenbloom, 2013; Otto-Bliesner et al., 2006; Shin et al., 2003; Zhu et al., 2017; Zhu et al., 2021; Zhu & Poulsen, 2021). CESM2, for instance, has the highest ECS (5.6°C) and also simulates the lowest LGM global temperature among the CESM models, a temperature that is at least 5°C lower than a recent observationally based estimate and the CESM1 LGM global temperature (Tierney et al., 2020; Zhu et al., 2021). CESM2 also overestimates global and regional temperature responses for past warm climates including the Early Eocene (an extreme greenhouse climate of ~50 million years ago) and the Pliocene (the most recent warm climate of ~3.2 million years ago with atmospheric CO_2 comparable to today's) (Feng, Otto-Bliesner, Brady, & Rosenbloom, 2020; Zhu, Poulsen, & Otto-Bliesner, 2020). Taken together, these paleoclimate simulations suggest that CESM2 is too sensitive to large external forcings and that its high ECS and strong cloud feedback are likely unrealistic. The excessive cooling in the CESM2 LGM simulation has been attributed to the strong shortwave cloud feedback in the Southern Hemisphere subtropics and mid-to-high latitudes (Zhu et al., 2021). However, it remains unclear which aspects of the cloud feedback processes (such as processes related to stratiform cloud microphysics, unified turbulence, ice nucleation, and convection) in CESM2 are causing the unrealistic climate sensitivity.

In this study, we use LGM constraints to examine details of the cloud feedback processes in CESM2 and to develop a paleoclimate-calibrated version of CESM2 that has a realistic sensitivity to LGM forcings. We adopt the fully coupled LGM configuration in Zhu et al. (2021) and utilize the fact that CESM2 with CAM5 simulates a much more realistic LGM global surface temperature than with CAM6. We evaluate the impact of individual CAM6 cloud schemes on simulated LGM global cooling through simulations in which CAM6 schemes are replaced, one at a time, with older CAM5 schemes. Additionally, we explore physical and numerical aspects of key cloud parameterizations. Finally, we compare the paleoclimate-calibrated version of CESM2 to present-day observations including the scale-aware and definition-aware diagnostics available in satellite simulators. Our study demonstrates that paleoclimate information in concert with modern observations should be used to evaluate cloud parameterizations, which critically determine climate sensitivity.

2. Models and experiments

CESM2 consists of state-of-the-art models of the atmosphere, ocean, land, sea ice, and river and has the capability to simulate ice-sheet dynamics (Danabasoglu et al., 2020). Among the substantial science and infrastructure improvements from CESM1 to CESM2, updates to the cloud-related parameterizations in CAM6 are the primary reason for the high sensitivity to external forcings (Gettelman et al., 2019; Zhu et al., 2021). Specifically, the separate schemes of the moist turbulence in planetary boundary layer, shallow convection, and cloud macrophysical quantities have been replaced with a unified treatment, the Cloud Layers Unified by Binormals (CLUBB; Bogenschutz et al., 2013; Larson & Golaz, 2005). CLUBB is a higher-order turbulence closure scheme that uses a double-Gaussian probability density function to provide a self-consistent closure treatment of higher-order turbulence moments of vertical velocity,

temperature, and moisture, as well as boundary layer cloud properties of both stratocumulus and cumulus. CAM6 uses an updated cloud microphysics scheme (MG2) that predicts rather than diagnoses the mass and number concentration of rain and snow (Gettelman & Morrison, 2015). In addition, MG2 links the mixed-phase ice nucleation to aerosols, rather than just temperature, through the implementation of a classical-theory-based heterogeneous ice nucleation scheme (HetFrz; Hoose, Kristjánsson, Chen, & Hazra, 2010; Y. Wang, Liu, Hoose, & Wang, 2014). Additional updates and modifications have been implemented to schemes of aerosols, deep convection, orographic gravity wave, and boundary layer form drag (Danabasoglu et al., 2020).

We employ the same LGM initial and boundary conditions as in Zhu et al. (2021). GHGs are 190 ppm, 375 ppb, and 200 ppb for CO₂, CH₄, and N₂O, respectively. Ice sheets are from the ICE-6G reconstruction at 21 ka (thousand years before present) with changes in land surface properties, surface topography, and land-sea mask (Peltier, Argus, & Drummond, 2015). Earth orbital parameters are fixed at the 21-ka values. Preindustrial aerosol emissions and vegetation cover are used in all the LGM simulations. Similar to Zhu et al. (2021), coupled preindustrial (PI) and LGM simulations are run with prescribed satellite vegetation phenology (unless noted), which allows us to focus on the radiative climate feedback without the need to be concerned about the vegetation phenology feedback. Different from Zhu et al. (2021), a lower horizontal resolution of the atmosphere and land is used to save computing resources (1.9×2.5° instead of 0.9×1.25°; referred to as FV2 and FV1, respectively). CESM2 FV2 differs from FV1 in the tuning parameters, which are required to achieve an overall top-of-atmosphere (TOA) energy balance for the preindustrial simulation.

We perform paired PI and LGM simulations using different configurations of the atmosphere model within the fully coupled CESM2 framework (Table 1). The first two

configurations use CAM6 and CAM5 as the atmosphere component model, respectively (referred to *CAM6* and *CAM5*; hereafter italic font is used for a specific CESM2 configuration). To explore the reason for the greater LGM cooling in *CAM6* than in *CAM5*, additional sensitivity configurations are tested with one cloud scheme in CAM6 either replaced with the older CAM5 version or altered from the default setting (*cf.* Gettelman et al., 2019). In *HetFrzOff*, we use the *CAM6* configuration, except that the new heterogeneous ice nucleation scheme (HetFrz) is replaced with the older scheme in CAM5. In *ClubbOff*, we replace the unified moist turbulence scheme (CLUBB) in CAM6 with the corresponding CAM5 schemes. In *Mg2Off*, we replace the new cloud microphysics scheme (MG2) with the older version (MG1). Considering its overall importance, we developed additional configurations (*NoNimax* and *Mg2Sub8*) to further examine details of the cloud microphysics (see Section 3.2 and 3.3 for the rationale for these sensitivity configurations). In *NoNimax*, a limiter on the cloud ice number concentration is removed in MG2. In *Mg2Sub8*, a microphysical substep of 8 is used (the default value being 1), which decreases the MG2 time-step size from 300s to 37.5s. An additional configuration (*NnSub8*) that combines *NoNimax* and *Mg2Sub8* is also tested (substep numbers of 4 and 16 are also performed but only briefly discussed in this paper). We emphasize that no parameter tuning is performed in any of the configurations, so the difference between *CAM6* and a sensitivity configuration is due to the cloud scheme or modification in question. These fully coupled simulations with various configurations are performed for 100 model years after initializing from the same PI or LGM state. Although many of the simulations have not reached equilibrium in surface climate after 100 model years (Table 1), they are sufficiently integrated to demonstrate the sensitivity of the simulated LGM cooling and cloud feedback to individual cloud schemes and modifications (see results below). Averages of the last 30 years of each simulation are used for analysis.

To directly show the impacts of each configuration on ECS and to link the cloud feedbacks in paleoclimate and present-day climate simulations, paired PI and $2\times\text{CO}_2$ simulations with each CESM2 configuration are performed using a slab ocean model (SOM). The same mixed layer depth and heat transport convergence (“q-flux” hereafter; derived from a coupled PI simulation) are prescribed in each SOM simulation. No parameter tuning is performed for the SOM simulations except for *ClubbOff*, in which the relative humidity threshold for low clouds (rhminl) is increased from 0.95 to 0.99 to prevent the model from producing a PI global mean surface temperature (GMST) higher than 20°C . Each SOM simulation is carried out for 80 years and has reached equilibrium ($\text{TOA net radiation} < |0.1| \text{ W m}^{-2}$) with the last 30 years used for calculation of ECS (denoted as ECS_{SOM}) and the shortwave cloud feedback.

We use the approximate partial radiative perturbation method (APRP) to quantify the shortwave cloud feedback (Taylor et al., 2007). APRP uses monthly model output of radiation fields to build a simplified radiation model and quantify the shortwave feedbacks. The shortwave cloud feedback parameters in the paired PI and LGM in a fully coupled configuration and the paired PI and $2\times\text{CO}_2$ in a SOM configuration are denoted as $\lambda_{\text{sw_cld_LGM}}$ and $\lambda_{\text{sw_cld_2\times}}$, respectively. The longwave feedback in the simulations is not quantified because it is not a major driver for the differences in ECS and the LGM temperature response between CESM2 configurations (Gettelman et al., 2019; Zhu et al., 2021).

We use the LGM proxy sea-surface temperature (SST)-derived global cooling of 5.6°C ($4.6\text{--}6.8^\circ\text{C}$; 95% confidence interval) (Tierney et al., 2020) as a benchmark to evaluate the performance of each CESM2 configuration.

After the individual cloud schemes and changes are evaluated, a paleoclimate-calibrated CESM2 configuration (PaleoCalibr) in FV2 is developed. A suite of DECK (Diagnostic, Evaluation and Characterization of Klima) simulations and a CMIP6 historical simulation are performed (Eyring et al., 2016), which follows the experimental setup of the simulations using the standard CESM2. Results from the PaleoCalibr preindustrial, historical Atmospheric Model Intercomparison Project (AMIP), historical, and abrupt 4×CO₂ simulations are discussed. The historical AMIP simulation is run with the satellite simulator to facilitate a direct comparison with satellite observations (Swales, Pincus, & Bodas-Salcedo, 2018). We also have additional atmosphere-only simulations with prescribed SST and sea ice from observation at 2000 CE that are used to quantify the aerosol-cloud interaction and to test sensitivity to some parameters (see details below).

3. Sensitivity of LGM global temperature to cloud microphysical processes

3.1 Role of individual cloud schemes

CESM2(CAM6) with a ~2° atmosphere significantly overestimates the LGM global cooling, which is consistent with the results with a ~1° atmosphere in Zhu et al. (2021). The LGM ΔGMST in *CAM6* reaches −9.0°C with a large TOA imbalance of approximately −1.0 W m^{−2} after 100 model years, suggesting that if the simulation were extended further, additional cooling would be expected (red in Figure 2; Table 1). In contrast, ΔGMST in *CAM5* is −6.3°C (brown) and falls within the proxy suggested range of LGM global cooling (gray patch). Similar to *CAM5*, *Mg2Off* (green) and *HetFrzOff* (orange) have LGM ΔGMSTs of −6.3 and −5.9°C after 100 years, respectively, which also fall within the proxy range. In contrast, *ClubbOff* has a ΔGMST of −8.9°C that is comparable to the *CAM6* value (blue versus red).

The different LGM Δ GMSTs in these configurations are linked to the strength of shortwave cloud feedback. $\lambda_{\text{sw_cld_LGM}}$ in *CAM6* is $0.81 \text{ W m}^{-2} \text{ K}^{-1}$, more than double the *CAM5* value of $0.29 \text{ W m}^{-2} \text{ K}^{-1}$ (Figure 3 red versus brown; Table 1). $\lambda_{\text{sw_cld_LGM}}$ in *CAM6* is larger than in *CAM5* over all latitudes, especially over the Southern Hemisphere (SH) subtropics and the Southern Ocean (SO). $\lambda_{\text{sw_cld_LGM}}$ is 0.49, 0.37, and $0.64 \text{ W m}^{-2} \text{ K}^{-1}$ in *Mg2Off*, *HetFrzOff*, and *ClubbOff*, respectively. In the subtropics, *Mg2Off* produces a $\lambda_{\text{sw_cld_LGM}}$ comparable to *CAM5* (green vs brown), indicating that the stronger subtropical $\lambda_{\text{sw_cld_LGM}}$ in *CAM6* than in *CAM5* is largely due to the new cloud microphysics scheme (MG2). Over the SO, *HetFrzOff* produces a $\lambda_{\text{sw_cld_LGM}}$ comparable to *CAM5* (orange vs brown), indicating that the new ice nucleation scheme (HetFrz) explains the stronger SO $\lambda_{\text{sw_cld_LGM}}$ in *CAM6*. In addition, *HetFrzOff* produces a weaker shortwave cloud feedback than *CAM6* over the SH subtropics, although not as weak as in *CAM5*, indicating that the ice nucleation of mixed-phase clouds is important for both SH high latitudes and subtropics. *HetFrzOff* simulates greater amounts of ice nucleation particles and cloud ice than *CAM6* (Figure 4b), which, we speculate, produces more negative cloud phase and lifetime feedbacks due to the greater cloud phase transition from ice to liquid in response to warming (Mülmenstädt et al., 2021; Tan et al., 2016).

The tests of individual cloud schemes (*Mg2Off*, *HetFrzOff*, and *ClubbOff*) suggest that the cloud microphysical processes, including those related to mixed-phase and liquid clouds, are important in driving the strong cloud feedback in *CAM6* and are likely responsible for the unrealistically high CESM2 ECS. Nevertheless, the new cloud schemes were developed according to theory and process-level understanding and were found to be critical to the improved simulation of the SO cloud phase distribution (Gettelman et al., 2020). Given that the

new schemes in CAM6 are “better physics”, we next examine details of the cloud microphysical processes while using these more advanced cloud schemes.

3.2 Role of a cloud-ice-number limiter

A cloud-ice-number limiter (named “nimax” in MG2) sets the maximum allowed cloud ice number and was first designed in MG1 to avoid excessive nucleation with the old ice nucleation scheme and with the long microphysical time step. “nimax” was not modified in MG2 when the new mixed-phase ice nucleation scheme was introduced. As a result, the heterogeneous ice nucleation processes can increase cloud ice mass but not the number concentration, leading to artificially inflated ice particle size and increased sedimentation (Shaw, McGraw, Bruno, Storelvmo, & Hofer, 2021). With “nimax”, the cloud ice number also has less freedom to adjust to internal or forced variations. We examine the role of “nimax” through a suite of simulations (*NoNimax*), in which “nimax” is removed to improve the physical consistency in mixed-phase clouds. Other considerations of *NoNimax* include that “nimax” may be no longer needed due to the much shorter microphysical time step (300s in MG2 versus 1800s in MG1) and that the new ice nucleation scheme is more process-based and coded differently from the old scheme (Hoose et al., 2010; Y. Wang et al., 2014).

NoNimax has minor impact on the preindustrial GMST but warms the LGM by close to 3°C in 100 years, leading to a much-improved LGM Δ GMST of -6.8°C (yellow versus red in Figure 2). As expected, *NoNimax* changes the response to LGM forcing by affecting the cloud feedback. The global mean $\lambda_{\text{sw_cld_LGM}}$ is $0.64 \text{ W m}^{-2} \text{ K}^{-1}$ in *NoNimax*, 20% smaller than the CAM6 value (Table 1). Zonal mean $\lambda_{\text{sw_cld_LGM}}$ in *NoNimax* is weaker over the SH subtropics and the mid-to-high latitudes in both hemispheres (yellow versus red in Figure 3). To some degree,

NoNimax impacts cloud properties and feedbacks over the SH subtropics in a similar way as *HetFrzOff*, likely indicating a similar mechanism through increasing cloud ice content (Figure 4b) and strengthening the (negative) cloud phase and lifetime feedback. We note that the projected LGM Δ GMST for *NoNimax* is $\sim -8^{\circ}\text{C}$, estimated by extrapolation using TOA radiation and GMST (yellow in Figure 2d), and indicates that *NoNimax* would likely overestimate the LGM Δ GMST if the simulation were extended beyond 100 years.

NoNimax, with the limiter removed, produces an unrealistic simulation of cloud ice number concentration (Figure 5). The zonal-mean in-cloud ice number concentration in *CAM6* is largely less than 50 L^{-1} below $\sim 400 \text{ hPa}$ with maximum centers in the middle troposphere at the mid-latitudes and in the lower troposphere at polar regions. In the stratosphere, the zonal-mean in-cloud ice number reaches values greater than 900 L^{-1} . The high values over the stratosphere likely reflect a model bias, while values over the middle and lower troposphere are roughly of the same order as observations (e.g., DeMott et al., 2010; Patnaude, Diao, Liu, & Chu, 2021). Without the limiter, *NoNimax* simulates a zonal mean in-cloud ice number greater than *CAM6* almost everywhere. Over the Northern Hemisphere (NH) mid-latitudes, the zonal-mean in-cloud ice number reaches values $>900 \text{ L}^{-1}$ at $\sim 400 \text{ hPa}$ and $>300 \text{ L}^{-1}$ below; these values are roughly an order larger than observations (e.g., DeMott et al., 2010).

3.3 Role of substepping in microphysics

The large overestimation of in-cloud ice number in *NoNimax* motivates us to explore whether substepping in the microphysics helps to improve the simulation. Microphysical substepping decreases the time-step size through increasing the substep number of microphysical calculations per calculation of the other model physical parameterizations. For simplicity, we

perform a suite of atmosphere-only simulations forced by the observed climatological SST and sea ice from 2000 CE. These simulations are run with *NoNimax* and with an increased microphysical substep of 2, 4, 8, 16, and 32, respectively (Figure 5). At the NH mid-latitudes, the zonal mean in-cloud ice number at 400 hPa decreases from $\sim 900 \text{ L}^{-1}$ to $\sim 300 \text{ L}^{-1}$ with 2 MG2 substeps (*NnSub2*; microphysical time step of 150 s) and to $\sim 100 \text{ L}^{-1}$ with 4 substeps (*NnSub4*; microphysical time step of 75 s). At $\sim 700 \text{ hPa}$, the cloud ice number decreases from ~ 300 to $< 50 \text{ L}^{-1}$ with substeps greater than 8. Overall, the simulated cloud ice number is converging after 8–16 MG2 substeps (a microphysical time step $\leq 37.5\text{s}$).

Employing microphysical substepping together with *NoNimax* further decreases the shortwave cloud feedback and the simulated LGM global cooling, in addition to improving the simulation of cloud ice number. Three pairs of coupled PI and LGM simulations are performed with *NoNimax* and microphysical substep of 4, 8, and 16 (referred to as *NnSub4*, *NnSub8*, and *NnSub16*, respectively). The LGM ΔGMST are -6.4 , -6.5 , and -6.5°C after 100 model years in *NnSub4*, *NnSub8*, and *NnSub16*, respectively. The global mean $\lambda_{\text{sw_cld_LGM}}$ are 0.53, 0.49, and $0.49 \text{ W m}^{-2} \text{ K}^{-1}$, respectively. The decrease of $\lambda_{\text{sw_cld_LGM}}$ with the microphysical substepping reaches saturation at 8 substeps: successive substep increases from 1 to 4, 8, and 16 decrease $\lambda_{\text{sw_cld_LGM}}$ by 0.11, 0.04, and $0.00 \text{ W m}^{-2} \text{ K}^{-1}$, respectively. Consistent with the global mean, the zonal mean $\lambda_{\text{sw_cld_LGM}}$ also exhibits convergence with an MG2 substep of 8 or higher (Figure 6). Although the decrease of the LGM global cooling is small from *NoNimax* (with a substep of 1) to *NnSub8* (ΔGMST of -6.8 versus -6.4°C after 100 model years), the projected LGM ΔGMST is much larger (-8.0 versus -7.0°C ; yellow versus black in Figure 2d), which is consistent with the large impact on the shortwave cloud feedback (Figure 3) and TOA radiation (Table 1; see also the ECS_{SOM}).

To understand the processes that weaken the cloud feedback with an increase in microphysical substeps, we perform an additional pair of coupled PI and LGM simulations with *CAM6* and 8 microphysical substeps (referred to *Mg2Sub8*). *Mg2Sub8* has the active “nimax” limiter and simulates a low tropospheric cloud ice number like *CAM6* (not shown). Compared to *CAM6*, the global mean $\lambda_{\text{sw_cld_LGM}}$ in *Mg2Sub8* decreases by $0.09 \text{ W m}^{-2} \text{ K}^{-1}$ from 0.81 to $0.72 \text{ W m}^{-2} \text{ K}^{-1}$ (Table 1). In comparison, $\lambda_{\text{sw_cld_LGM}}$ decreases by $0.15 \text{ W m}^{-2} \text{ K}^{-1}$ between *NoNimax* and *NnSub8* with “nimax” removed. Both configurations with (*CAM6* and *Mg2Sub8*) and without “nimax” (*NoNimax* and *NnSub8*) consistently show decreases of $\lambda_{\text{sw_cld_LGM}}$ in the subtropics and SH mid-latitudes (Figure 6). These results suggest that a large part of the weakening of cloud feedback with microphysical substepping is through pathways other than changing cloud ice number, such as the warm rain process (Gettelman et al., 2021).

3.4 Connected cloud feedback between LGM and $2\times\text{CO}_2$ simulations

A strong correlation between $\lambda_{\text{sw_cld_LGM}}$ and $\lambda_{\text{sw_cld_2\times}}$ is found across the major configurations that are explored in this study (Figure 3). In the global mean, the correlation coefficient between $\lambda_{\text{sw_cld_LGM}}$ and $\lambda_{\text{sw_cld_2\times}}$ is 0.95 (Figure 3d). A similar strong correlation (–0.93) is also found between LGM ΔGMST and ECS_{SOM} among these CESM2 configurations (Table 1). Averaged across all the configurations, $\lambda_{\text{sw_cld_2\times}}$ is larger than $\lambda_{\text{sw_cld_LGM}}$ by $0.11 \text{ W m}^{-2} \text{ K}^{-1}$, which is consistent with previous findings that the shortwave cloud feedback increases with GMST (Zhu & Poulsen, 2020; Zhu, Poulsen, & Tierney, 2019). In the zonal mean, $\lambda_{\text{sw_cld_2\times}}$ is larger than $\lambda_{\text{sw_cld_LGM}}$ over the middle-to-high latitudes (Figure 3c), likely linked to the more positive cloud-phase feedback in response to warming than to cooling (Zhu & Poulsen, 2020). $\lambda_{\text{sw_cld_LGM}}$ is larger than $\lambda_{\text{sw_cld_2\times}}$ in the tropics, which could be linked to the stronger glacial trade winds and the impact on low clouds through increasing latent heat flux (Zhu et al., 2021).

This high correspondence between global and regional shortwave cloud feedback in paleoclimate and present-day simulations (as well as between the LGM ΔGMST and ECS_{SOM}) supports the notion that paleoclimate information can be used to constrain the cloud feedback and ECS (Zhu et al., 2021). Moreover, $\lambda_{\text{sw_cld_LGM}}$ is obtained with paired, short PI and LGM simulations of 100 model years, which may still have large GMST trends and TOA energy imbalances (Figure 2; Table 1). The high correlation between $\lambda_{\text{sw_cld_LGM}}$ and $\lambda_{\text{sw_cld_2\times}}$ (obtained in equilibrated SOM simulations) suggests that our major findings on the shortwave cloud feedback depend little on the equilibration state of the coupled simulations. This is further supported by the high correlation (0.95) between $\lambda_{\text{sw_cld_LGM}}$ and $\lambda_{\text{sw_cld_2\times}}$ if shorter coupled PI and LGM simulations of 50 years are used.

4. A paleoclimate-calibrated configuration of CESM2

As in Zhu et al. (2021); (Zhu et al., 2020), we find that CESM2 with CAM6 is not well suited for simulating climates under large radiative forcing that exceeds the historical range. To mitigate this shortcoming, we develop a paleoclimate-calibrated CESM2 configuration (PaleoCalibr) based on *NnSub8*, although we note that other configurations of CESM2, including *CAM5*, *HetFrzOff*, and *Mg2Off* also produce acceptably realistic LGM global cooling (Figure 2). An advantage of *NnSub8* over these other configurations is that it uses the advanced cloud schemes in CAM6, in particular the ice nucleation and microphysical schemes that are based more on theory or process-level understanding. Another advantage of *NnSub8* is that it represents a minimal departure in model code from *CAM6* and probably its future versions. Moreover, *HetFrzOff* and *CAM5* simulates a negative shortwave cloud feedback over the Southern Ocean at $\sim 50\text{--}60^\circ\text{S}$ (Figure 3b), which is inconsistent with the positive values estimated using the satellite observations (Myers et al., 2021). Based on *NnSub8*, PaleoCalibr incorporates additional minor

tuning. The CLUBB gamma parameter is lower from 0.280 to 0.275 to decrease the TOA radiation imbalance in the preindustrial simulation. The dust emission scaling factor (dust_emis_fact) is lower from 0.70 to 0.55 to ensure a more realistic global mean dust aerosol optical depth. Additionally, a new and simple limiter on cloud ice number ($N_i < 1000 \text{ L}^{-1}$) is added at the end of the microphysical calculations to ensure a realistic simulation of cloud ice number over the stratosphere. This additional cloud-ice-number limiter has no impact on the cloud feedback and LGM cooling, which has been confirmed in additional test simulations (not shown).

We perform 500-year simulations for both the preindustrial and LGM using PaleoCalibr and the same experimental setups as the standard CESM2 runs. PaleoCalibr PI has a similar GMST as CESM2 (13.9 versus 14.1°C) and a small TOA energy imbalance (0.03 W m^{-2}) at the end of the simulation. PaleoCalibr LGM has a ΔGMST of -6.7°C and a TOA radiation imbalance of -0.08 W m^{-2} (Figure 7). The projected LGM ΔGMST , using a linear regression between LGM GMST and TOA radiation, is approximately -7.3°C in PaleoCalibr, which is marginally too cold when compared with the proxy estimation (Tierney et al., 2020). We contend that the PaleoCalibr LGM is acceptably realistic and suitable for glacial climate research, considering the uncertainty in the ice sheet forcing and the absence of LGM dust forcing in our simulations (Abe-Ouchi et al., 2015; Ohgaito et al., 2018). We note that the land biogeochemistry (BGC) model is inactive in the PaleoCalibr LGM simulation but is active in PaleoCalibr PI. The PI simulation (and the associated historical and abrupt $4\times\text{CO}_2$ simulations) with land BGC is consistent with the available standard CESM2 DECK simulations. We decided not to include land BGC in the PaleoCalibr LGM because it produces an extra LGM cooling of $>1^\circ\text{C}$ after 100 simulation years (not shown) due to vegetation phenology feedbacks. This

vegetation phenology-induced LGM cooling is consistent with results in CESM1.2 (Zhu & Poulsen, 2021) but we do not know how realistic it is, given that the land vegetation processes are highly parameterized for the present climate and may not work well under a much colder environment with a much lower CO₂ (Lawrence et al., 2019).

4.1 A realistic simulation of the present-day climate

We first evaluate the cloud simulation of PaleoCalibr in an AMIP historical simulation with an active Cloud Feedback Model Intercomparison Project Observational Simulator Package (COSIP). We use the Taylor diagram (Taylor, 2001) for a compact visualization of the model performance (Figure 8). The Taylor diagram evaluates a suite of model variables against observations using multiple metrics including the area-weighted pattern correlation and normalized root-mean-squared differences (RMSDs), as well as the relative bias. Cloud observations that are used in the model evaluation include the climatology of TOA cloud radiative forcing from Clouds and the Earth's Radiant Energy System Energy Balanced and Filled Edition-4.1 (CERES-EBAF; Loeb et al., 2018) and the cloud fraction products from the International Satellite Cloud Climatology Project (ISCCP) (Pincus, Platnick, Ackerman, Hemler, & Patrick Hofmann, 2012), the Multiangle Imaging Spectro-Radiometer (MISR) (Marchand, Ackerman, Smyth, & Rossow, 2010), and the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation (CALIPSO) (Chepfer et al., 2010), as well as the liquid and ice cloud fraction from CALIPSO. Averages between 2000 and 2014 CE are used in the model-data comparison, except that CALIPSO cloud fraction between 2008 and 2020 CE is used.

PaleoCalibr improves the simulations of cloud fraction and its liquid-ice partition over the standard CESM2 but has degradations in cloud radiative forcing. In the total cloud fraction,

PaleoCalibr shows smaller centered pattern errors than CESM2, i.e., normalized RMSDs that are closer to one when compared with ISCCP (1.33 versus 1.37; labeled “1”), MISR (1.43 versus 1.50; labeled “2”), and CALIPSO (1.40 versus 1.47; labeled “3”). PaleoCalibr cloud fraction also has a greater pattern correlation with CALIPSO (0.90 versus 0.85) than CESM2. The phase partition of cloud fraction in PaleoCalibr shows large improvements over the standard CESM2 with greater pattern correlation with the CALIPSO liquid clouds (0.86 versus 0.76; label “4”) and smaller centered pattern error in both liquid (1.31 versus 1.38 in the normalized RMSDs) and ice (1.47 versus 1.61 in the normalized RMSDs; Label “5”) clouds. In SWCF, PaleoCalibr exhibits a slightly smaller centered pattern error (1.08 vs 1.11; label “6”) than CESM2 but has degradations in the pattern correlation with observations (0.85 to 0.88). PaleoCalibr LWCF degrades slightly from CESM2 with larger centered pattern error (0.91 versus 0.99 in the normalized RMSD from observation; label “7”). For all the metrics that are examined in PaleoCalibr and CESM2, the relative biases from observations (marker size in the Taylor diagram) fall within the same category, indicating that the improvements / degradations in PaleoCalibr come from a redistribution of cloud properties across the globe rather than a uniform shift.

From a spatial view, PaleoCalibr improves the cloud simulation in the Arctic but shows mixed results over other places (Figure 9). The standard CESM2 overestimates the Arctic cloud fraction in CALIPSO by as much as 20%, which results primarily from a larger modeled liquid cloud fraction. PaleoCalibr largely removes the model bias in CESM2 by simulating a smaller liquid cloud fraction that agrees much better with observation. In the subtropics and mid-latitudes, PaleoCalibr simulates a greater cloud fraction that agrees better with satellite observations (Figure 9a,b), but at the expenses of degradations in the SWCF (Figure 9d),

reflecting a stubborn “too-few-and-too-bright” model bias (Nam, Bony, Dufresne, & Chepfer, 2012). In the deep tropics, PaleoCalibr simulates a smaller cloud fraction than CESM2, which agrees worse with observations. Over the SO, PaleoCalibr cloud fraction and its phase partition are similar to the standard CESM2, suggesting that the improvement from CESM1 to CESM2 in the SO clouds is largely preserved in PaleoCalibr. On average, PaleoCalibr has a more positive SWCF over middle-to-high latitudes and more negative SWCF over the lower latitudes than CESM2.

We next evaluate the coupled simulation of PaleoCalibr in a CMIP historical simulation. PaleoCalibr reproduces the magnitude of the global warming ($\sim 1.1^{\circ}\text{C}$; Figure 10) from 1850 to 2014 CE in the Hadley Centre-Climate Research Unit Temperature Anomalies (HADCRU4) and the Goddard Institute for Space Studies Surface Temperature Analysis (GISTEMP) (Jones et al., 2012; Lenssen et al., 2019). The large internal variability relative to the forced response prevents us from a more quantitative evaluation of the temporal characteristics of the historical simulation (green in Figure 10; Kay et al., 2015), but a visual examination suggests that the performance of PaleoCalibr is as good as the ensemble of three CESM2 historical simulations (red, orange, and pink in Figure 10).

The spatial characteristics of the PaleoCalibr historical simulation match observations and reanalysis reasonably well with skills largely similar to the standard CESM2, which is summarized in a Taylor diagram (Figure 11). The model performance is evaluated against observations of SST from the Extended Reconstructed Sea Surface Temperature version 5 (ERSST; Huang et al., 2017), precipitation from the Global Precipitation Climatology Project version 2.3 (GPCP; Adler et al., 2018), TOA cloud radiative forcing from CERES-EBAF (Loeb et al., 2018), and the surface air temperature, sea-level pressure, and zonal wind at 300 hPa from

the ERA5 (Hersbach et al., 2020). All the metrics are calculated for the mean fields averaged between 1979 and 2014, except for the CERES-EBAF cloud radiative forcing that is averaged between 2000 and 2014. The mean bias of all the fields examined is in the same category between PaleoCalibr and CESM2 (marker size in the Taylor diagram), except for precipitation that has a larger relative bias in PaleoCalibr (11.2% versus 9.6%). Statistics for surface air temperature (labeled “2”) and longwave cloud forcing (labeled “5”) are very similar between the PaleoCalibr and CESM2. The shortwave cloud forcing (SWCF) (labeled “4”) shows a larger difference, which is consistent with results from the AMIP simulations. As a result of the more positive SWCF over middle-to-high latitudes and more negative SWCF over the lower latitudes, SST in PaleoCalibr is warmer over mid-to-high latitudes and colder over lower latitudes with a larger centered pattern error than in CESM2 (label “3” in Figure 11; Figure 12). Small degradation in the normalized RMSD is also found in zonal wind at 300 hPa (label “6”) and precipitation (label “7”) with the former having insufficient spatial variance and the latter having too much spatial variance.

Based on the above analysis, we conclude that PaleoCalibr performs as good as the standard CESM2 in the simulation of key cloud and climate observations. We note that some aspects of PaleoCalibr simulations could be improved through additional parameter tuning that may have little net impact on climate sensitivity, but an extensive re-tuning of the model is beyond the scope of this study.

4.2 A lower ECS and weaker cloud-aerosol interactions

ECS is quantified to be 3.9°C in PaleoCalibr by regressing GMST and TOA radiation in an abrupt 4×CO₂ simulation of 150 years, which is much lower than the 5.3°C in CESM2 (Figure

13). If the first 20 years are used in the regression, the difference in the estimated ECS between PaleoCalibr and CESM2 is much smaller ($\Delta\text{ECS} = 0.2^\circ\text{C}$; 3.2 versus 3.4°C), suggesting that the effect from PaleoCalibr changes manifests mostly at timescales longer than 1–2 decades. With additional SOM simulations with an abrupt $2\times\text{CO}_2$, ECS_{SOM} are estimated to be 4.0 and 6.1°C in PaleoCalibr and CESM2, respectively. The lower ECS in PaleoCalibr is consistent with the much smaller magnitude of LGM global cooling (Figure 7). The shortwave cloud feedback averaged over the last 20 years of the $4\times\text{CO}_2$ simulations are 0.52 and $0.74 \text{ W m}^{-2} \text{ K}^{-1}$ in PaleoCalibr and CESM2, respectively. The shortwave cloud feedback shows lower values over the mid-latitudes and the SH subtropics (Figure 14a). Compared to CESM2, the reduced shortwave cloud feedback in PaleoCalibr is more consistent with the observation-based estimates (Ceppi & Nowack, 2021; Cesana & Del Genio, 2021; Myers et al., 2021).

PaleoCalibr simulates an aerosol-cloud interaction (ACI) that is 20% weaker than CESM2. ACI is quantified as the change in the net cloud radiative forcing between a pair of atmosphere-only simulations with aerosol emissions at 2000 CE and 1850 CE, forced with the same observational SST and sea ice (IPCC, 2013). ACI are -1.3 and -1.7 W m^{-2} in PaleoCalibr and CESM2, respectively. ACI weakening is mostly found at mid-to-high latitudes, where we also observe decreases in the shortwave feedback (Figure 14). This highlights the fact that aerosol forcing and cloud feedback are not independent variables (Gettelman et al., 2019; Kiehl, 2007). A weaker GHG-induced warming and a weaker aerosol-induced cooling may explain the comparable historical warming between PaleoCalibr and CESM2 (Meehl, Senior, et al., 2020; C. Wang et al., 2021).

5. Conclusions and discussion

In this study, we have investigated the impact of key cloud parameterizations of CESM2 on the simulated LGM global temperature through coupled simulations with individual CAM6 schemes substituted one-at-a-time by older CAM5 schemes. Our investigation takes advantage of the fact that CESM2(CAM6) (referred to *CAM6*) simulates an excessive LGM cooling but the CESM2(CAM5) (*CAM5*) LGM simulation falls within the proxy suggested range (4.6–6.8°C) (Tierney et al., 2020). The different performances of the LGM simulations imply that changes in the cloud parameterizations between CAM5 and CAM6 are likely responsible for the excessive LGM cooling and therefore the unrealistic climate sensitivity of CESM2. Our simulations show that the substitution of CAM6 ice nucleation or cloud microphysics scheme with the CAM5 version (*HetFrzOff* or *Mg2Off*) produces a much more realistic LGM than the default *CAM6*. In contrast, substituting the moist turbulence scheme to the CAM5 version (*ClubbOff*) has a small impact. Specifically, the LGM ΔGMST after 100 model years are -9.0 , -6.3 , -6.3 , -5.9 , and -8.9°C in the LGM simulations using *CAM6*, *CAM5*, *Mg2Off*, *HetFrzOff*, and *ClubbOff*, respectively. The different magnitude of LGM cooling in these simulations is primarily caused by variations of the shortwave cloud feedback, which are 0.81 , 0.29 , 0.49 , 0.37 , and $0.64 \text{ W m}^{-2} \text{ K}^{-1}$, respectively. These sensitivity tests suggest that the increased climate sensitivity in CESM2 is largely determined by cloud microphysical processes, which has guided our further examination.

Further exploration suggests that the removal of a limiter on cloud ice number (“nimax”) in the microphysical scheme (*NoNimax*) weakens the shortwave cloud feedback from 0.81 to $0.64 \text{ W m}^{-2} \text{ K}^{-1}$ and reduces the simulated LGM ΔGMST to -6.9°C after 100 model years. The original implementation of “nimax” in the CESM2 microphysical scheme is physically inconsistent (Shaw et al., 2021). Without the limiter, the cloud ice number also has more

freedom to adjust to internal or forced variations. As a result, *NoNimax* simulates a larger cloud ice content, which presumably causes a more negative cloud phase and lifetime feedback (Mülmenstädt et al., 2021; Tan et al., 2016). Although *NoNimax* has a more physically based treatment of the ice nucleation processes and a largely improved LGM simulation, its projected LGM ΔGMST is too low ($\sim -8^\circ\text{C}$) and the cloud ice number in the preindustrial simulation is about one order greater than observations.

Building upon *NoNimax*, decreasing the microphysical time-step size (microphysical substepping) lowers the cloud ice number to the observational range and further improves the LGM simulation by decreasing the cloud feedback. Through a suite of simulations with the “nimax” removed, we find that an increase of the microphysical substep from 1 to 8 (a decrease of the microphysical time-step size from 300s to 37.5s; *NnSub8*) produces a realistic cloud ice number and a convergent solution in the shortwave cloud feedback. Specifically, *NnSub8* reduces the LGM ΔGMST from -6.9°C in *NoNimax* to -6.4°C and decreases the shortwave cloud feedback from 0.64 to $0.49 \text{ W m}^{-2} \text{ K}^{-1}$ after 100 model years. The decrease of the shortwave cloud feedback ($0.15 \text{ W m}^{-2} \text{ K}^{-1}$) is largely through processes other than decreasing cloud ice number, which is supported by additional simulations with the microphysical substepping and the “nimax” limiter (*Mg2Sub8*) that show a decrease of the shortwave cloud feedback by $\sim 0.1 \text{ W m}^{-2} \text{ K}^{-1}$ (compared to *CAM6*). Findings here are generally consistent with results in Santos, Caldwell, and Bretherton (2020), who find that multiple microphysical processes are poorly resolved with a default microphysical time step in atmosphere-only simulations of the present day. Our results further show that these poorly resolved processes have an impact on the cloud feedback and climate sensitivity and that a microphysical substep of

8 and higher seems to produce a convergent shortwave cloud feedback. Further study is needed to examine which microphysical processes are responsible for the time-step dependence.

A paleoclimate-calibrated CESM2 configuration (PaleoCalibr) is developed, which consists of removing the “nimax” limiter (*NoNimax*) and substepping (*Mg2Sub8*) in the cloud microphysics, as well as a minimal model tuning. A historical simulation using PaleoCalibr reproduces the observed 20th century warming. PaleoCalibr also simulates the spatial characteristics of key cloud and climate variables very well with improvements in the cloud fraction and its phase partition. In the Arctic, PaleoCalibr corrects a large model bias in CESM2 by removing the excessive liquid clouds. In the subtropics, PaleoCalibr simulates a slightly greater cloud cover that agrees better with satellite observations but introduces a compensating bias by decreasing the shortwave cloud forcing. Due to the changes in shortwave cloud forcing, PaleoCalibr exhibits small degradations from CESM2 in the spatial pattern of SST and the associated wind and precipitation fields in coupled simulations. Performance of PaleoCalibr could be further improved through parameter tuning, which we did not perform for simplicity.

PaleoCalibr has a lower ECS (~4°C) than the standard CESM2 (~5–6°C) and realistic LGM global cooling (~7 °C). PaleoCalibr simulates a 20% smaller aerosol cloud interaction. Compared to the standard CESM2, removing the cloud-ice-number limiter represents a more physically consistent treatment of the cloud ice nucleation process and microphysical substepping provides better numerical performance of cloud microphysical processes. We believe PaleoCalibr is a more useful tool than CESM2 in climate change studies, especially when a large climate forcing is involved.

We note that all the test simulations and the paleoclimate-calibrated configuration in this study use the CESM2 with a $\sim 2^\circ$ atmosphere. We expect that the overall impact from removing the “nimax” and microphysical substepping is largely independent of model resolution, but some details including the tuning parameters need to be examined if the $\sim 1^\circ$ atmosphere model is used. For example, the exact microphysical substep number that produces a converging cloud feedback could be different due to the different model resolution and parameters. We note further that we have intentionally not performed parameter tuning for each CESM2 sensitivity configuration, which leads to a warmer preindustrial GMST in coupled and SOM simulations in some configurations (e.g., GMST is 17.8°C in the PI SOM simulation with *Mg2Off*). As a consequence and caveat, part of the differences in ECS and cloud feedback between CESM2 configurations could be caused by their state dependence, instead of changes in cloud treatment. However, we believe that the impact of state dependence on the shortwave cloud feedback is small ($\ll 0.1 \text{ W m}^{-2} \text{ K}^{-1}$) in simulations presented here, considering that the shortwave cloud feedback in CESM2 increases from 0.97 to $1.07 \text{ W m}^{-2} \text{ K}^{-1}$ when the background GMST increases from 15.2 to 20.7°C (Zhu & Poulsen, 2020).

Our study highlights the unique value of paleoclimate constraints in informing the cloud parameterizations and ultimately future climate projections. Among the CESM2 configurations that are explored in this study, a close correlation is found in cloud feedbacks and temperature responses between CO_2 increasing and paleoclimate simulations (Table 1 and Figures 1 and 3d), which indicates that a common set of physical processes are active in past and future climates and serves as the physical basis for a paleo-constraint on clouds and climate sensitivity. Although the paleoclimate forcing and global temperature response do not provide process-level constraints on cloud feedback processes, they serve as a critical “out-of-sample” test for the

cloud parameterizations that are usually developed to match the present-day observations. We encourage the use of paleoclimate constraints as an important tool in future model development and validation, as our knowledge of past climates continues to improve and climate models become more complex. We have ongoing work to evaluate the performance of the paleoclimate calibrated CESM2 in simulating past warm climates, such as the Early Eocene (Zhu et al., 2020).

Table 1. List of top-of-atmosphere net radiation (ΔN ; units: W m^{-2}) in the coupled preindustrial (PI) and Last Glacial Maximum (LGM) simulations, the derived global mean surface temperature change (ΔT_{LGM} ; units: $^{\circ}\text{C}$) and shortwave cloud feedback ($\lambda_{\text{SW_CLD_LGM}}$; units: $\text{W m}^{-2} \text{K}^{-1}$) in the LGM simulations, and equilibrium climate sensitivity (ECS_{SOM} ; units: $^{\circ}\text{C}$) and shortwave cloud feedback ($\lambda_{\text{SW_CLD_2}\times}$; units: $\text{W m}^{-2} \text{K}^{-1}$) derived in a pair of slab ocean simulations with the PI condition and an abrupt $2\times\text{CO}_2$ forcing. Results from the last 30 years of simulations with various configuration of the atmosphere model are shown. *CAM6* uses the default CESM2(*CAM6*); *CAM5* uses the old *CAM5* cloud parameterizations; *ClubbOff* uses the *CAM5* shallow convection and boundary layer schemes; *HetFrzOff* uses the *CAM5* ice nucleation scheme; *Mg2Off* uses the *CAM5* cloud microphysics; *NoNimax* removes the “nimax” limiter; *Mg2Sub8* uses 8 substeps in the microphysical scheme; *NnSub8* removes the “nimax” limiter and uses 8 substeps in the microphysics. See text for details of these configurations.

Configurations	PI ΔN	LGM ΔN	ΔT_{LGM}	$\lambda_{\text{sw_cld_LGM}}$	ECS_{SOM}	$\lambda_{\text{sw_cld_2}\times}$
<i>CAM6</i>	-0.18	-1.01	-9.0	0.81	6.1	0.95
<i>CAM5</i>	0.30	0.27	-6.3	0.29	3.7	0.32
<i>HetFrzOff</i>	0.42	0.15	-5.9	0.37	3.8	0.47
<i>ClubbOff</i>	-0.48	-1.1	-8.9	0.64	6.2	0.86
<i>Mg2Off</i>	0.41	0.01	-6.3	0.49	4.3	0.54
<i>NoNimax</i>	0.13	-0.29	-6.9	0.64	5.0	0.79
<i>Mg2Sub8</i>	-0.21	-0.81	-8.2	0.72	4.8	0.74
<i>NnSub8</i>	0.09	-0.14	-6.4	0.49	4.0	0.59

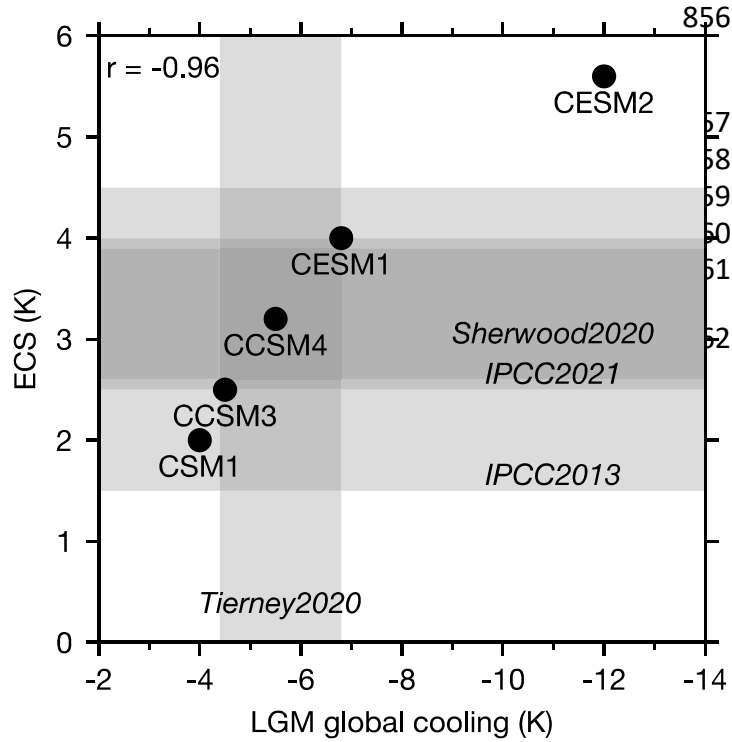

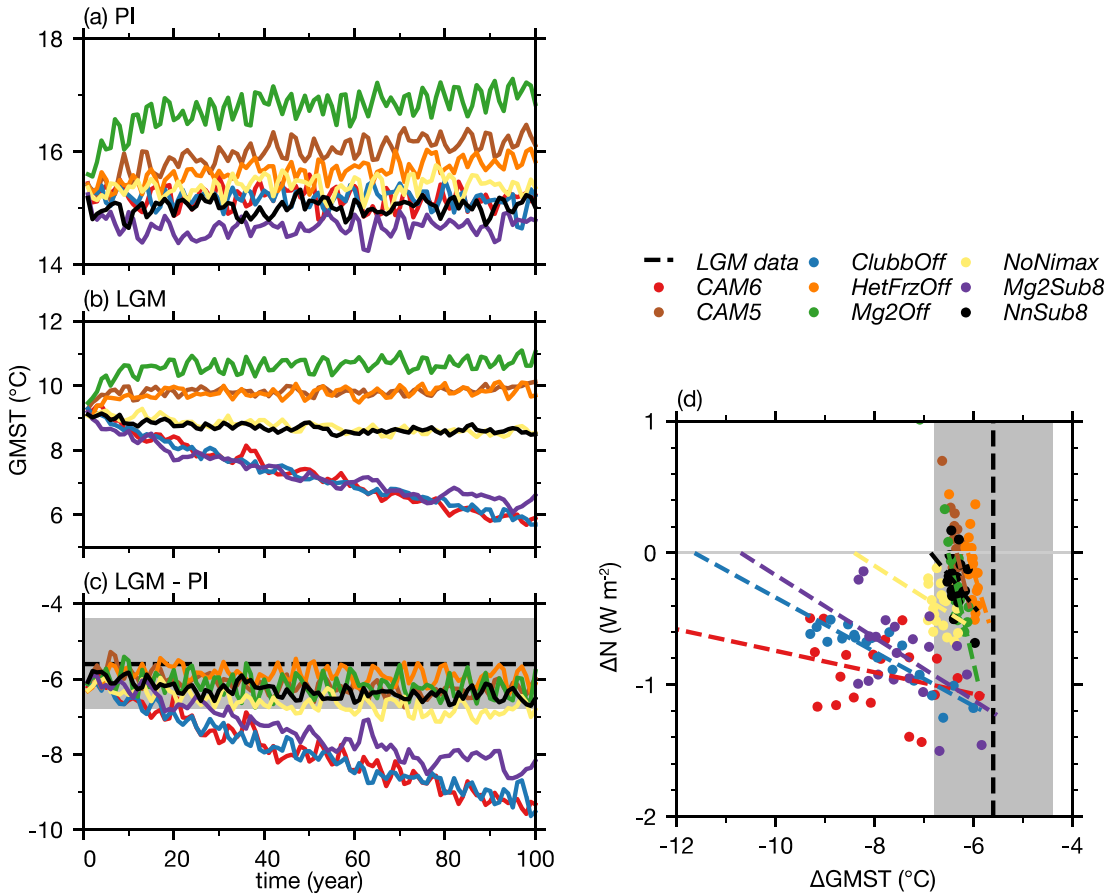

Figure 1. Model simulated LGM global cooling and ECS in different versions of CESM. ECS is estimated using coupled simulation with a slab ocean (see text for references). Vertical patch indicates the 95% confidence interval of proxy estimation of the LGM global cooling from Tierney et al. (2020). Horizontal patches denote the 66% confidence intervals of ECS from the IPCC Assessment Report 5 (IPCC, 2013; light gray), Assessment Report 6 (IPCC, 2021; medium gray) and Sherwood et al. (2020; dark gray).

870

871 **Figure 2.** Time series of global mean surface temperature (GMST) in (a) the preindustrial (PI)
 872 and (b) the Last Glacial Maximum (LGM) simulations using various atmosphere model
 873 configurations within the coupled CESM2 framework. (c) Changes in GMST between paired
 874 LGM and PI simulations. (d) Changes in top-of-atmosphere radiation (ΔN) versus GMST
 875 ($\Delta GMST$) in paired simulations. ΔN and $\Delta GMST$ (markers) are the 5-year running mean of the
 876 LGM time series with the last-30-year averages of the PI simulation subtracted. A linear
 877 regression between ΔN and $\Delta GMST$ is shown as dashed line for each configuration. In (c) and
 878 (d), the LGM $\Delta GMST$ and the 95% uncertainty interval from Tierney et al. (2020) are shown.
 879 See text and Table 1 for details of the model configurations.

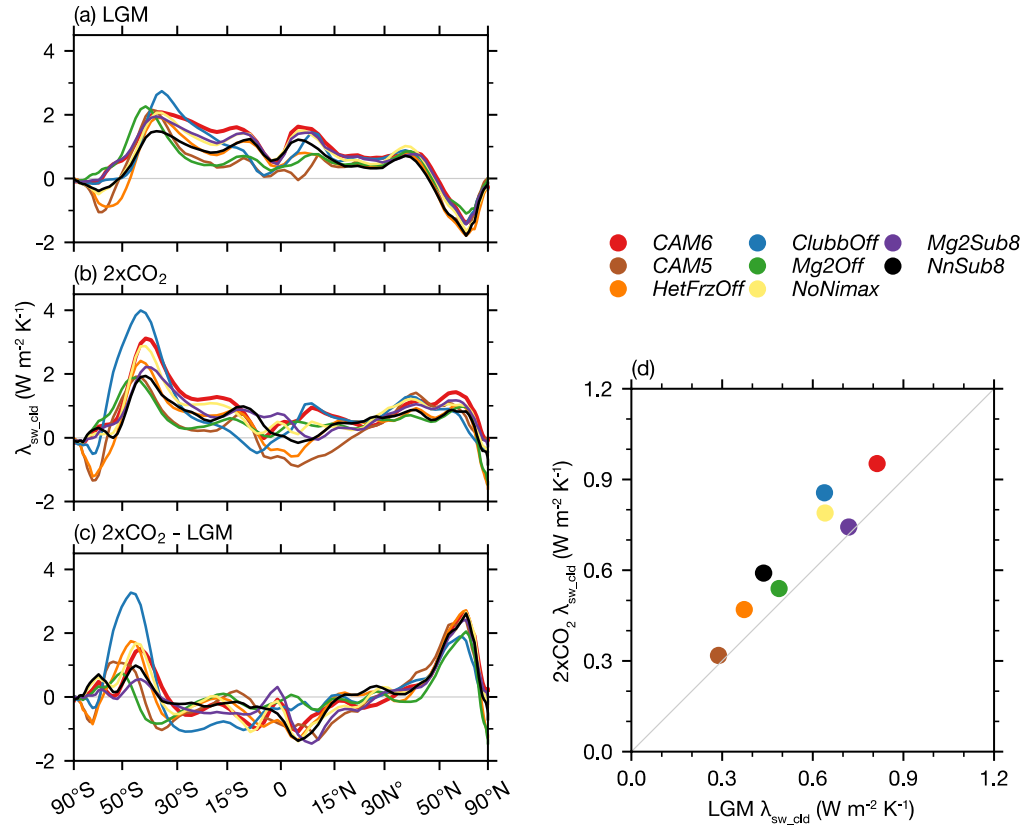

Figure 3. Zonal mean shortwave cloud feedback (λ_{sw_cld} ; units: $W m^{-2} K^{-1}$) for various atmosphere model configurations in (a) the paired preindustrial and Last Glacial Maximum (LGM) simulations using fully coupled CESM2 and (b) the paired preindustrial and 2xCO₂ simulations using CESM2 slab ocean model. (c) Differences in λ_{sw_cld} between the LGM and 2xCO₂ simulations using the same atmosphere model configuration. (d) Scatter plot of the global mean λ_{sw_cld} in the LGM and 2xCO₂ simulations. See text and Table 1 for details of the model configurations.

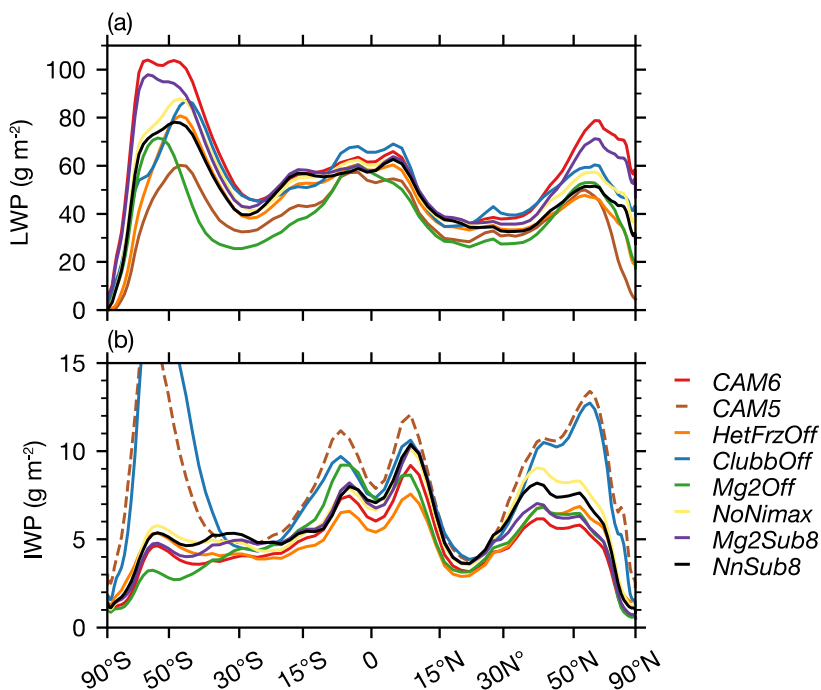

Figure 4. (a) Zonal mean cloud liquid water path (LWP) in the preindustrial simulations with various atmosphere model configurations in the coupled CESM2 framework. (b) as (a) but for the cloud ice water path (IWP). Note that CAM5 IWP in (b) has been multiplied by 0.5 for illustrative purpose (shown as dashed brown line). See text and Table 1 for details of the model configurations.

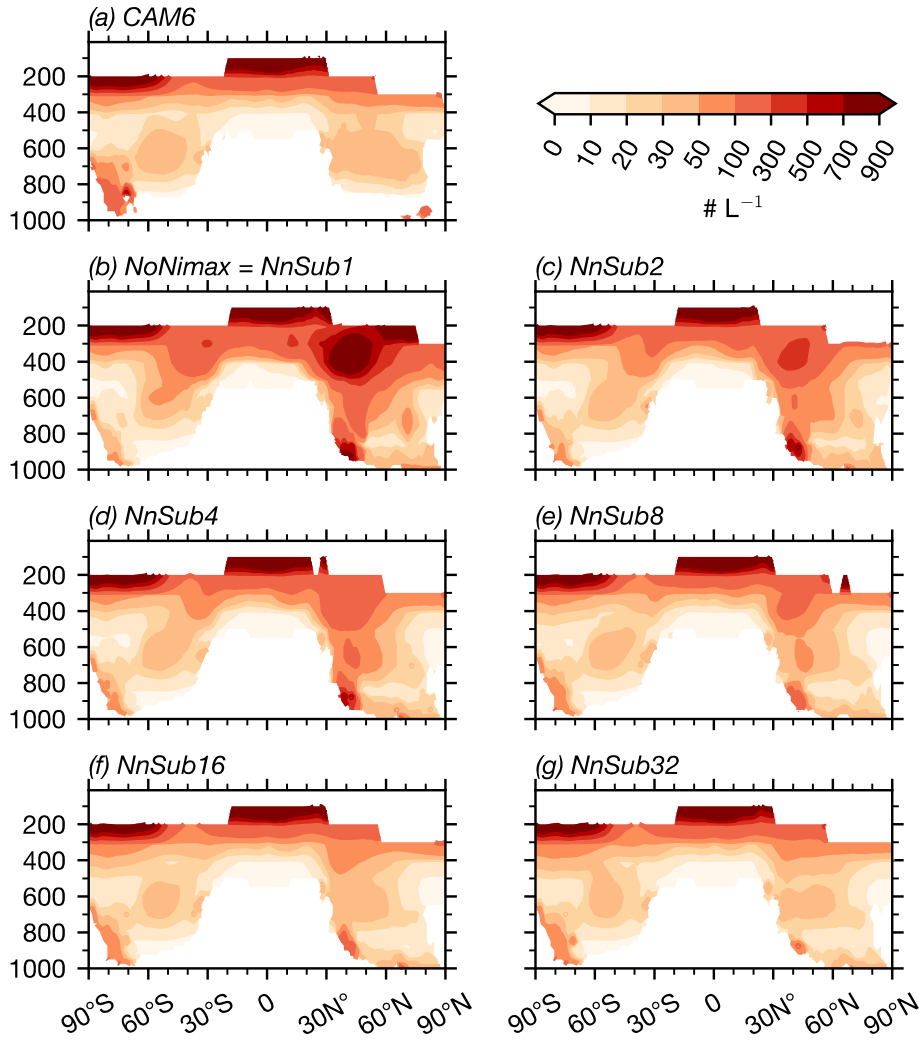

Figure 5. Pressure–latitude section of the zonal mean in-cloud cloud ice number in (a) the default *CAM6* simulation and (b)–(g) simulations with the “nimax” limiter removed and with substep of 1, 2, 4, 8, 16, and 32 in the microphysical scheme, respectively. Pressure is the y-axis with units of hPa. Results are from atmosphere-only simulations forced by the observed present-day sea surface temperature and sea ice (results are similar if coupled simulations are used). The in-cloud ice number is constructed by averaging monthly cloud ice numbers for grid points with a cloud ice mixing ratio greater than 0.01 part-per-million by mass.

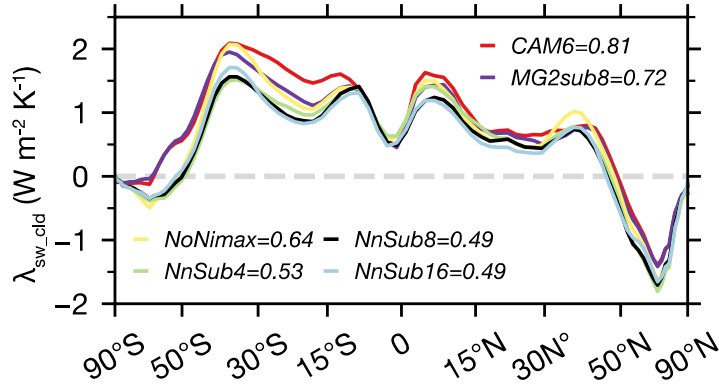

Figure 6. Zonal mean shortwave cloud feedback ($\lambda_{\text{sw_cld}}$) calculated in the paired preindustrial and Last Glacial Maximum simulations with various configurations. See text and Table 1 for details of the model configurations. *NnSub4* and *NnSub16* are the same as *NnSub8* except for the 4 and 16 substeps in the microphysics, respectively.

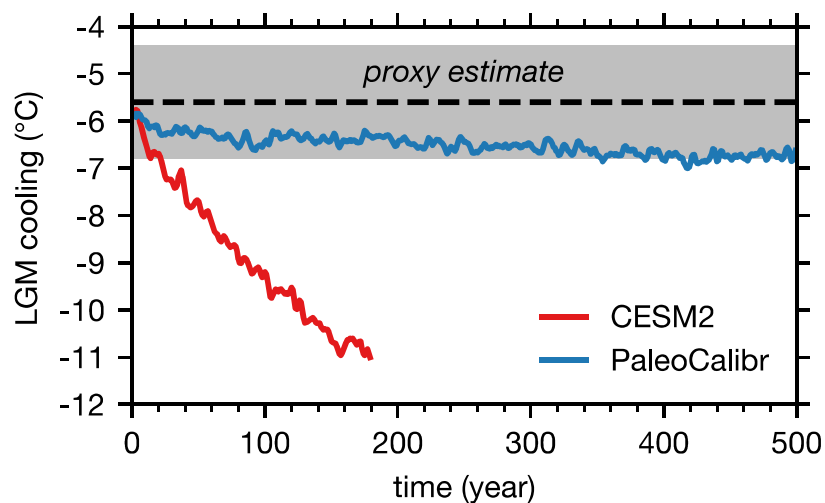

Figure 7. Time series of the global mean surface temperature anomaly in the LGM simulations with CESM2 and the paleoclimate-calibrated (PaleoCalibr) configurations. Black dashed line with the gray patch denotes the 95% uncertainty interval from Tierney et al. (2020) for the LGM global cooling.

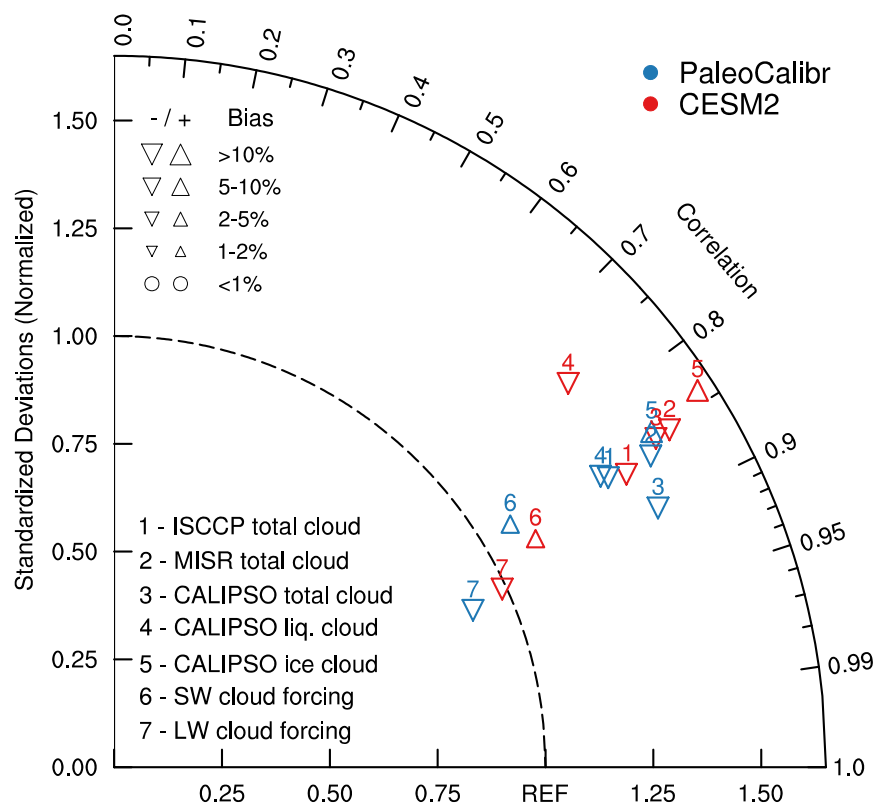

Figure 8. Taylor diagram evaluating key cloud variables in CESM2 and PaleoCalibr with satellite observations. Model variables are from AMIP historical simulations with an active Cloud Feedback Model Intercomparison Project Observational Simulator Package. Cloud observations are the total cloud fraction from ISCCP (60°S–60°N), MISR (60°S–60°N and ocean-only), and CALIPSO, the cloud phase partition between liquid and ice from CALIPSO, and the shortwave and longwave cloud radiative forcing (SWCF and LWCF) from CERES-EBAF. Averages between 2000 and 2014 are used for the model-data comparison, except for the CALIPSO cloud fraction that is averaged between 2008 and 2020.

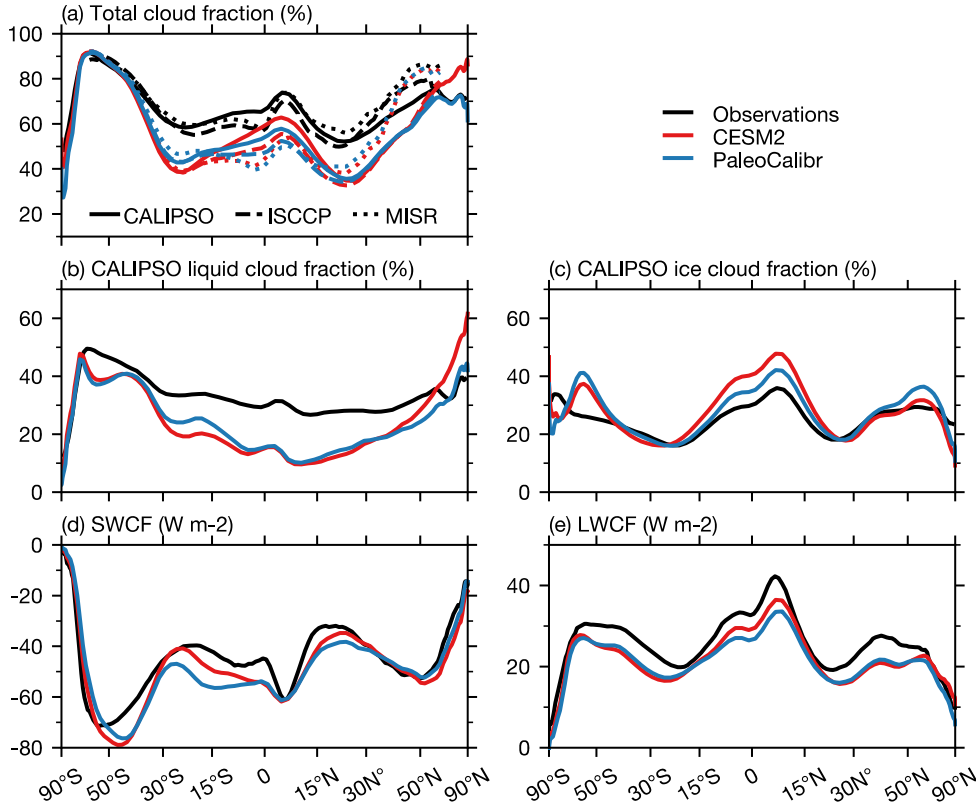

Figure 9. Comparison of model simulations against (a) the zonal mean total cloud fraction in CALIPSO, ISCCP, and MISR, (b) the CALIPSO liquid cloud fraction, (c) the CALIPSO ice cloud fraction, (d) the CERES-EBAF shortwave cloud forcing (SWCF), and (e) the CERES-EBAF longwave cloud forcing (LWCF). Model variables are from AMIP historical simulations with an active Cloud Feedback Model Intercomparison Project Observational Simulator Package. Averages between 2000 and 2014 are used for the model-data comparison, except for the CALIPSO cloud fraction and phase partition that are averaged between 2008 and 2020. ISCCP and MISR cloud fraction is plot between 60°S and 60°N. MISR cloud fraction values are over ocean only.

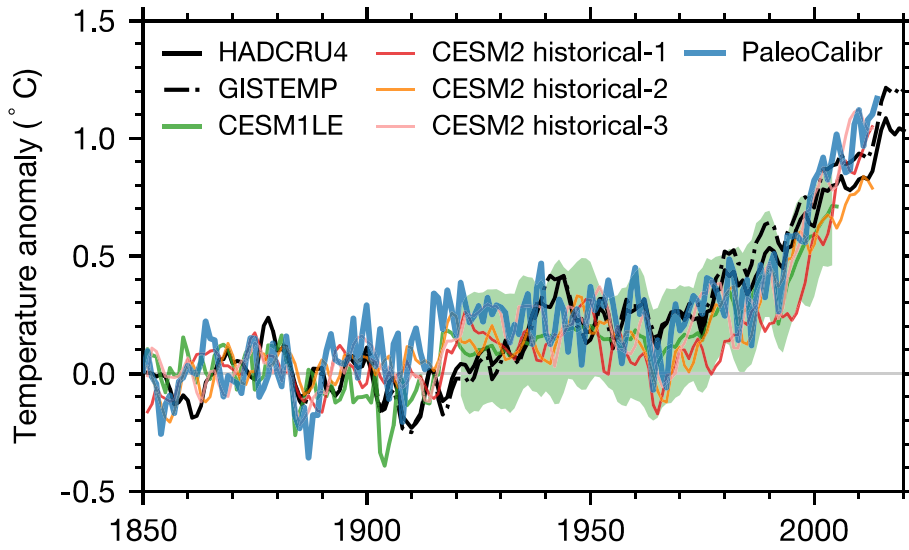

Figure 10. Time series of the global mean surface temperature anomaly during the historical period from observations (black), the CESM2 historical simulations using CAM6 (three members in red, orange, and pink), and the paleoclimate-calibrated configuration (PaleoCalibr; blue). Results from the CESM1 Large Ensemble (CESM1LE; green) are shown as a reference for a possible range of internal variability. The observations are from the HADCRU4 and GISTEMP. Temperature anomalies are calculated from the respective 1850–1900 averages.

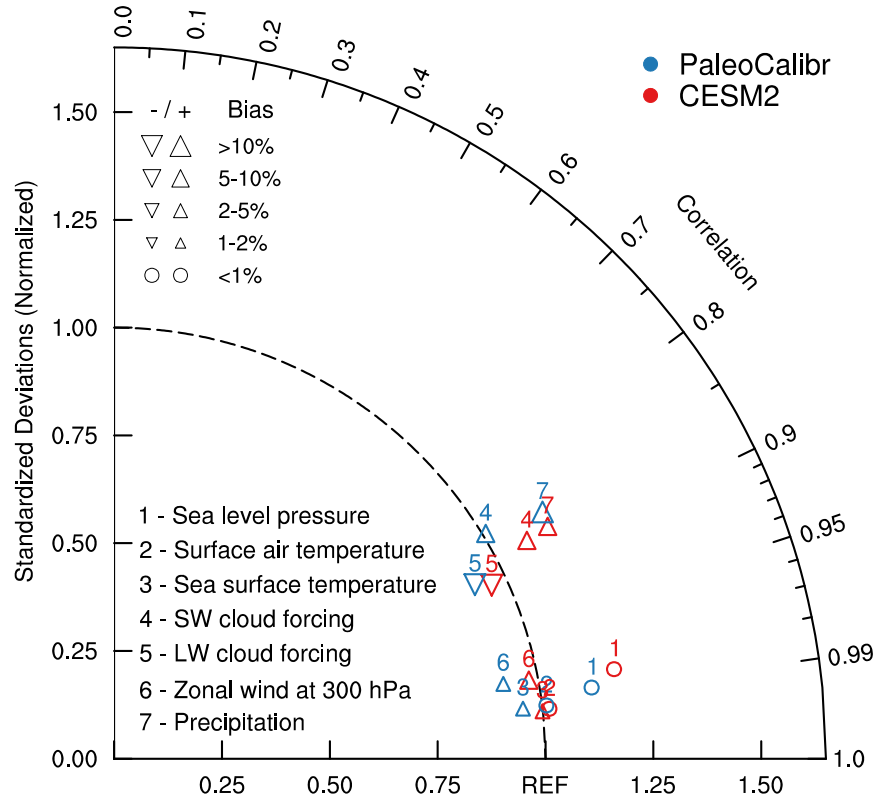

Figure 11. A Taylor diagram evaluating key climate variables in CESM2 and PaleoCalibr coupled historical simulations using observational and reanalysis datasets. Model simulated sea level pressure, surface air temperature, and zonal wind at 300 hPa are compared with averages between 1979 and 2014 from ERA5, shortwave and longwave cloud radiative forcing compared with averages between 2000 and 2014 from CERES-EBAF, precipitation compared with averages between 1979 and 2014 from GPCP, and sea surface temperature compared with averages between 1979 and 2014 from ERSST.

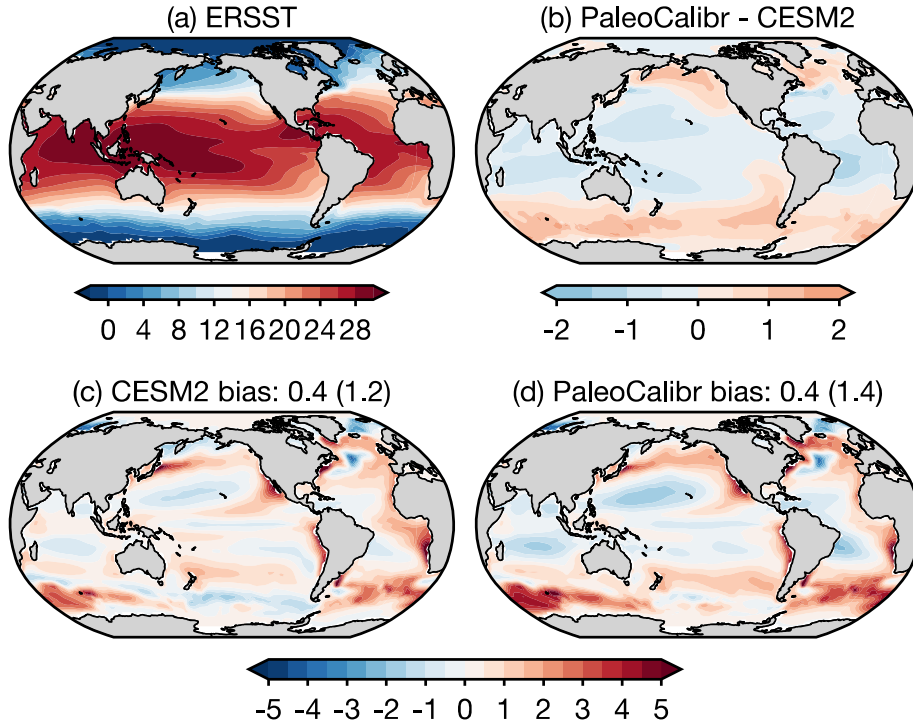

Figure 12. (a) Sea surface temperature (SST; units: °C) averaged between 1979 and 2014 CE in observations. (b) Difference in SST between the historical simulations using PaleoCalibr and CESM2. (c) Difference in SST between the historical simulation using CESM2 and observations. (d) as (c) but in the historical simulation using *PaleoCalibr*. Numbers in (c) and (d) are the global mean model bias and the area-weighted root-mean-squared error (in parentheses).

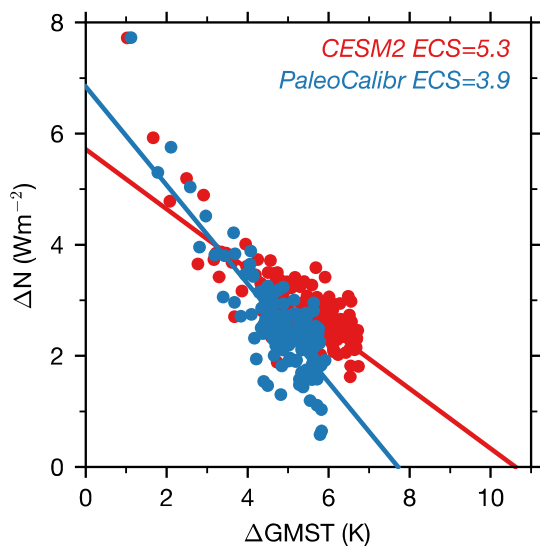

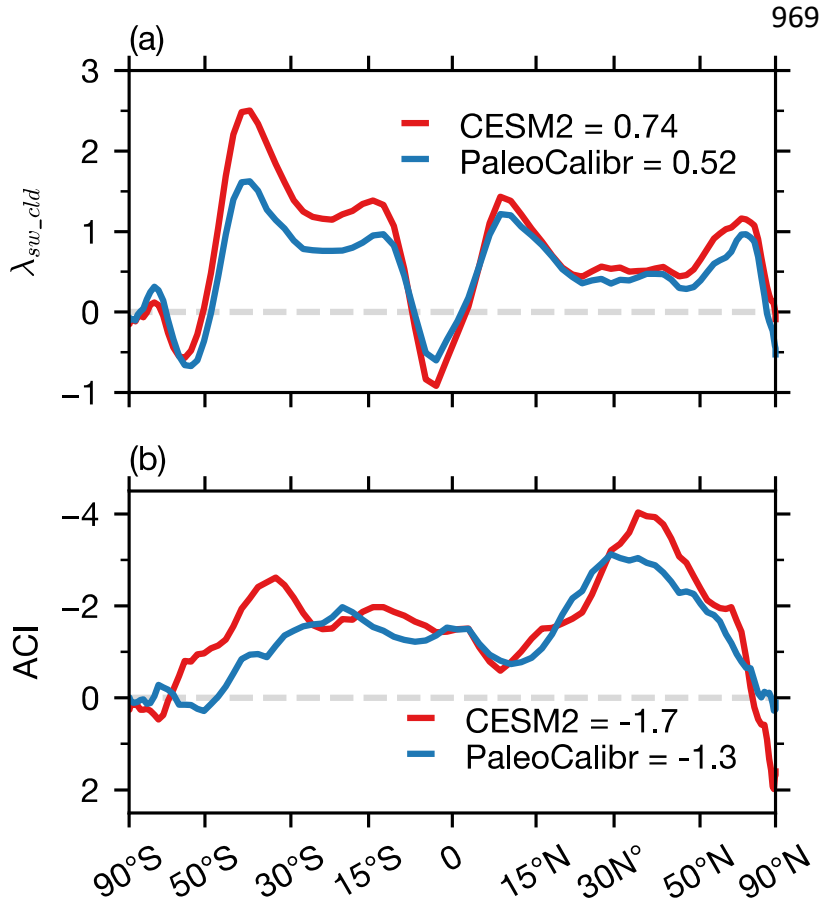

Figure 13. Scatter plot of the global mean surface temperature anomaly (ΔGMST) and the top-of-atmosphere net radiation (ΔN) in the abrupt $4\times\text{CO}_2$ simulations using CESM2 and PaleoCalibr. $4\times\text{CO}_2$ simulations are run for 150 model years. Equilibrium Climate Sensitivity (ECS) is estimated using the regression method, i.e., a half of the x-axis intercept.
