Abstract

This work documents the ICON-Earth System Model (ICON-ESM V1.0), the first coupled model based on the ICON (ICOsa-hedral Non-hydrostatic) framework with its unstructured, isosahedral grid concept. The ICON-A atmosphere uses a nonhydrostatic dynamical core and the ocean model ICON-O builds on the same ICON infrastructure, but applies the Boussinesq and hydrostatic approximation. The oceanic carbon cycle and biogeochemistry is represented by the HAMOCC6 module and the terrestrial biogeophysical and biogeochemical process are integrated in the new JSBACH4 module.

We describe the tuning and spin-up of a base-line version at a resolution typical for models participating in the Coupled Model Intercomparison Project (CMIP). The performance of ICON-ESM is assessed by means of a set of standard CMIP6 simulations. Achievements are well-balanced top-of-atmosphere radiation, stable key climate quantities in the control simulation, and a good representation of the historical surface temperature evolution. The model has overall biases, which are comparable to those of other CMIP models, but ICON-ESM performs less well than its predecessor, the MPI-ESM. Problematic biases are diagnosed in ICON-ESM in the vertical cloud distribution and the mean zonal wind field. In the ocean, sub-surface temperature and salinity biases are of concern as is a too strong seasonal cycle of the sea-ice cover in both hemispheres. ICON-ESM V1.0 serves as a basis for further developments that will take advantage of ICON-specific properties such as spatially varying resolution, and coupled configurations at very high resolution.

Key Points:

- This work documents ICON-ESM 1.0, the first version of a coupled model based on the ICON framework
- Performance of ICON-ESM is assessed by means of CMIP6 DECK experiments at standard CMIP-type resolution
- ICON-ESM features good performance in the stability of TOA radiation balance and reproduces the observed temperature evolution. Biases in clouds, winds, sea-ice, and ocean properties are somewhat larger than in MPI-ESM at similar resolution.

Abstract

This work documents the ICON-Earth System Model (ICON-ESM V1.0), the first coupled model based on the ICON (ICOsahedral Non-hydrostatic) framework with its unstructured, isosahedral grid concept. The ICON-A atmosphere uses a nonhydrostatic dynamical core and the ocean model ICON-O builds on the same ICON infrastructure, but applies the Boussinesq and hydrostatic approximation. The oceanic carbon cycle and biogeochemistry is represented by the HAMOCC6 module and the terrestrial biogeophysical and biogeochemical process are integrated in the new JSBACH4 module. We describe the tuning and spin-up of a base-line version at a resolution typical for models participating in the Coupled Model Intercomparison Project (CMIP). The performance of ICON-ESM is assessed by means of a set of standard CMIP6 simulations. Achievements are well-balanced top-of-atmosphere radiation, stable key climate quantities in the control simulation, and a good representation of the historical surface temperature evolution. The model has overall biases, which are comparable to those of other CMIP models, but ICON-ESM performs less well than its predecessor, the MPI-ESM. Problematic biases are diagnosed in ICON-ESM in the vertical cloud distribution and the mean zonal wind field. In the ocean, sub-surface temperature and salinity biases are of concern as is a too strong seasonal cycle of the sea-ice cover in both hemispheres. ICON-ESM V1.0 serves as a basis for further developments that will take advantage of ICON-specific properties such as spatially varying resolution, and coupled configurations at very high resolution.

Plain Language Summary

ICON-ESM is a completely new coupled climate and earth system model that applies novel design principles and numerical techniques. This article describes how the component models for atmosphere, land, and ocean are coupled together and how we achieve a stable climate by setting certain tuning parameters and performing sensitivity experiments. We evaluate the performance of our new model by running a set of experiments under pre-industrial and historical climate conditions as well as a set of idealized greenhouse-gas-increase experiments. These experiments were designed by the Coupled Model Intercomparison Project (CMIP) and allow us to compare the results to those from other CMIP models and the predecessor of our model, the Max Planck Institute for Meteorology Earth System Model. While we diagnose overall satisfying performance, we find that ICON-ESM features somewhat larger biases in several quantities compared to its predecessor at comparable grid resolution. We emphasize that the present configuration serves as a basis from where future development steps will open up new perspectives in earth system modelling.

1 Introduction

ICON-ESM (V1.0) is the first release of a new Earth System Model that is developed at the Max Planck Institute for Meteorology (MPI-M). It is based on the ICON framework, a joint development of MPI-M, the German Weather Service (Deutscher Wetterdienst, DWD), the Karlsruhe Institute for Technology, and other partner institutions in Germany and Switzerland. ICON-ESM combines the ocean ICON-O (Korn, 2017) and atmosphere ICON-A (Giorgetta et al., 2018) components of the ICON modelling system together with ICON-Land, including JSBACH 4, a complete re-write of the land model JSBACH 3 (Reick et al., 2021, 2013), and the ocean biogeochemistry module HAMOCC6 (Ilyina et al., 2013). The ocean and atmosphere are coupled using the newly developed coupling software Yet Another Coupler (YAC; Hanke et al., 2016). ICON stands for ICOsahedral Nonhydrostatic, where the latter is only realized for the atmosphere component.

At MPI-M, ICON-ESM succeeds the well-established Max Planck Institute for Meteorology Earth System Model (MPI-ESM; Mauritsen et al., 2019) with its component models for the atmosphere ECHAM6 (Stevens et al., 2013) and the ocean MPIOM (Jungclaus

77 et al., 2013), the land model JSBACH 3 (Reick et al., 2013, 2021), and the ocean bio-
 78 geochemistry module HAMOCC (Ilyina et al., 2013). Together with its predecessors, MPI-
 79 ESM1.2 has represented three decades of successful model development (see Mauritsen
 80 and Roeckner (2020)). The development of a completely new model system is an answer
 81 to the requirement for increasing resolution, the need for conservation for the represen-
 82 tation of chemical tracers in the atmosphere, and for excellent scalability at high-performance
 83 computers (HPC). While these properties of ICON-ESM will be most beneficial in very
 84 high-resolution coupled configurations, we present here, as a first step to introduce ICON-
 85 ESM to the scientific community, the physical model at a resolution that can be called
 86 “standard” in the context of climate simulations for the ongoing Coupled Model Inter-
 87 comparison Project (CMIP6, Eyring et al. (2016)). We focus on a set-up with 158 km
 88 grid spacing in ICON-A and 40 km in ICON-O. Focusing on experiments in climate mode,
 89 i.e. at least century-long simulations with parameterized physics, the set-up described
 90 here offers an efficient configuration for simulations of past, present and future climates,
 91 and large ensembles. It also forms the basis for higher-resolution versions as well as for
 92 configurations using specific properties of the ICON system, for example grid refinement
 93 in ICON-O (Logemann et al., 2021) or nesting in ICON-A (Klocke et al., 2017). In this
 94 manuscript, we present the first results of ICON-ESM and provide an examination of
 95 the model characteristics in a set of experiments following the CMIP6 Diagnosis, Eval-
 96 uation, and Characterization of Klima (DECK) protocol and include an ensemble of five
 97 CMIP6 “historical” simulations (Eyring et al., 2016). We compare and evaluate the sim-
 98 ulations with observations and reanalysis data as well as other CMIP6 models and MPI-
 99 ESM.

100 Typically, model tuning happens initially at the component model level (Giorgetta
 101 et al. (2018), Korn P. et al., ”ICON-O: The ocean component of the ICON Earth Sys-
 102 tem Model - global simulation characteristics and local telescoping capability”). Cou-
 103 pled together, the completely new ICON components for ocean, sea-ice, land and atmo-
 104 sphere repeatedly revealed unexpected behavior that required detailed investigations and
 105 major tuning efforts, which we partly describe in this manuscript (section 3). In the fol-
 106 lowing, we provide information on the general circulation models for atmosphere and ocean,
 107 the land and sea-ice components, the ocean biogeochemistry module, and the coupler.
 108 Then we describe the spin-up and tuning of the coupled system that has led to the pre-
 109 industrial control simulation (piControl) under constant forcing agents. Evaluation in
 110 comparison with observations and reanalyses data is based on the last decades of a small
 111 ensemble of CMIP6 historical simulations and the model’s climate sensitivity character-
 112 istics are assessed in idealized global warming experiments (i.e., the 1%CO₂ yr⁻¹ increase
 113 experiment (1pctCO2) and the experiment with an abrupt four-fold CO₂ concentration
 114 (abrupt4xCO2)). We discuss tuning choices in section 5 and end with a summary and
 115 conclusion (section 6).

116 2 Model overview

117 The ICON model system (Zängl et al., 2015) provides common infrastructure (e.g.
 118 grid construction and output handling) and, in part, common numerical operators for
 119 the component models. A common feature is the basic grid construction based on un-
 120 structured, icosahedral grids. The grids for both the ICON-A and ICON-O model are
 121 created by recursively dividing the original twenty triangles of the icosahedron. This is
 122 done by bisecting the edges. The vertices at each step are projected at the Earth sphere.
 123 The primary cells are triangles, while the dual cells are hexagons, except for the orig-
 124 inal twelve pentagons of the icosahedron which remain. A detailed description of the pro-
 125 cess is given in H. Wan et al. (2013) and Giorgetta et al. (2018). The spring dynamics
 126 optimization is applied on both grids, as described in Tomita et al. (2001) and Tomita
 127 et al. (2002). The grids are symmetrized with respect to the equator by reflecting the
 128 northern hemisphere to the south. The equatorial-symmetric grid has been tested with

129 the ICON-O for shallow water set-ups and showed reduced errors (Korn & Linardakis,
 130 2018). Local asymmetries in grids can be the cause of increased numerical errors (Weller
 131 et al., 2009). For the icosahedron, these asymmetries occur most profoundly in the vicinity
 132 of the pentagons (Korn & Linardakis, 2018). It is desirable to keep these “hot” spots
 133 away from areas where large velocities may occur, for example due to the orography. There-
 134 fore the grid was rotated 37° eastwards, to avoid placing a pentagon over the Himalaya
 135 region. In the set-up presented here, the resolution for the ICON-A grid is 158 km, mea-
 136 sured as the square root of the average triangle area, with a total of 20480 triangles (the
 137 R2B4 grid in Table 1 of Giorgetta et al. (2018)). The ICON-O grid has an average res-
 138 olution of 40 km and 235403 triangles, the land triangles being removed to reduce mem-
 139 ory and computing resources. The bathymetry was interpolated from the SRTM3 PLUS
 140 dataset (Becker et al., 2009), adjusted to conform with the sea-land mask given by the
 141 GLCC 2.0 dataset (Global Land Cover Characterization (GLCC), doi:10.5066/F7GB230D).
 142 The ICON-O sea-land mask is then projected to the coarser ICON-A grid, allowing for
 143 triangles to be partially ocean.

144 The numerical schemes of the atmosphere and the ocean share commonalities but
 145 feature also significant differences. Identical in both components is the spatial discretiza-
 146 tion of differential operators such as divergence and curl through mimetic methods (cf.
 147 Korn (2017)). This takes advantage of identical grid structures and the staggering of vari-
 148 ables. The staggering necessitates reconstructions and interpolations to connect variables
 149 that are located at different grid positions to calculate fluxes. This is accomplished in
 150 ICON-O by the novel concept of *Hilbert space admissible reconstructions* (for details see
 151 Korn (2017), Korn and Linardakis (2018)). In contrast, ICON-A relies on several inter-
 152 polation methods (see Zängl et al. (2015)).

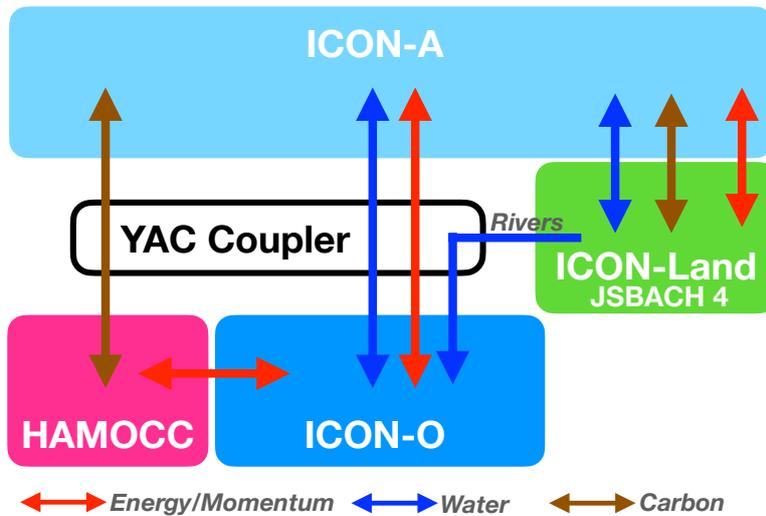

Figure 1. Schematic representation of the model components of the ICON-ESM and the coupling scheme.

153 2.1 Atmosphere

154 The atmosphere component of the ICON-ESM is the icosahedral nonhydrostatic
 155 atmospheric general circulation model ICON-A. The model version used here is similar
 156 to version 1.3.00 described in detail by Giorgetta et al. (2018), which was evaluated by
 157 Crueger et al. (2018). Modifications with respect to this earlier version are described be-

low. The dynamical core of the model (Zängl et al., 2015) and the transport scheme are shared with a configuration used for numerical weather prediction (NWP) at the DWD. Other variants of the ICON atmosphere model include the option to interactively couple to the Aerosol and Reactive Trace gases scheme ART (Rieger et al., 2015) and a configuration including the upper atmosphere (UA-ICON, Borchert et al., 2019). The excellent scaling capabilities of ICON have enabled global storm-resolving simulations down to a horizontal grid resolution of about 2.5 km (Stevens et al., 2019).

The model configuration used here differs from the NWP variant in particular with respect to the physics package, which was adopted from the ECHAM6 general circulation model (Stevens et al., 2013) used in the MPI-ESM (Giorgetta et al., 2013; Mauritsen et al., 2019). The physics parameterizations include the PSrad radiation scheme of Pincus and Stevens (2013), a scheme for turbulent vertical diffusion based on a total turbulent energy approach as proposed by Mauritsen et al. (2007), a convection parameterization based originally on the Tiedtke (1989) mass flux scheme, a parameterization for the representation of stratiform clouds including microphysics based on a scheme by Lohmann and Roeckner (1996) and cloud cover diagnosed following Sundqvist et al. (1989), a representation of the effects of gravity waves and blocking from sub-grid scale orography following Lott (1999), and the Hines (1997) parameterization of the effects of non-orographic gravity waves. Adaptations of the original ECHAM parameterization schemes for the use in ICON-A are described by Giorgetta et al. (2018). As in the latter publication, we are using ICON-A here with a horizontal grid resolution of 158 km. In the vertical, the model employs a terrain following hybrid sigma-height grid with 47 layers extending to a model lid at 83 km.

Compared to the ICON-A version 1.3.00 described by Giorgetta et al. (2018) the following modifications have been made. (A) The coupling of the physical processes has been serialized completely using the following sequence: (1) radiative effects by terrestrial longwave and solar shortwave radiation, (2) vertical diffusion with implicitly coupled land surface processes, (3) non-orographic gravity wave drag, (4) subgrid-scale orographic (SSO) effects, (5) cumulus convection, and (6) cloud microphysics. This improved the numerical stability and allowed to increase the model time step from 10 to 15 minutes. Further, the time step for radiation, the only process not computed at every model time step, was shortened from 120 to 90 minutes. (B) The non-orographic gravity wave and SSO effects were re-tuned. Here, new SSO parameters for the statistical description of the unresolved terrain were used, which resolve both issues discussed in section 4.7.1 of Giorgetta et al. (2018), i.e. the error in the azimuthal angle of the unresolved mountains, and the standard deviation of unresolved orographic height, which is now computed with respect to the resolved sloped terrain. Further, a weighting factor for the non-ocean fraction has been introduced to account for the fact that the SSO parameters are computed for the area fraction that is land or lake or glacier, i.e. non-oceanic. And (C) the physical processes were re-tuned for a balanced top-of-atmosphere (TOA) radiation balance and in order to minimize the systematic errors in AMIP simulations.

In step (B), tuning parameters (see Table 1) G , which scales the magnitude of the orographic gravity wave drag, and C_d , which scales the blocking of low-level flow by unresolved orography, were tested with values in the range of 0.01 to 1 with the following goals: The first target was to reduce the systematic error in zonal mean zonal wind in DJF at 60° N at 10 hPa. The secondary target was then to minimize errors in the zonal mean zonal wind in JJA as well as errors in annual mean pressure at sea level and annual mean zonal wind stress at the ocean surface. This led to new default parameters $G = 0.05$ and $C_d = 0.05$, instead of $G = 0.10$ and $C_d = 0.01$ (Giorgetta et al., 2018). The tuning parameters for the non-orographic gravity wave drag remained as in Giorgetta et al. (2018).

In step (C) a range of tests was conducted with modifications in tuning parameters for fractional cloud cover, entrainment of environmental air in convective plumes,

211 overshooting mass flux fraction at the top of convection, and cloud microphysics. From
 212 all tests a configuration with three modifications was chosen, compared to Giorgetta et
 213 al. (2018): The entrainment coefficients for deep and shallow convection were set to $\epsilon_{shallow} =$
 214 $\epsilon_{pen} = 0.0003 \text{ m}^{-1}$, and the convective mass flux fraction across the level of neutral buoy-
 215 ancy at the top of convection was reduced to $c_{mfctop} = 0.1$. This configuration performed
 216 best following a similar evaluation as presented in Giorgetta et al. (2018). However, it
 217 should be noted that other tested configurations were equally acceptable concerning the
 218 radiation balance at the top of the atmosphere, which was the primary tuning goal.

219 The resulting atmospheric model configuration provided the starting point for the
 220 development of the coupled model system in the pre-industrial control experiment, which
 221 lead to additional changes of tuning parameters for dynamics as well as physics, as de-
 222 scribed in Section 3 and reviewed in the discussion section.

223 2.2 Ocean

224 ICON-O, the ocean general circulation model that provides the ocean component
 225 of ICON-ESM, solves the hydrostatic Boussinesq equations. These dynamical equations
 226 are also referred to as the “primitive equations”. The state vector consists of horizon-
 227 tal velocity, the oceanic tracers potential temperature and salinity, as well as the sur-
 228 face elevation, due to the free surface boundary condition. The primitive equations are
 229 solved on the triangular ICON grid with an Arakawa C-type staggering that places trac-
 230 ers at the circumcenter of a triangular cell and the normal component of the velocity vec-
 231 tor at the midpoint of the cells edge. The vertical coordinate-axis is given by the z-coordinate
 232 (or geopotential height). The two-dimensional triangles are simply extended by a height-
 233 based dimension. This generates three-dimensional prisms. The number of vertical lev-
 234 els depends on the topography and varies from cell to cell $N_z = N_z(K)$. The thickness
 235 of the prisms is constant, except for the surface layer, where the sea surface elevation is
 236 taken into account. Alternative vertical coordinates such as the z^* -coordinate are avail-
 237 able in ICON-O and are described in Sing and Korn, manuscript in preparation ”A structure-
 238 preserving discretization of ocean models in generalized vertical coordinates”. In the work
 239 presented here we use z-coordinates as the classical choice with well-understood advan-
 240 tages and disadvantages.

241 The subgrid scale closure for velocity uses a biharmonic operator based on the vec-
 242 tor Laplacian with a viscosity coefficient that scales with the square root of edge length
 243 times cell center distance to the third power. Eddy-induced diffusion and eddy-induced
 244 advection are parameterized following Redi (Redi, 1982) and Gent-McWilliams (GM)
 245 (P. Gent & McWilliams, 1990), respectively. We employ the variational approach of Griffies
 246 et al. (1998) and Griffies (1998). The discretization of the variational approach is, how-
 247 ever, different from the triad approach of Griffies et al. (1998) and uses inherently un-
 248 structured grid methods. The Hilbert-space-compatible reconstructions and mimetic dif-
 249 ferential operators of ICON-O’s dynamical core provide a discrete Hilbert space that al-
 250 lows a direct and structure-preserving discretization of the eddy parameterization. Full
 251 details are given in Korn (2018). Since the 40km ocean grid used here is barely eddy-
 252 permitting, we keep the GM scheme switched on using a default eddy diffusivity param-
 253 eter of $400 \text{ m}^2 \text{ s}^{-1}$.

254 As equations of state that approximates the density as a function of potential tem-
 255 perature, salinity and depth we use the UNESCO-80 formulation. For the parameter-
 256 ization of turbulent vertical mixing, ICON-O offers different choices: a Richardson-number-
 257 dependent parameterization (Pacanowski & Philander, 1981) (PP) including an addi-
 258 tional wind-mixing formulation as in MPIOM, the KPP scheme (Large et al., 1994), or,
 259 as the standard setting used here, a scheme based on a prognostic equation for turbu-
 260 lent kinetic energy (TKE) that implements the closure suggested by Gaspar et al. (1990).
 261 Vertical dissipation and vertical diffusion are discretized implicitly. The transport of the

oceanic tracers potential temperature and salinity uses a flux-corrected transport method with a Zalessak limiter that utilizes flux calculation by compatible reconstructions (Korn, 2017).

The sea-ice model consists of a dynamic and a thermodynamic component. The thermodynamics of sea-ice describe the freezing and melting of sea-ice by a single-category, zero-layer formulation (Semtner, 1976). The sea-ice dynamics are based on the sea-ice dynamics component of the Finite Element Sea Ice Model (FESIM, (Danilov et al., 2016)), which uses the standard elastic-viscous-plastic (EVP) formulation. As ICON-O applies an analogue of an Arakawa C-grid and FESIM uses an Arakawa A-grid type staggering, an interpolation between the ICON-O grid and the FESIM sea-ice dynamics is necessary. Furthermore, an additional rotation of the oceanic and atmospheric variables is required, because ICON-O uses local coordinates, whereas FESIM is based on rotated geographic spherical coordinates. Besides the computational overhead, the coupling between FESIM and ICON-O introduces numerical diffusion, e.g. at least three grid cell wide passages are required to allow a sea-ice transport. To overcome this limitations we are currently working on the integration of a newly developed sea ice dynamic model (Mehlmann & Korn, 2021).

ICON-O's time stepping applies a semi-implicit Adams-Bashford-2 scheme. The free surface equation is solved implicitly in time with an iterative solver based on the conjugated gradient method. The remaining state variables are discretized explicitly. For details we refer to Korn (2017).

2.3 Ocean Biogeochemistry

In ICON-ESM, ocean biogeochemistry is represented by the HAMburg Ocean Carbon Cycle module, HAMOCC6, which simulates biogeochemical tracers in the water column and in the upper sediment (Ilyina et al., 2013; Paulsen et al., 2017; Mauritsen et al., 2019). In the water column, currently at least 20 biogeochemical tracers are prognostically calculated, generally following an extended nutrient, phytoplankton, zooplankton, and detritus (NPZD) approach, also including dissolved organic matter, as described in Six and Maier-Reimer (1996). The co-limiting nutrients consist of phosphate, nitrate, silicate and iron. A fixed stoichiometry for all organic compounds is considered. Phytoplankton is represented by bulk phytoplankton and diazotrophs (nitrogen fixers; Paulsen et al. (2017)). Particulate organic matter (POM) is produced by zooplankton grazing on bulk phytoplankton and enters the detritus pool. Export production is separated explicitly into CaCO_3 and opal particles, each sinking with its own sinking velocity. The POM sinking speed can be assigned using one of the three implemented methods: constant speed, linearly increasing speed with depths below the euphotic zone (also known as the 'Martin curve'; Martin et al. (1987)) or calculated using the recently developed M4AGO scheme (Maerz et al., 2020). The remineralization of detritus throughout the water column is either aerobic (if seawater oxygen concentration $> 0.5 \mu\text{molL}^{-1}$) or anaerobic by denitrification and sulphate reduction. The upper sediment is resolved by 12 biologically active layers and a burial layer and simulates the dissolution and decomposition of particulate inorganic and organic matter and the diffusion of pore water constituents. The HAMOCC model is also part of the MPI-ESM and has been extensively evaluated in previous single-model, e.g. Ilyina et al. (2013); Paulsen et al. (2017); Müller et al. (2018a); Mauritsen et al. (2019); Maerz et al. (2020) and multi-model studies, e.g. Bopp et al. (2013); Kwiatkowski et al. (2020); Séférian et al. (2020).

Within the HAMOCC core subroutines, only the biological and chemical sources and sinks, as well as tracer sinking and ascending are computed. Therefore, when implementing HAMOCC6 (a model version used in CMIP6 simulations) in ICON-ESM, the HAMOCC6 interface to the ocean and atmosphere components was adjusted to the ICON-ESM infrastructure accordingly. This adjustment includes the transport of bio-

313 geochemical tracers with the same routines and numerical schemes as the physical tracers
 314 of the ICON-O model. As in previous model versions, it was ensured that all chemical
 315 constituents in HAMOCC are mass conserving within computational precision in this
 316 implementation.

317 2.4 Land

318 ICON-Land is a novel framework developed at MPI-M for the modeling of land pro-
 319 cesses in ICON that clearly separates model infrastructure from land surface process de-
 320 scriptions. It features a flexible scheme of land surface tiling and object-oriented organ-
 321 ization of physical and biogeochemical processes. Apart from the ICON-ESM configu-
 322 ration, ICON-Land is used in the ICON-A atmosphere configuration and can also be run
 323 in a land stand-alone mode (see e.g. Nabel et al., 2020). The ICON-Land implementa-
 324 tion used in the ICON-ESM v1, comprises physical and biogeochemical processes pro-
 325 vided by the JSBACH 4 land model, a port of JSBACH 3.2 (Reick et al., 2021) to the
 326 ICON-Land framework. Previous JSBACH versions have been the land components of
 327 the MPI-ESM versions used in CMIP5 (Giorgetta et al., 2013) and CMIP6 (Mauritsen
 328 et al., 2019).

329 Comparing to Reick et al. (2021) JSBACH 4 features certain improvements of the
 330 physical processes at and below the surface, including a five-layer snow scheme and the
 331 phase change of water within the soil (Ekici et al., 2014; de Vrese et al., 2021). Also in-
 332 cluded are the options to calculate the soil thermophysical properties depending on the
 333 soil water content and the general properties depending on the organic matter content
 334 of a given soil layer. Surface runoff and sub-surface drainage from ICON grid cells are
 335 routed through a hydrologic discharge model (Hagemann & Dümenil, 1997) using a novel
 336 method for generating river directions (Riddick, 2021); the resulting river discharge is
 337 coupled as freshwater flux to the ocean via the YAC coupler (see section 2.5). Surface
 338 temperature of lakes is computed by a simple mixed-layer scheme including ice and snow
 339 on lakes (Roeckner et al., 2003). The surface energy balance and the soil thermal lay-
 340 ers on land are coupled implicitly to the vertical diffusion scheme of ICON-A.

341 Biogeochemical processes in JSBACH 4 in this study are simplified relative to JS-
 342 BACH 3 (Reick et al., 2021). Natural vegetation dynamics (Brovkin et al., 2009) cou-
 343 pled to land-use transitions (Reick et al., 2021), as well as the coupling of terrestrial car-
 344 bon and nitrogen cycle (Goll et al., 2017) have not yet been ported from JSBACH 3, how-
 345 ever, are partially planned to be ported for future ICON-ESM versions. In the piCon-
 346 trol and historical simulation ensemble (section 4), natural vegetation and anthropogenic
 347 land cover change have been prescribed by annual maps of cover fractions on these 11
 348 PFTs based on Pongratz et al. (2008) and transient crop and pasture fractions derived
 349 from LUH2 v2h (Hurtt et al., 2019) as described in Mauritsen et al. (2019).

350 2.5 Coupling

351 Ocean and atmosphere processes run concurrently and perform a parallel neigh-
 352 bourhood search and data exchange between the two horizontal grids via the YAC cou-
 353 pling library (Hanke et al., 2016). Fig 1. depicts a schematic view of the model compo-
 354 nents and the exchange of coupling fields.

355 Here, we use YAC version 1.5, which contains bug fixes and performance improve-
 356 ments. The components of the wind- and velocity vectors are interpolated using Bernstein-
 357 Bézier polynomials following Liu and Schumaker (1996). We use the interpolation stack
 358 of YAC and fill all target cells, which do not get any data with this standard interpo-
 359 lation, by applying a 4-nearest-neighbour arithmetic average interpolation. The river dis-
 360 charge is remapped to the target grid in a way that each source cell containing a river
 361 discharge value is assigned to a coastal target cell on the ocean grid. All other fields are

362 interpolated using 1st-order conservative remapping. The grids and masks are constructed
363 in a way that all source cells are covered with this standard interpolation. The calcu-
364 lation of the neighbourhood-relations and the interpolation stencils is performed by YAC
365 repeatedly during the initialisation of each model run, solely based on geographical lo-
366 cations of grid cell vertices and centers.

367 The atmosphere component provides the zonal and meridional components of the
368 wind-stress separately over ice and over water, the surface fresh water flux as rain and
369 snow over the whole grid cell and evaporation over the ocean fraction of the cell, short-
370 and longwave radiation and latent and sensible heat fluxes over the ocean, sea ice sur-
371 face and bottom melt potentials, the 10 m wind speed and sea level pressure. The ocean
372 provides the sea surface temperature, the zonal and meridional components of velocity
373 at the sea surface as well as ice- and snow thickness, and ice concentration. The data
374 exchange encompasses aggregation, averaging and re-partitioning of the exchange fields.
375 YAC routines are called at every model time step, and data are accumulated inside the
376 YAC library. At user-defined coupling events - here every 1800 seconds - data are av-
377 eraged and sent to the respective receiving processes.

378 **2.6 Computational configuration and performance**

379 All simulations were performed with the bullx DLC 720 high performance comput-
380 ing system for Earth system research (HLRE-3) of the “Deutsches Klimarechenzentrum”
381 (DKRZ). The simulations utilize 120 “Broadwell” compute nodes of the system named
382 “Mistral”, which include 36 processing units each.

383 The domain decomposition is performed separately for ocean and atmosphere: the
384 ocean decomposition at 40 km horizontal resolution, which includes only ocean grid points,
385 and the global atmosphere decomposition of 158 km horizontal resolution. The sea-ice
386 model is included in the ocean code and runs on the ocean grid, the land model works
387 within the atmospheric decomposition. The YAC coupling library is linked to each of
388 the two components of the ICON model (atmosphere/land and ocean/sea-ice) and per-
389 forms the aggregation, averaging and re-partitioning of the exchange fields using their
390 respective decomposition.

391 Due to this technical setup, the load balancing has to be optimized for these two
392 major components, only. The heavy workload due to multiple tracers in configurations
393 with HAMOCC requires different weightings for run with and without ocean biogeochem-
394 istry. The best compromise between shortest return time and parallelization overhead
395 was obtained for a load balancing of 74 nodes (2664 mpi-processes) for running ocean
396 and sea-ice (without HAMOCC) on the 40 km grid and concurrently using 46 nodes (1656
397 mpi-processes) for atmosphere and land on the 158 km grid. With this configuration we
398 achieve an average performance of ten simulation years in one batch-job executing within
399 roughly two hours. Without any queuing-time at the machine (depending on the load
400 of the machine, or by assigning high-priority to the job-chain) it results in a performance
401 of 120 simulated years per day. A hybrid configuration using mpi- as well as openmp-
402 (shared memory) parallelization was tested and exhibited less performance on the DKRZ
403 machine, which is probably due to partly missing optimizations in the code. In the runs
404 including HAMOCC, the best optimization was achieved for a load balancing of 46 nodes
405 for atmosphere and land and 154 nodes for the ocean (physics and biogeochemistry) and
406 sea ice. An average performance of 40 simulated years per day was achieved with this
407 configuration.

3 Tuning and spin-up

3.1 Tuning principles and targets

Model tuning is an integral part of the model development process (Mauritsen et al., 2012). In the coupled system, a first-order tuning goal is to achieve stable climate conditions to minimize drifts in the piControl climate used as reference for climate change simulations. A near-zero top-of-atmosphere energy-flux balance is required as well as long-term stable circulation, for example the Atlantic Meridional Overturning Circulation (AMOC) in the ocean. Furthermore, it is desired to match the model results with observed climate conditions, for example a global mean surface air temperature close to the observational estimates for the second half of the 19th century. Based on experience gained in the tuning of the stand-alone ocean and atmosphere set-ups (Giorgetta et al., 2018), a small number of parameters associated with the parameterization of specific processes were selected for tuning. In the atmosphere these are mainly related to cloud properties and to subgrid-scale orographic processes. Parameters modified for tuning purposes in the ocean include the value of biharmonic viscosity, parameters in the TKE mixing scheme, and the isoneutral diffusion and eddy diffusivity coefficients in the Gent-McWilliams closure (Korn, 2018). Apart from albedo settings in the atmosphere, the sea-ice tuning parameters determine the change in ice-thickness distribution during melting and freezing, respectively (Notz et al., 2013; Mauritsen et al., 2012).

The tuning parameters used in the initial sensitivity experiment and the final spin-up are listed in Table 1.

Table 1. Parameters used for tuning.

ICON Parameter	Symbol in reference	Reference	Description
<i>Atmosphere</i>			
crs	$r_{0,surf}$	Giorgetta et al. (2018)	critical relative humidity for condensation (surface)
crt	$r_{0,top}$	Giorgetta et al. (2018)	critical relative humidity for condensation (upper troposphere)
entrpen	ϵ^1	Nordeng (1994)	entrainment in deep convection
gkdrag	G	Lott (1999)	subgrid-scale orographic (SSO) gravity wave drag
gkwake	C_d	Lott (1999)	SSO low-level blocking
gklift	C_1	Lott (1999)	SSO lifting
<i>Ocean</i>			
K	K	Korn (2018)	GM isoneutral diffusion
κ	κ	Korn (2018)	eddy diffusivity
<i>sea ice</i>			
leadclose 1	cmelt	Notz et al. (2013)	ice area change during melting
leadclose 2/3	cfreeze	Notz et al. (2013)	ice area change during freezing

3.2 Spin-up and tuning history

The ocean initial conditions for temperature and salinity were taken from the Polar Science Center Hydrographic Climatology data set (Steele et al., 2001). First, a 200-year long stand-alone ICON-O simulation was carried out using the atmospheric climatology forcing and the respective bulk formulae described in Marsland et al. (2003). Starting from the restart fields obtained from the stand-alone ocean simulation, several experiments with different tuning choices were conducted, partly sequentially with parameter changes on the fly, partly in parallel to study difference in drift behavior. The final tuning sequence is documented in Fig. 2.

The start of the coupled simulation (slo1304) is characterized by a large drift, where both atmosphere and ocean are cooling and the TOA radiation balance is negative (not shown). Introducing background tropospheric aerosols in the run slo1307 led to even stronger

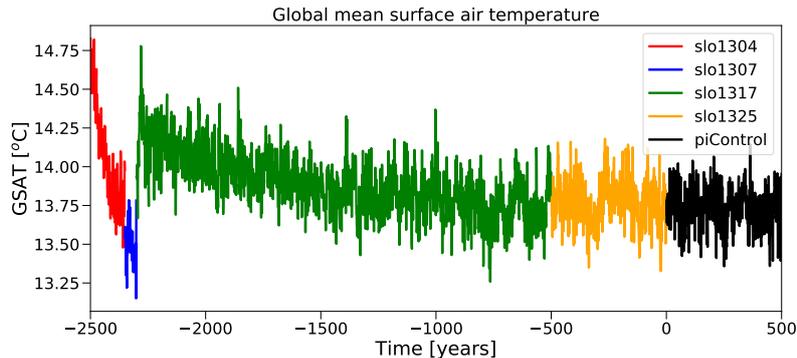

Figure 2. Spin-up history of the coupled simulation: time series of global mean surface air temperature from a sequence of simulations leading to the piControl experiment.

441 decrease in GSAT that required counter-tuning. This was achieved by increasing the crit-
 442 ical relative humidities for condensation crs and crt and the entrainment parameter $entrpen$
 443 which led in particular to a reduction of global mean cloud fraction and an increase of
 444 net incoming radiation at the TOA. While this resulted initially in overly strong warm-
 445 ing, the long-term drift cooled the model to acceptable values and we finally obtained
 446 a solution with small overall drift. While this may appear as a very straightforward tun-
 447 ing process, a large number (order 100) of further model experiments with different pa-
 448 rameter settings and simulated lengths of a few years to several hundreds of years have
 449 been performed to arrive at this spin-up sequence. The influences of some of the tun-
 450 ing choices on the simulated climate are discussed in several parts of the model evalu-
 451 ation of Section 4 and in section 5.

452 A bug-fix related to erroneous snow accumulation in a few grid points required an
 453 update of the code in run slo1325 without noticeable effects on the climate. This simu-
 454 lation was carried out for another 500 years, where we defined the start of the piCon-
 455 trol simulation. The starting point of piControl was also used to initialize the DECK ex-
 456 periments 1pctCO2 and abrupt4xCO2, and one realization of the historical simulations.
 457 Further realizations were started from different dates of piControl. In addition, an AMIP
 458 simulation was included using the same code version as the coupled experiments.

459 After the completion of the DECK experiments presented in this paper, a coding
 460 error was detected in the vertical diffusion of ICON-A. The bug is related to the way ocean
 461 currents are taken into account in the wind-stress calculation. The effects of the error
 462 turned out to be time-step and grid-size dependent and had detrimental effects in a very
 463 high-resolution (5km) coupled proto-type model. At the low resolutions applied here,
 464 we were able to identify typical effects of this error (e.g. some changes in the represen-
 465 tation of the equatorial current system in the ocean), but most of the analyzes and il-
 466 lustrations presented here remain largely unaffected. The most notable effect is an even
 467 stronger variance of the ENSO time series, but we diagnosed otherwise very similar char-
 468 acteristics of the variability (not shown). We have concluded that the bug must be fixed
 469 but changes to the results were too minor to justify a repetition of the DECK experi-
 470 ments and their post-processing. All conclusions regarding benefits and shortcomings
 471 of the ICON-ESM DECK simulations presented here remain unaffected.

472 The tuning of the ocean biogeochemistry was carried out after the tuning of the
 473 coupled setup. A first-order tuning goal for the ocean biogeochemistry in an ESM is to
 474 limit significant drifts in the biogeochemical tracer fields and fluxes in the piControl run.
 475 Furthermore, parameters are adapted within a reasonable range to drive the model closer
 476 to observations. In the first step of the tuning procedure, presented here, the focus is on

477 the upper ocean biogeochemical fields reflecting the representation of the chemical and
 478 biological processes in the model. The initial conditions for the biogeochemical tracer
 479 fields in the water column and sediment were interpolated from a previously well spun-
 480 up MPIOM piControl run. Ocean and atmosphere were initialized from the end of the
 481 slo1325 run and ICON-ESM was run with the piControl climate. The atmospheric CO₂
 482 concentration was set to 278 ppm, representing a pre-industrial climate. The dust de-
 483 position climatology of Mahowald et al. (2005) and historical nitrogen deposition fields
 484 from the CMIP6 input database (<https://esgf-node.llnl.gov/projects/input4mips/>) were
 485 used. The POM sinking speed was calculated based on the Martin curve.

486 To account for the ocean circulation simulated by ICON-ESM, some of the HAMOCC
 487 tuning parameters were changed from their default values. The appropriate weathering
 488 rates, which are used to compensate the loss of carbon and nutrients from the water col-
 489 umn to the sediment, were calculated and updated during the spin-up procedure. Af-
 490 ter a simulation length of 500 years, the model approached a semi-steady state in the
 491 upper ocean global monitoring values such as the global surface alkalinity, POM export
 492 and nutrients.

Table 2. Overview on the ICON-ESM simulations.

Experiment	Description	Period	Ens.size	Initialization
piControl	Preindustrial Control	500 years	1	spin-up run
1pctCO2	idealized CO ₂ -increase	150 years	1	spin-up run
abrupt4xCO2	idealized CO ₂ increase	150 years	1	spin-up run
historical	Transient forcing	1850-2014	5	piControl (yrs 0, 100, 200, 300, 400)
AMIP	atmosphere-only	1978-2014	1	n.a.

493 4 Model evaluation

494 The set of experiments described in this paper is listed in table 2. We start with
 495 a brief account of the piControl experiment. Since the evaluation in comparison with ob-
 496 servations is based on data from the recent decades, we base the analyzes on the histor-
 497 ical ensemble. The idealized climate change experiments 1pctCO2 and abrupt4xCO2 are
 498 used to estimate the climate sensitivity of ICON-ESM in section 4.4.

499 4.1 The pre-industrial control simulation (piControl)

500 The global mean surface air temperature (GSAT) is stable over the 500 year long
 501 piControl simulation with a small cooling of -0.01 K per century (Fig. 3). The time mean
 502 of 13.73°C is consistent with estimates of warming over the historical period and the es-
 503 timated global temperatures from reanalyses (Hawkins & Sutton, 2016). The goal of a
 504 very stable TOA radiation is achieved and only a small residual of less than 0.02 Wm⁻²
 505 assures that long-term integrations can be run with this model version. The AMOC is
 506 a key quantity for the meridional heat exchange in the Atlantic Ocean and its stability
 507 is important for maintaining a proper sea-ice distribution and North Atlantic deep wa-
 508 ter formation (for more details see section 4.2.5). The control run has a time-mean AMOC
 509 strength at 26°N of slightly less than 16 Sv ($1Sv = 1Sverdrup = 10^6 m^3 s^{-1}$). The AMOC
 510 is stable over the simulation, but exhibits relatively strong multidecadal variations with
 511 an amplitude of up to 3 Sv.

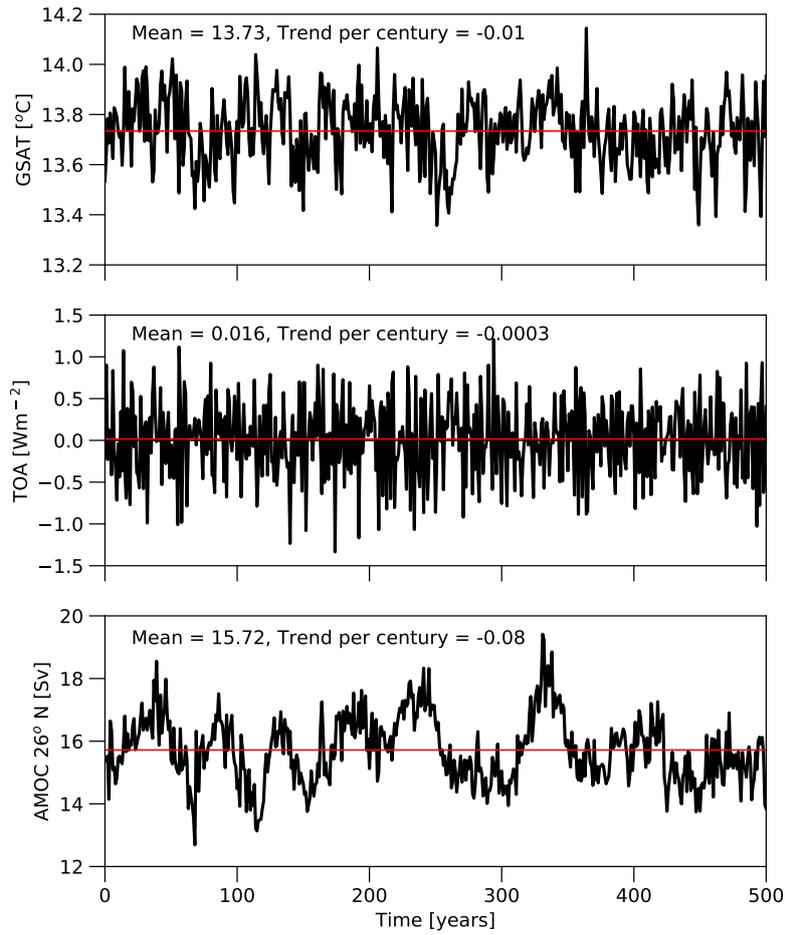

Figure 3. Evolution of key quantities during the piControl experiment: (upper) global mean surface air temperature, (middle) top-of-atmosphere radiation balance, and (lower) the strength of the Atlantic Meridional Overturning streamfunction at 26°N and 956m depth. Red lines indicate the time mean.

ICON-ESM reproduces the evolution of the global mean surface temperature largely in good agreement with observational products (Fig. 4). The mid-20th century warming and the subsequent cooling towards the 1970s agree in magnitude and timing, and the effects of volcanic eruptions like Agung (1963/64) and Pinatubo (1991) are captured. The simulations slightly disagree with the observational records in the late 20th to early 21st century because the model overestimates the warming trends from the 1970s onward. On the other hand, the warming trends are underestimated near the end of the simulation so that the simulated temperatures agree with the observations at the end of the simulated period. A decomposition into northern (Fig. 4b) and southern (Fig. 4c) hemispheres reveals that the deviations stem mainly from the northern hemisphere. Assessing the reason for this discrepancy requires further investigations but the more pronounced biases in the northern hemisphere point to an underestimation of the cooling effect of anthropogenic aerosols (Mauritsen et al., 2019) rather than too high climate sensitivity in ICON-ESM (see section 4.4).

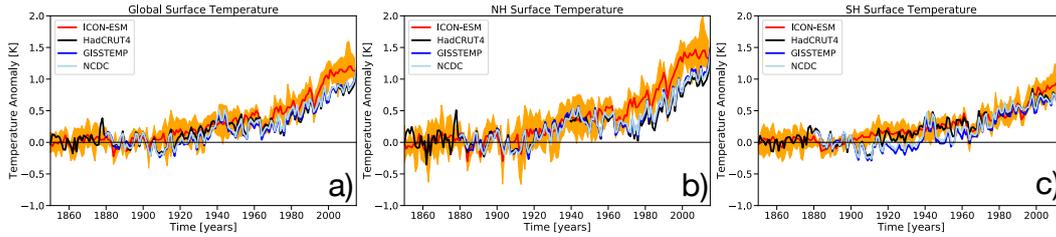

Figure 4. Time series of surface temperature over a) the globe, b) the northern hemisphere, and c) the southern hemisphere for (red-orange) the ICON-ESM historical ensemble, and observational compilations by (blue) the Goddard Institute for Space Studies Surface Temperature product (Lenssen et al., 2019), (black) the blended Hadley Center/Climate Research Unit global temperature data set (Morice et al., 2012), and (light blue) the NOAA NCDC historical merged land–ocean surface temperature data set (Smith et al., 2008; Zhang et al., 2019). The simulated global temperature is constructed using SSTs over the ocean and surface air temperatures over land.

528

4.2.2 Atmosphere

Table 3. Data used for evaluation of atmospheric quantities. Further data used for the computation of skill scores are specified by Crueger et al. (2018).

Quantity	Name	Period	Reference
sea level pressure	ERA-Interim	1979 - 2014	Dee et al. (2011)
zonal mean temperature	ERA-Interim	1979 - 2014	Dee et al. (2011)
zonal mean zonal wind	ERA-Interim	1979 - 2014	Dee et al. (2011)
cloud fraction	CALIPSO-GOCCP (v3.1.2)	2007-2019	Chepfer et al. (2010)

536

For the evaluation of atmospheric quantities we follow as closely as possible plotting styles and use of data sets as in Crueger et al. (2018) to enable a comparison of the performance of the coupled ICON-ESM with AMIP-style (i.e. atmosphere-only) simulations by ICON-A and predecessors. Data sets used in the comparison are listed in Table 3. We only use data from after the beginning of the satellite era and compare to ICON-ESM output from the same period of the historical simulation. As model biases are in general large in comparison to the spread between different ensemble members we only use one ensemble member for the comparisons.

541

542

543

544

545

To allow a quantitative comparison of global model performance with predecessors and uncoupled simulations of this and earlier model versions, we present skill scores for simulated annual mean quantities as proposed by Reichler and Kim (2008) in Fig. 5. We calculate these scores in the same way and with respect to the same observational data as described by Crueger et al. (2018). Skill scores for model biases are calculated with respect to model biases in a reference simulation for which we use the historical CMIP6 simulation with the MPI-ESM-LR-1.2 (Mauritsen et al., 2019). It is obvious that the ICON-ESM performs worse than the reference model for many quantities both globally and in the three geographic regions tropics, northern and southern extratropics. It performs also

546 worse than the predecessor MPI-ESM-LR (Stevens et al., 2013). The performance has
547 clearly improved only for some quantities in the southern extratropics.

548 In general, a better agreement of uncoupled simulations with observations is ex-
549 pected as they are driven by observed sea surface temperatures and sea ice. This bet-
550 ter agreement is clearly visible in Fig. 5, where uncoupled scores for many quantities are
551 below one in most regions, i.e. the agreement with observations is better than in the cou-
552 pled reference simulation. Differences between our simulation and the uncoupled AMIP
553 experiment of Crueger et al. (2018) are expected due to the coupling, but also due to
554 parameter changes related to the tuning of the coupled model as described in Sections 3.2
555 and small code modifications as described in Section 2.1. The latter two effects can be
556 estimated from comparing the skill scores of the ICON-ESM AMIP simulation with the
557 predecessor ICON-A-1.3.00 used by Crueger et al. (2018). Although some quantities im-
558 prove, the skill in the uncoupled experiment is lower than in the AMIP simulation. A
559 lower skill can be expected because our tuning aimed at the performance in the coupled
560 simulation. In the following we evaluate the spatial patterns of some atmospheric quan-
561 tities.

562 Figure 6 shows annual mean sea level pressure from the ERA-Interim reanalysis
563 and the difference of the ICON-ESM to this dataset. Maximum anomalies of up to about
564 10 hPa are of the same order as anomalies simulated in the uncoupled model (Crueger
565 et al., 2018). However, the spatial structure is very different. While in the uncoupled model
566 there was an underestimation in most parts of the tropics and sub-tropics and a strong
567 positive bias in particular over the Arctic, here we simulate strong positive biases cent-
568 tred near about 45° in both hemispheres. Extratropical biases showed some sensitivity
569 to the SSO parameters (see Table 1) in the tuning process. The Arctic positive bias of
570 mean sea-level pressure over the Arctic found in Crueger et al. (2018) could be reduced
571 by activating SSO mountain lift forces of using the parameter *gklift*. The tropical low
572 bias was a feature in all our tuning attempts.

573 According to the skill scores presented in Fig. 5, the ICON-ESM simulates precip-
574 itation over land and ocean in the extratropics similar or even better than predecessors
575 or uncoupled model versions. It performs worse, however, in the tropics. Fig. 7 shows
576 annual mean precipitation patterns in the ICON-ESM in comparison to data from the
577 Global Precipitation Climatology Project (GPCP). The model simulates the typical dis-
578 tribution of tropical and extratropical rainfall patterns. In the Pacific, rainfall maxima
579 are too high and a double-ITCZ bias, typical for many climate models, can be identi-
580 fied. These features were also reported for the uncoupled ICON AMIP simulation from
581 Crueger et al. (2018). Improvements with respect to this uncoupled simulation can be
582 identified in the tropical Atlantic and Indian oceans. Concerning the seasonal cycle, a
583 major bias is a shift of maximum precipitation from summer to winter in the boreal for-
584 est zone (50N-65N) over the continental interior of Eurasia (not shown), which leads to
585 a large regional deficit in simulated vegetation productivity.

586 Figs. 8 and 9 show global annual mean total cloud fraction and zonal mean ver-
587 tically distributed cloud fraction, respectively, in comparison to the GCM Oriented Cloud
588 Calipso Product (CALIPSO-GOCCP) data. Total cloud fraction is clearly too low in sub-
589 tropical regions in both hemispheres, a feature which was visible but less strong in the
590 AMIP simulations of Crueger et al. (2018). The vertical distribution of cloud fraction
591 indicates that this is in particular related to an underestimation of low clouds in the sub-
592 tropics and tropics. High clouds are, by contrast, overestimated in the tropics and mid-
593 dle to high latitudes. Different tuning choices would be able to alleviate these deficien-
594 cies, but we did not reach a global energy balance for a realistic global mean tempera-
595 ture and better cloud distributions at the same time.

596 The skill scores indicate that the performance of the ICON-ESM for annual zonal
597 means of both temperature and zonal wind is in general worse than that of its prede-

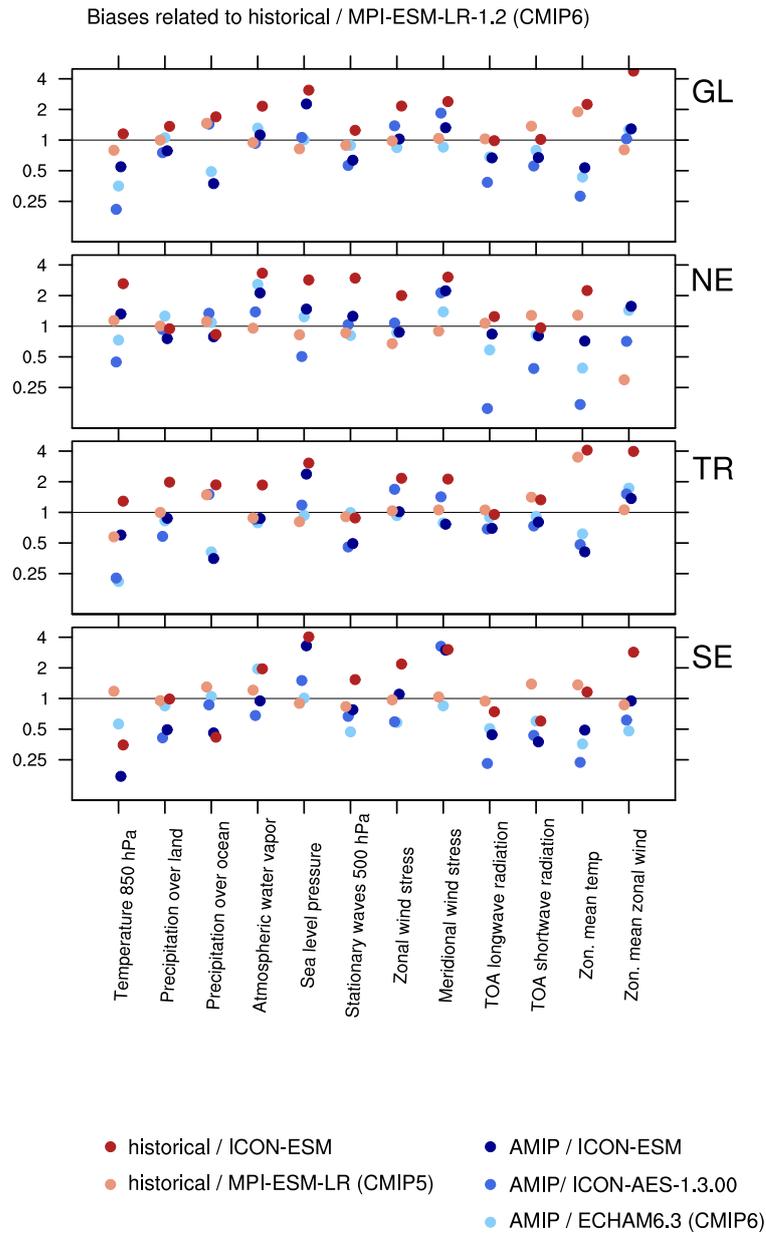

Figure 5. Standardized annual mean climatological errors of selected variables in several simulations with reference to the CMIP6 historical simulation with MPI-ESM-LR-1.2. A value smaller/larger than 1 indicates a smaller/larger bias compared to this reference for the evaluation period 1979 – 2008. Scores are averaged over (from top to bottom) the full globe, the northern extratropics, the tropics (30°S - 30°N), and the southern extratropics. Colored dots indicate scores for the coupled simulations with (red) the ICON-ESM and (orange) the MPI-ESM-LR (Stevens et al., 2013), as well as for the AMIP simulations with (dark blue to light blue) the ICON-ESM, ICON-A-1.3.00 (Crueger et al., 2018), and ECHAM6.3 (Mauritsen et al., 2019). See Section 4.2.2 for further details on the skill scores.

598 cessors. In particular, the score for zonal wind is high in all geographical regions, but
 599 it should be noted, that zonal wind biases were very low for the reference simulation (Fig.
 600 B3, Mauritsen et al., 2019). The large positive temperature bias in the high latitude mid-
 601 dle atmosphere and the cold bias near the high-latitude tropopause (Fig. 10) are recur-
 602 rent features of our models (Crueger et al., 2018), but partly stronger in the ICON-ESM.
 603 In the troposphere, the model shows in general a warm bias at low and a cold bias at
 604 high latitudes. The large zonal wind bias (Fig. 11) is dominated by too strong wester-
 605 lies in the mid-latitude troposphere and stratosphere, a feature which is strongest in both
 606 hemispheres during boreal winter. The position of subtropical jets is biased poleward
 607 in both hemispheres. A reduction of the zonal wind biases would be possible through
 608 different tuning choices in the parameterization of SSO effects, but in our tuning exper-
 609 iments this came in general at the expense of larger biases in sea ice and the AMOC.

610 **4.2.3 Land**

611 We compare our model ensemble results for the surface albedo with the MODIS
 612 MCD43C3 CMG Albedo Product (C. Schaaf & Wang, 2015). Cescatti et al. (2012) and
 613 C. B. Schaaf et al. (2002) show that the product is suitable for climate model compar-
 614 isons. It comes with quality information for each data point (quality flags). These flags
 615 condense uncertainties in the elicitation of the data, such as atmospheric scattering and
 616 absorption, anisotropy, inadequate temporal, spatial and spectral sampling, and narrow-
 617 band to broadband conversions. For our comparison we first exclude MODIS data with
 618 a minor quality of the inversion (quality flags 4 and 5). Then we interpolate the data
 619 from the original MODIS grid of $0.05^\circ \times 0.05^\circ$ (about 5.6 km at the equator) and from
 620 our model grid to a Gaussian lon-lat grid of 96×192 (about 1.88° or 210 km at the equa-
 621 tor). As the albedo varies strongly throughout the year due to variations in the angle
 622 of the incoming radiation, in leaf area index (LAI), and in snow cover, we take January
 623 and July data to represent the winter and summer extremes, for which we average our

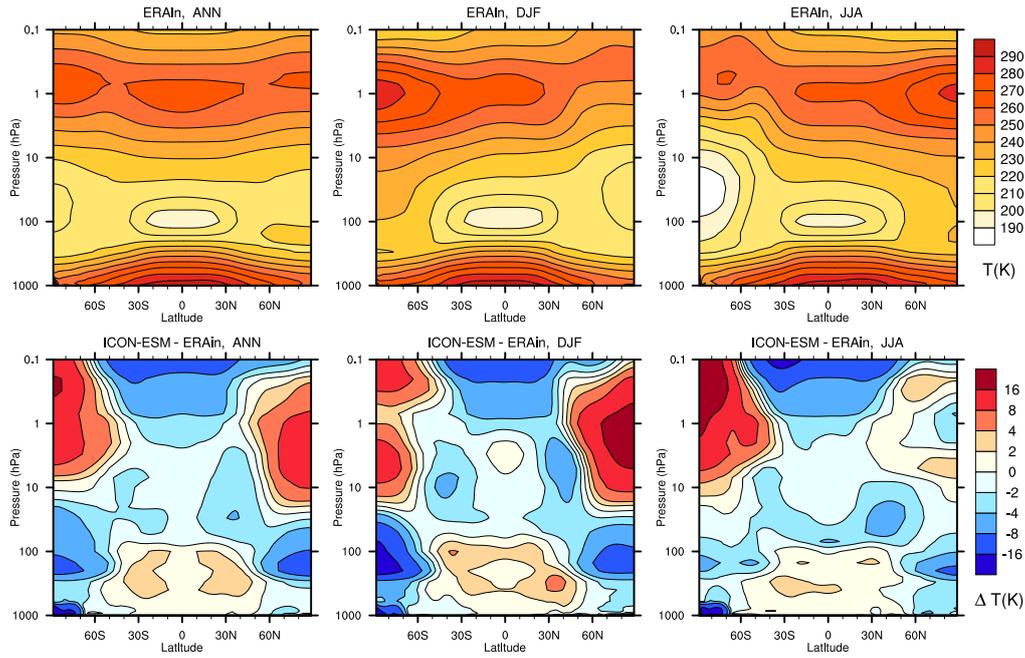

Figure 10. Zonal mean temperature (K) averaged over the period 1979-2014 (top row) from the ERA-Interim reanalysis and (bottom row) difference between ICON-ESM historical simulation and ERA-Interim. From left to right are shown the annual, boreal winter (DJF), and austral winter (JJA) averages.

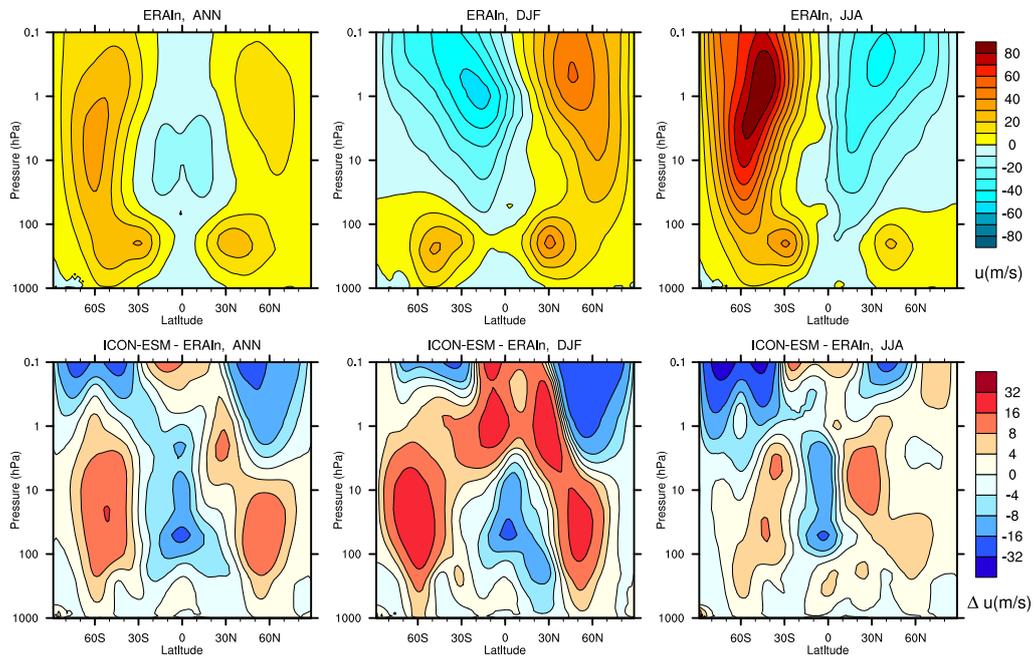

Figure 11. Zonal mean zonal wind (K) averaged over the period 1979-2014 (top row) from the ERA-Interim reanalysis and (bottom row) difference between ICON-ESM historical simulation and ERA-Interim. From left to right are shown the annual, boreal winter (DJF), and austral winter (JJA) averages.

624 model results and the MODIS data over the years 2001 till 2014. The differences are shown
 625 in Figure 12.

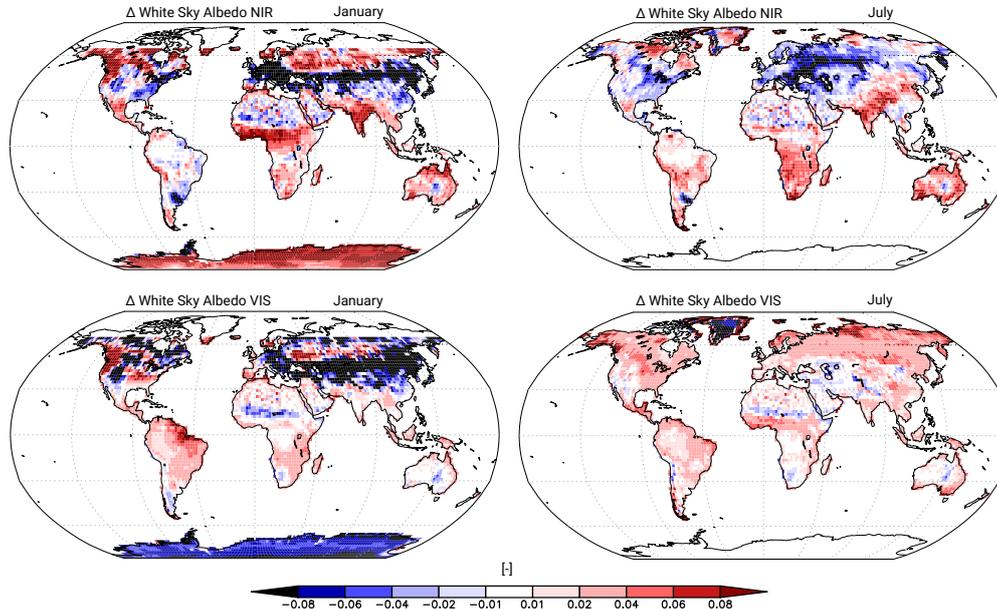

Figure 12. White Sky Albedo (WSA) differences between the ICON-ESM historical ensemble and the MODIS data. Shown are the NIR and VIS bands for January and July averaged from 2001 till 2014.

626 All albedo differences are in the range ± 0.1 . In general the biases are weak as
 627 compared to the absolute MODIS albedos. E.g. in January the global NIR albedo is 0.31
 628 for the absolute values of MODIS while the corresponding bias is only 0.003. Over glaciers
 629 we find a common pattern where the near-infrared (NIR) albedo is too high and the visible (VIS)
 630 albedo is too low (see in January over Antarctica and in July over Greenland),
 631 which is a direct result of the prescribed minimum and maximum albedo values for glaciers
 632 in JSBACH 4. In January, NIR and VIS albedo are too low in the northern mid latitudes,
 633 especially in eastern Europe and central Asia. Further analysis reveals that these biases
 634 are largely caused by a too small snow cover in JSBACH 4 (not shown). In July, the NIR
 635 albedo in eastern North America and large parts of Asia is too low. These low albedos
 636 are caused solely by the prescribed soil albedo of the model. Except for the mentioned
 637 areas, the albedos tend to be higher in JSBACH 4, e.g. in most of Africa, Australia and
 638 India. However, the causes for this overestimation are rather complex and their inves-
 639 tigation is beyond the scope of this paper; a deeper analysis of this issue will be published
 640 in a forthcoming paper.

641 For the evaluation of land surface temperature (LST) of our model ensemble, we
 642 use the MOD11C1 Moderate Resolution Imaging Spectroradiometer (MODIS) Terra Land
 643 Surface Temperature/Emissivity V006 data set (Z. Wan et al., 2015). For our analysis
 644 we excluded the data points where the quality flags indicate no retrieval because of clouds.
 645 The spatial resolution of the data set is $0.05^\circ \times 0.05^\circ$ (about 5.6 km at the equator). Fur-
 646 thermore, we compare our results with the first five ensemble members of the MPI-ESM
 647 CMIP6 historical simulations (Wieners et al., 2019).

648 The global ICON-ESM LST time series (Figure 13, green lines) fits well with sim-
 649 ulation results from MPI-ESM 1.2 (blue lines) but shows a higher monthly variability

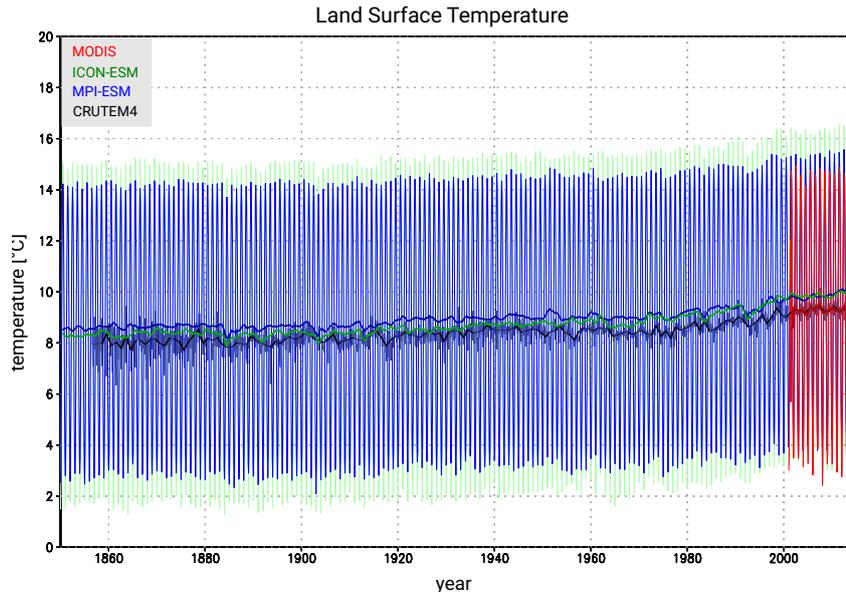

Figure 13. Land Surface Temperature evolution over historical times. Thin lines are monthly means, thick lines are yearly means. Red: MODIS data. Green: ICON-ESM historical ensemble. Blue: MPI-ESM CMIP6 ensemble mean of the first five ensemble members. Black: CRUTEM4 historical reconstruction. Note, as CRUTEM4 includes only temperature changes without a determined absolute temperature the absolute offset is chosen to fit the curve with the satellite data.

650 (about 2°C). Over the historical period until about 1990, the annual averages of ICON-
 651 ESM are slightly colder than those of MPI-ESM 1.2 but about 0.6°C warmer than ob-
 652 served by MODIS (red lines) while monthly variability is - as for MPI-ESM - about 2°C
 653 higher than observed. However, its January temperatures are more or less the same as
 654 for MODIS, only the July temperatures are much higher causing the warmer annual tem-
 655 peratures. Even when on short time scales both models annual means are not in good
 656 agreement with the historical CRUTEM4 reconstruction (black lines), they agree with
 657 long term trend (e.g. the temperature rise after 1980).

658 The geographical LST comparison between ICON-ESM and MODIS averaged be-
 659 tween 2001 and 2014 (Figure 14) reveals strong regional differences. The zonal means
 660 show a warm bias in the inner tropics and the extratropics. In principle, this can also
 661 be seen in the January and July averages. Regionally, the warm bias is throughout the
 662 year mostly pronounced in Europe, central Asia, central to north-eastern N-America, the
 663 Amazon region, and western Antarctica. The warm bias over Eurasia in January is at
 664 least partly caused by the too low snow cover and the associated snow-albedo feedback.
 665 The comparison with MPI-ESM (Figure 15) shows that the warm bias in Europe, cen-
 666 tral Asia and Amazonia, which is most pronounced in July, was much weaker or not ex-
 667 istent in MPI-ESM. ICON-ESM is colder than the MODIS data in the outer tropics (see
 668 zonal means). Regionally, the locations of the cold biases vary with the seasons but Aus-
 669 tralia, India and central eastern Antarctica (except for the coastal areas) are colder through-
 670 out the year. In Australia and central eastern Antarctica the cold bias was much weaker
 671 or not existent in MPI-ESM.

672 Overall, the zonal mean bias pattern of ICON-ESM as compared to MODIS de-
 673 picts more or less the global atmospheric circulation and thus indicates mainly an at-
 674 mospheric origin. Due to the complex continental distribution a land origin seems un-

675 likely. Nevertheless, the albedo biases surely contribute to the LST biases of ICON-ESM,
676 especially in central Asia and over glaciers.

677 **4.2.4 Ocean**

678 The simulated sea surface temperature (SST) obtained from the ensemble mean
679 of the historical simulations and averaged over the period 1980 – 2014 is compared to
680 the PHC 3.0 data set in Figure 16 a, c. Deviations from the observation-based data set
681 are largely smaller than 1°C over the open oceans, but we diagnose prominent regions
682 with large errors. The most pronounced cold anomalies are found in the subpolar North
683 Atlantic. As in many other coarse-resolution and even eddy-permitting models (e.g., Kee-
684 ley et al., 2012) this feature is related to an overly zonal North Atlantic Current (Drews
685 et al., 2015) and likely also related to too weak meridional heat transport. For MPI-ESM,
686 Gutjahr et al. (2019) have shown that moving to eddy-resolving resolution in the ocean
687 improves the sub-polar cold bias in the North Atlantic. Corresponding errors in atmo-
688 spheric sea-level pressure (Fig. 6) indicate that wind-driven circulation biases also con-
689 tribute to the error. Large atmospheric SLP and circulation biases in the North Pacific
690 are likely responsible for strong warm biases over the Kuroshio region.

691 The cold-tongue bias in the equatorial Pacific is also a well known model feature,
692 but the ICON-ESM performs less well than the MPI-ESM (Müller et al., 2018b), even
693 though MPI-ESM-LR features much lower resolution in the ocean compared to the ICON
694 ocean used here. The bias is a surface expression of the generally too cold sub-surface
695 waters in the tropical oceans (Fig. 17) so that the outcropping isotherms in the west-
696 ern Pacific are too cold. In the coupled system, the equatorial cold bias is important for
697 the variability characteristics of ENSO and the associated precipitation distribution (sec-
698 tion 4.2.7). Warm biases are diagnosed in the upwelling regions at the western coasts
699 of the tropical oceans. They are most pronounced at the African coast south of the Equa-
700 tor. These features are common in coupled models and, in particular in the case of Africa,
701 are related to insufficient resolution in the atmosphere where coastal orography and along-
702 shore winds cannot be properly simulated (Milinski et al., 2016).

703 The sea surface salinity (SSS) biases (Fig. 16b, d) in ICON-ESM are relatively small
704 over most of the oceans, except the high northern latitudes and around the Antarctic
705 continent. The Arctic fresh bias extends also into the sub-polar North Atlantic, where
706 overly fresh water is transported with the gyre circulation into the interior ocean mak-
707 ing the cold bias in Fig. 16c a fresh bias as well.

708 The time-mean bias in zonal averages over the global ocean reflect misrepresenta-
709 tions of water mass pathways and processes like vertical and along-isopycnal mixing. The
710 most prominent error feature in the ICON-ESM ocean is a generally too cold interior
711 ocean with strong cold biases in the sub-tropical and tropical oceans (Fig. 17) that are
712 accompanied by overly fresh conditions. The reasons for the overly strong cooling are
713 not fully understood, but comparison with an earlier version using the Pacanowski-Philander
714 mixing scheme (PP, Pacanowski and Philander (1981)) showed that the PP scheme in
715 combination with the wind-mixing parameterization used in MPIOM (Marsland et al.,
716 2003) showed a better performance than the TKE scheme used here. Regarding the up-
717 per ocean, this is consistent with the findings of Gutjahr et al. (2019) for the MPI-ESM.
718 Since the TKE scheme is more advanced and shall be further improved by including an
719 energy-consistent scheme for the background mixing in the interior (see Gutjahr et al.,
720 2021), we decided to keep the TKE scheme and attend to an improved tuning in forth-
721 coming versions of ICON-ESM.

722 The overly cold sub-thermocline waters lead to a too strong stratification near the
723 thermocline in particular in the tropical oceans and are likely responsible for too strong
724 ENSO variability (see section 4.2.7). The salinity biases resemble those in temperature
725 in the tropical and southern sub-tropical region, but higher northern latitudes feature

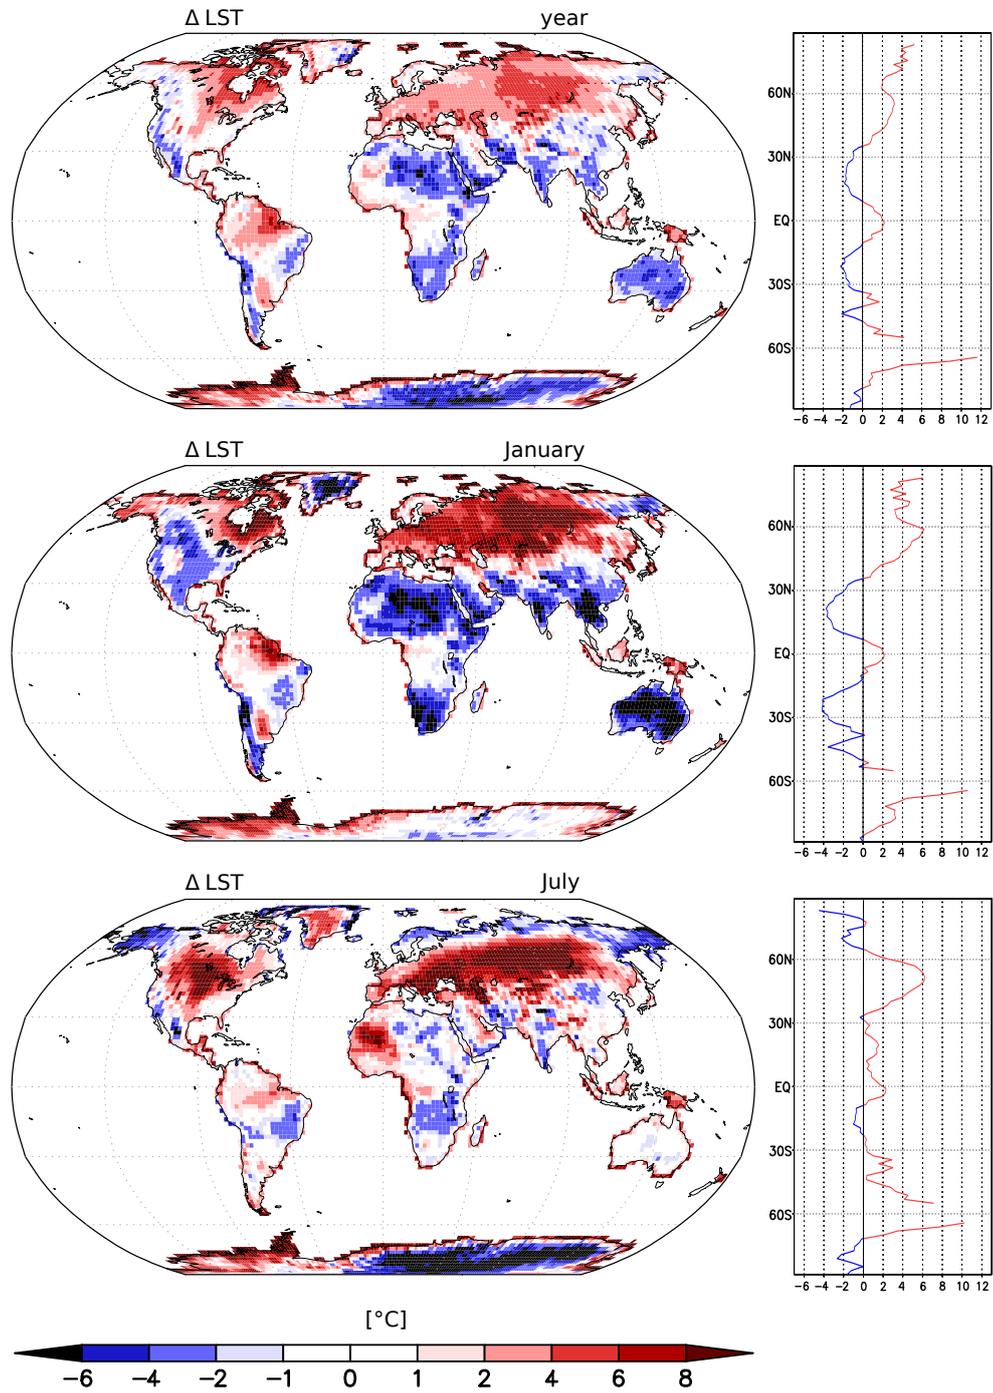

Figure 14. LST differences between the ICON-ESM historical ensemble and MODIS data averaged from 2001 to 2014. The curves on the right side show zonal means.

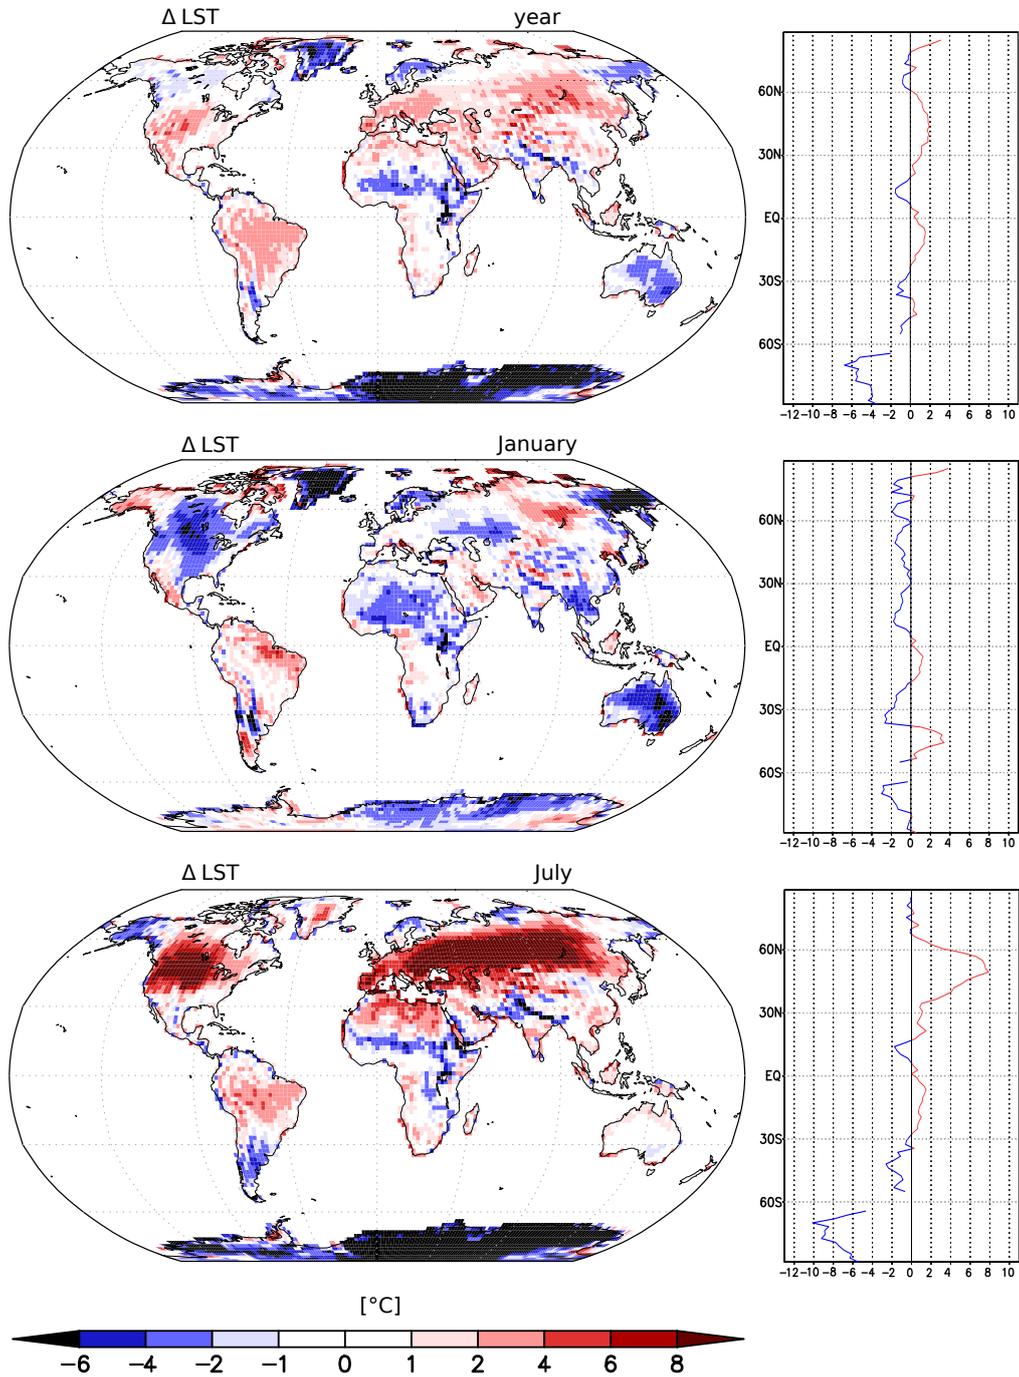

Figure 15. LST differences between the ICON-ESM historical ensemble and MPI-ESM ensemble mean (r1i1p1f1, r2i1p1f1, r3i1p1f1, r4i1p1f1 and r5i1p1f1) averaged from 2001 to 2014. The curves on the right side show zonal means.

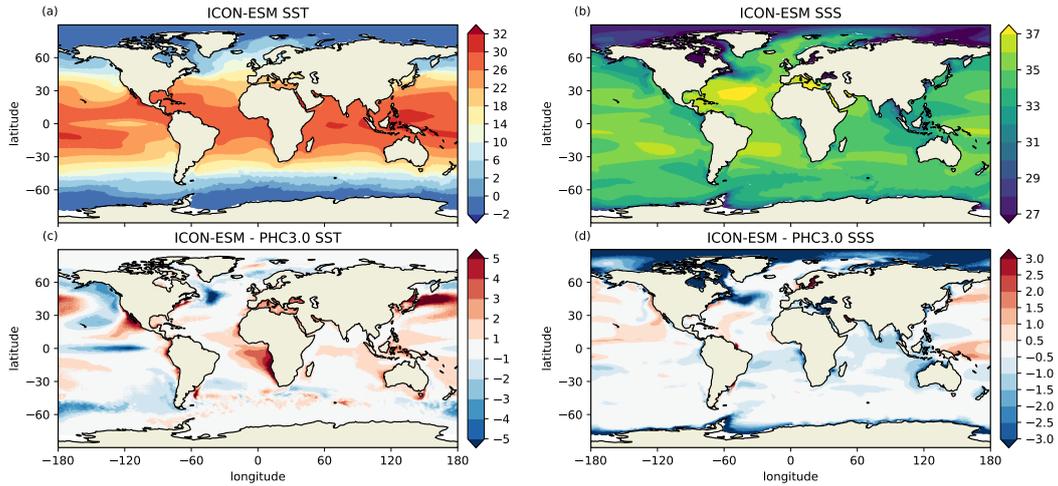

Figure 16. Climatology (1980 -2014) of a) sea surface temperature and b) sea surface salinity simulated in the ICON-ESM historical simulations together with the model biases for c) SST and d) SSS with respect to the observation-based PHC climatology (Steele et al., 2001). TODO: add labels

726 pronounced positive salinity in the sub-surface ocean. These underlay a too fresh sur-
 727 face layer and lead to a too strong halocline in the Arctic Ocean. The too fresh surface
 728 salinities could be related to an underestimation of Fram Strait sea ice export.

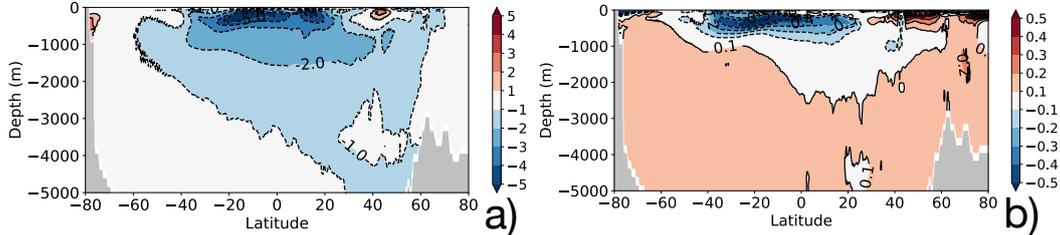

Figure 17. Zonal mean global ocean a) temperature, and b) salinity bias relative to the PHC climatology.

729 **4.2.5 Large-scale ocean circulation**

730 The AMOC is an important part of the global overturning circulation and it is an
 731 important carrier of heat and fresh water in the Atlantic. The AMOC stream function
 732 (Fig. 18a) represents the zonally integrated view. Facing west, the North Atlantic Deep
 733 Water cell is oriented clockwise and includes the downward motion associated with deep
 734 water formation in the Labrador Sea and Nordic Seas, as well as the overflows across the
 735 Greenland-Scotland Ridge. The maximum strength of the AMOC exceeds 16 Sv at approx-
 736 imately 40°N and we diagnose an export of about 14 Sv at 30°S. The lower, counter-
 737 clockwise oriented cell is associated with Antarctic Bottom Water (AABW) entering the
 738 Atlantic and upwelling in the basins. The strength of the AABW cell in the North At-
 739 lantic is roughly consistent with the observations from the RAPID project, but for the
 740 South Atlantic the simulations likely underestimate the AABW inflow. While the sim-

741 ulated AABW maximum is slightly above 2 Sv, observation-based estimates point to val-
 742 ues of 6 Sv (Ganachaud & Wunsch, 2003) or 8 Sv (Talley et al., 2003). Although the over-
 743 turning stream function cannot be compared directly with observation, the RAPID project
 744 has provided measurements of the respective flow components at 26.5°N. The profile ob-
 745 tained over more than a decade of observations (Smeed et al., 2018) is shown together
 746 with the profiles from the piControl runs and one historical simulation (Fig. 18b) and
 747 with their variability range estimated from the standard deviation of monthly fields. In
 748 the upper ocean, the model reproduces well the shape of the profile, the maximum near
 749 1000 m depth and also the range of variability. The zero crossing is located above 4000 m
 750 in the model, but resides a few hundred meters deeper in the RAPID data. Compared
 751 to various versions of MPI-ESM1.2 (Gutjahr et al., 2019) and other CMIP6 models (e.g.
 752 Held et al. (2019); Danabasoglu et al. (2020)), which show even shallower NADW cells,
 753 the ICON-ESM results are, however, closer to the observations.

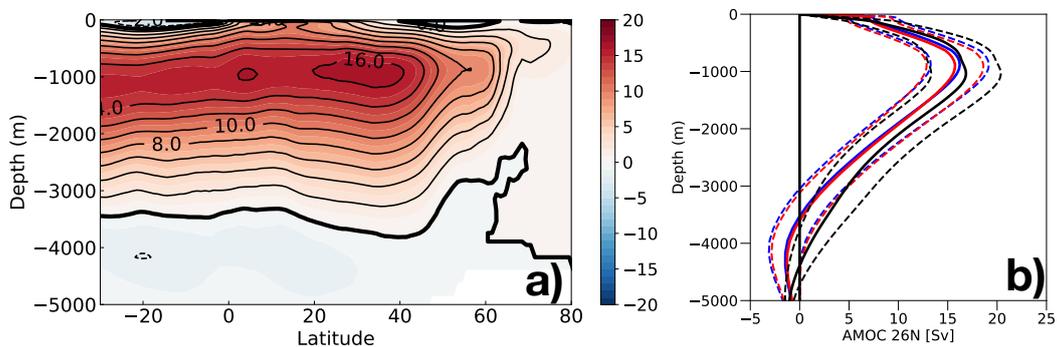

Figure 18. AMOC in ICON-ESM: a) ensemble mean overturning stream function in the Atlantic from the five historical simulations averaged over the period 1980-2014; b) AMOC profile at 26.5N for the historical ensemble (blue) and the piControl simulation (red) together with the observational estimate from RAPID (black); shown are the mean profiles (thick lines) and the range of variability derived from monthly standard deviations.

Table 4. Simulated and observed net volume transports (Sverdrups) across sections (positive means northward).

Section	ICON-ESM	Obs.	Reference
Bering Strait	0.7-0.8	0.7-1.1	Woodgate et al. (2006, 2012)
Fram Strait	- (2.6-2.8)	-1.75 ± 5.01	Fieg et al. (2010)
Denmark Strait	- (4.7-4.9)	-4.8	Hansen et al. (2008)
		-3.4 ± 1.4	Jochumsen et al. (2012)
Iceland-Scotland	4.7-4.9	4.8	Hansen et al. (2008)
		4.6 ± 0.25	Rosby and Flagg (2012)
Indonesian Throughflow	9.9-10.1	11.6 - 15.7	Gordon et al. (2010)
Drake Passage	108-112	134.0 ± 14.0	Nowlin Jr. and Klinck (1986)
		173.3 ± 10.7	Donohue et al. (2016)

754 The transport through selected passages reflects the representation of the large-
 755 scale ocean circulation and can be evaluated in comparison with observational estimates.
 756 The total depth-integrated transports through the passages given in Table 4 are mostly
 757 simulated within the observational uncertainty found in the literature. The transport
 758 through Bering Strait is a key element of the Arctic fresh water budget and the histor-
 759 ical simulations are close to the estimates by Woodgate et al. (2006, 2012). The exchange
 760 of water masses between the Atlantic Ocean and the Nordic Seas is important for the
 761 overturning circulation. The simulated transports are consistent with the circulation scheme
 762 by Hansen et al. (2008). The Indonesian Throughflow is another important contributor
 763 to the warm-water route of the global conveyor. The simulated transports are slightly
 764 underestimated in comparison with the estimate by Gordon et al. (2010). The Drake Pas-
 765 sage transport is clearly underestimated in ICON-ESM, both in comparison with the tra-
 766 ditional estimate around 135 Sv (Cunningham et al., 2003; Nowlin Jr. & Klinck, 1986)
 767 and with the more recent compilation by Donohue et al. (2016). At this stage it is not
 768 clear if the mismatch between observed and simulated Drake Passage (and likely Antarc-
 769 tic Circumpolar Current) is related to biases in the wind stresses or the settings of the
 770 eddy and background diffusivity in the ocean circulation (P. R. Gent et al., 2001).

771 The equatorial hydrography and the representation of the zonally-oriented current
 772 systems is important for variability features such as Tropical Instability Waves and for
 773 coupled ocean-atmosphere phenomena like the El-Nino Southern Oscillation (ENSO).
 774 Johnson et al. (2002) provided a compilation of temperature and salinity data and cur-
 775 rent measurements from the 1990s, which we compare with ICON-ESM results in Fig-
 776 ure 19. At 110°W, the placement of the eastward equatorial undercurrent (EUC) and
 777 the westward flows on its northern and southern flanks are reproduced well in the model
 778 and the depth of the core of the undercurrent lies roughly at the correct depth of 75m
 779 (Figure 19a, b). The model underestimates, however, the speeds of the eastward under-
 780 current and the westward currents flanking the undercurrent. Although the 24° and 26°
 781 isotherm outcrop at roughly the correct position, the stratification is stronger than in
 782 the observations and the 20° isotherm outcrops near the Equator whereas it stays sub-
 783 surface in the observations. The stratification in the thermocline in the northern and south-
 784 ern flanks is also much stronger than in the observations. Generally, ICON-ESM pro-
 785 duces too cold conditions above the thermocline (Figure 17) which is responsible for a
 786 pronounced cold bias along the Equator in the Pacific and possibly affects ENSO vari-
 787 ability (see section 4.2.7). The section along the Equator confirms that the position of
 788 the EUC’s core depth is well captured in the model, as are the amplitudes of the EUC
 789 and the westward flow near the surface. The weaker EUC seen in (b) is more related to
 790 a biased longitudinal positioning of the maximum strength of the EUC.

791 **4.2.6 Sea ice**

792 Sea-ice thickness distributions and extents for late winter and late summer are pre-
 793 sented in Figures 20 and 21 for both hemispheres. Arctic and Antarctic sea-ice edges are
 794 reproduced in good agreement with the EUMETSAT OSI SAF data set (EUMETSAT,
 795 2015) for the respective winter seasons but summer ice cover is clearly underestimated.
 796 In particular in the Arctic, simulated summer sea-ice concentrations are above 15% only
 797 between Fram Strait and the North Pole whereas observational data show sea-ice extents
 798 almost reaching the Canadian and Siberian coasts. Summer sea ice is also very thin, rarely
 799 reaching 1 m thickness. Winter sea-ice thickness is overly too homogeneous and lacks
 800 the typical pile-up of thicker ice (exceeding 3 m thickness) that is seen in the PIOMAS
 801 Arctic sea-ice volume reanalysis (Schweiger et al., 2011) (compare also: <http://psc.apl.uw.edu/research/projects/arctic-sea-ice-volume-anomaly/piomas-monthly-thickness-map>.)
 802 Deficits in the sea-ice thickness distributions are likely related to biases in the at-
 803 mospheric circulation as indicated by the sea-level pressure errors in Figure 6. Mismatches
 804 in the seasonal amplitude and the too thin summer ice need further attention. During
 805 the tuning process we tried different options for albedo parameters or the lead-closing
 806

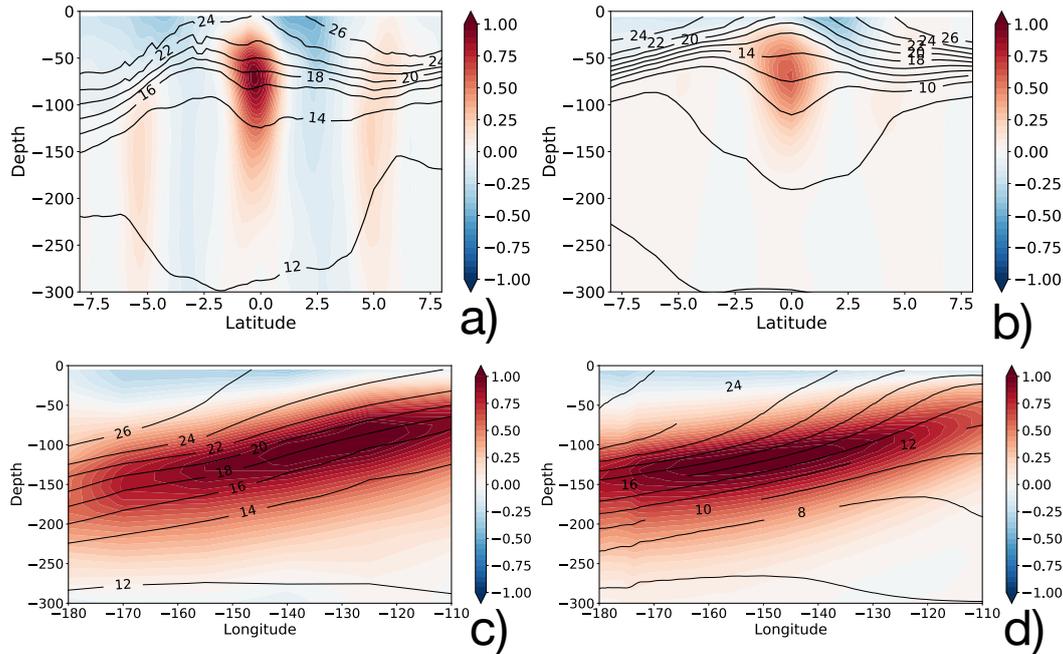

Figure 19. Tropical Pacific zonal velocities (color shading) and temperatures (contour lines) in the ICON-ESM simulation (left) compared to the observation-based estimate by Johnson et al. (2002) (right) at 110° W (upper row) and along the Equator (lower row).

807 scheme. These were either unsuccessful in improving summer sea ice or lead to overly
 808 large sea-ice extent in winter (in particular in the Labrador Sea) with negative conse-
 809 quences for deep water formation and the strength of the AMOC.

810 **4.2.7 Variability simulated by ICON-ESM**

811 The El-Nino-Southern Oscillation (ENSO) is one of the most important modes of
 812 tropical variability with global teleconnections. To analyse characteristic features of ENSO
 813 and related quantities we apply the Climate Variability Diagnostics Package (CVDP; Phillips
 814 et al., 2014). CVDP allows assessment of simulations in comparison with observation to
 815 be carried out in a consistent way. CVDP results presented here can easily be compared
 816 with collections of CMIP5 and CMIP6 model evaluations carried out by NCAR ([www.cesm](http://www.cesm.ucar.edu/workinggroups/CVC/cvdp/data-repository.html)
 817 [.ucar.edu/workinggroups/CVC/cvdp/data-repository.html](http://www.cesm.ucar.edu/workinggroups/CVC/cvdp/data-repository.html)). CVDP provides also
 818 links to observational data sets for comparison (ERSST (Smith et al., 2008) and HADSST
 819 (Rayner et al., 2003) for sea surface temperature and GPCP (Adler et al., 2018) for pre-
 820 cipitation). We show here a subset of ENSO features that are based on SST time series
 821 from the Nino3.4 region. First, we present spectra (Fig. 22) obtained for boreal winter
 822 (DJF) conditions from the five-member historical ensemble (red lines) and from the pi-
 823 Control simulation (blue lines). The latter was split into three sections of 160 years. All
 824 time series show a peak near three years and similar variability in the control and his-
 825 torical runs. The spectra are more pronounced than those from the CMIP6 version of
 826 the MPI-ESM-LR and the level of variability is considerably higher than the observed
 827 spectra. ERSST data as well for the entire period (ERSST5, 1920-2014) as well as those
 828 from the last 35 years (ERSST5.1) show a much broader spectrum and indicate less strong
 829 variability on the three-year scale. Regarding the level of spectral power, ICON-ESM
 830 is not an exception compared to other CMIP5 and CMIP6 models according to the NCAR
 831 repository, but it belongs certainly not to the better performing models. We presume

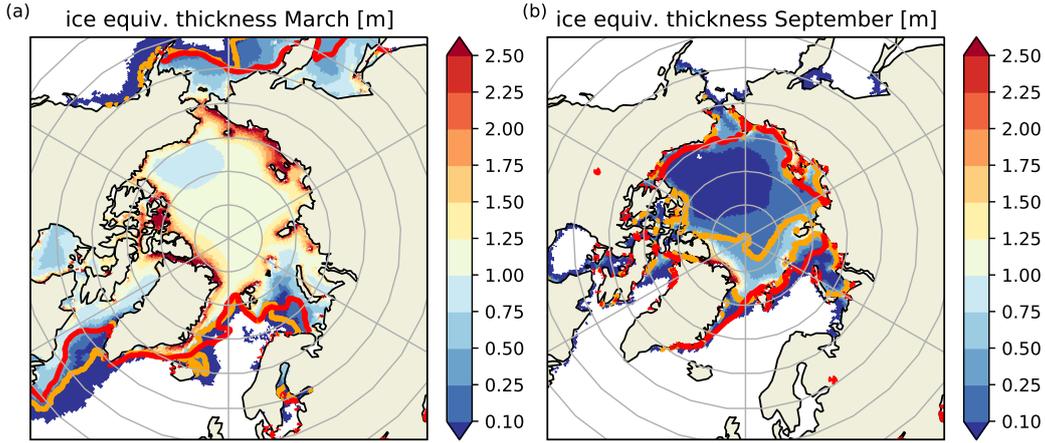

Figure 20. Ensemble mean sea-ice thickness (shading) for a) March and b) September in the northern hemisphere. Thick colored lines depict the 15% sea-ice extent boundary in the simulations (orange) and from the EUMETSAT OSI SAF observational data set (red).

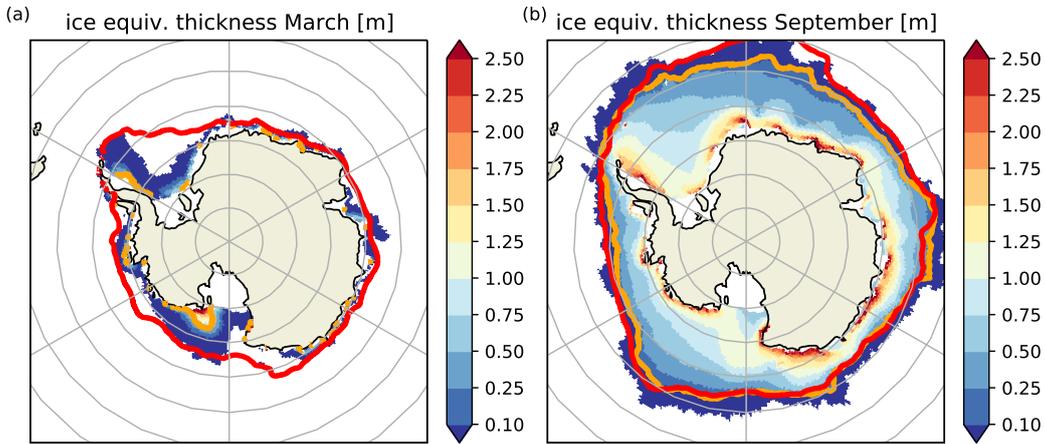

Figure 21. Ensemble mean sea ice thickness (shading) for a) March and b) September in the southern hemisphere. Thick colored lines depict the 15% ice extent boundary in the simulations (orange) and from the EUMETSAT OSI SAF observational data set (red).

832 that the sharp spectral peak at three years is related to the pronounced cold bias along
 833 the equatorial Pacific (Fig. 17) and the related upper ocean stratification. Spatial com-
 834 posites of boreal winter ENSO-related anomalies of temperature and precipitation are
 835 shown in Figures 23a and 23b, respectively. While the general patterns are reproduced
 836 well, there are deficits in the amplitude of SST variations at the Equator. In particular,
 837 positive anomalies reach too far into the warm pool region, where they also shift the pos-
 838 itive precipitation anomaly too far to the west (Fig. 23b).

839 **4.3 Ocean biogeochemistry simulated by HAMOCC**

840 The performance of ICON-ESM in simulating the ocean carbon cycle is evaluated
 841 in the piControl run. We compare the surface water $p\text{CO}_2$ averaged over the last 10 years
 842 of the spin-up run to the piControl results from MPI-ESM 1.2-LR (Mauritsen et al., 2019)

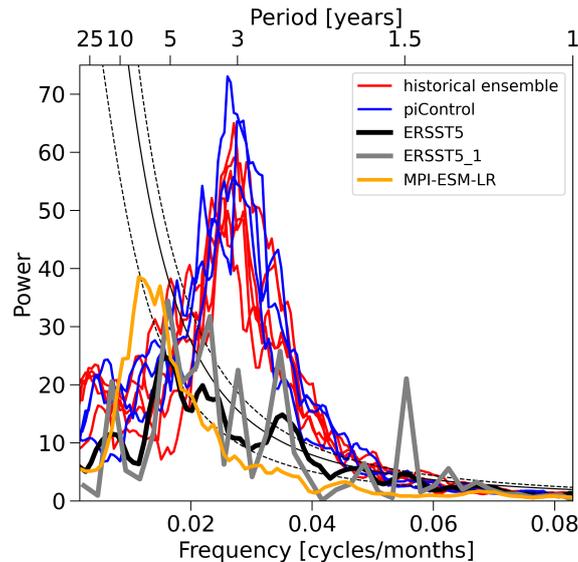

Figure 22. El Niño - Southern Oscillation (ENSO) variability derived from Niño3.4 time series from (red) the historical ensemble, (blue) the piControl simulation, and (orange) a MPI-ESM-LR historical simulation (Mauritsen et al., 2019). The piControl experiment was subdivided into three 160-year long sections. Estimates from the observational ERSST5 data set are included, where ERSST5.1 denotes a subset from the last 35 years). TODO: reference ERSST!

843 (Fig. 24). The overall regional patterns are well reproduced in this simulation with maximum
 844 values detected in the tropical Pacific and minimum values in the extra-tropical
 845 regions; but differences are also detected. ICON-ESM simulates a lower $p\text{CO}_2$ than MPI-
 846 ESM 1.2-LR in the equatorial Pacific, most regions of the subtropical Pacific and along
 847 the Kuroshio Current. On the contrary, in the Labrador Sea, Barents Sea and along the
 848 southern Chilean coast, ICON-ESM simulates higher $p\text{CO}_2$ than MPI-ESM 1.2-LR. The
 849 simulated annual global flux of CO_2 into the ocean is about 0.05 PgC/yr , representa-
 850 tive for the assumption of the pre-industrial steady-state condition.

851 To understand the drivers for the difference in the surface water $p\text{CO}_2$ in the two
 852 models, we decompose the changes in $p\text{CO}_2$ to changes in dissolved inorganic carbon (DIC),
 853 total alkalinity (TA), SST and SSS following Menviel et al. (2018). The sum of changes
 854 in DIC and TA are referred to as biogeochemical contributions and the sum of changes
 855 in SST and SSS are the physical contributions, respectively. The change in $p\text{CO}_2$ due
 856 to these contributions is calculated in each model and the difference is illustrated (Fig.
 857 24c,d). The sum of the biogeochemical and physical contributions (not shown) closely
 858 matches the difference between ICON-ESM and MPI-ESM $p\text{CO}_2$ shown in Fig. 24b. The
 859 lower $p\text{CO}_2$ in ICON-ESM in the eastern equatorial Pacific can be attributed to the lower
 860 SST, while in the subtropical Pacific, western equatorial Pacific and along the Kuroshio
 861 Current it is due to the biogeochemical contribution, mostly counteracting the impact
 862 of the circulation. Along the Labrador Current, the higher $p\text{CO}_2$ in ICON-ESM is at-
 863 tributed to biogeochemical changes, a result of lower simulated TA in ICON-ESM. In
 864 the Barents Sea, the higher $p\text{CO}_2$ results from the combined effect of a higher SST and
 865 higher DIC simulated by ICON-ESM.

866 These HAMOCC results represent a first-order tuning attempt and further sim-
 867 ulations will be required to obtain a fully tuned HAMOCC model. Therefore, the eval-
 868 uation of ocean biogeochemistry in a historical run will be the topic of a future study.

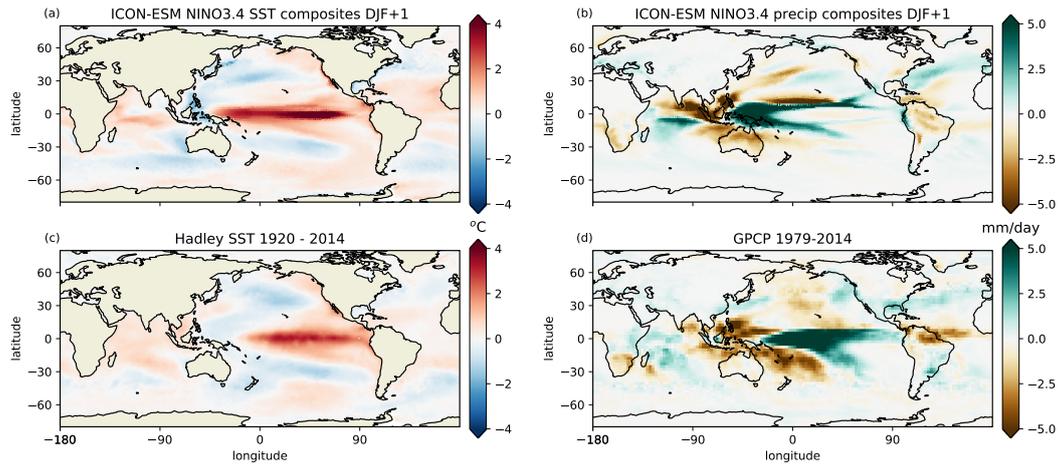

Figure 23. Spatial composites of ENSO (Nino3.4) events for a), c) SST, and b), d) precipitation from a), b) the historical ensemble mean, c) the HadSST, and d) the GPCP precipitation data sets.

Two measures of the model’s response to changes in radiative forcing are computed using the idealized CO₂-increase experiments in CMIP6 DECK: Transient Climate Response (TCR) and Equilibrium Climate Sensitivity (ECS). TCR is computed from the experiment where CO₂ increases by 1 percent per year (1pctCO₂). The TCR is estimated as the global temperature (TAS) increase around the time of CO₂-doubling, which happens after 70 years of simulation. To minimize effects of internal variability we take a 20-year average between years 60 and 79 as suggested by Meehl et al. (2020) and we arrive at a TCR of 2.1K. This value is slightly higher than the 1.8 K derived for the CMIP6 version of MPI-ESM-LR and in the middle of the range found in the CMIP6 multi-model assessment by Meehl et al. (2020). Differences in TCR are often related to variations in the ocean heat content changes under global warming, which could be different in MPIOM and ICON-O due to different formulations of vertical mixing and the GM parameters. ECS is estimated using the DECK “abrupt4xCO₂” experiment applying the method of Gregory et al. (2004), which has also been used by Meehl et al. (2020). We perform a linear regression between the global mean TAS and the net downward radiative flux at the top-of-atmosphere over 150 years of simulation. ECS is then estimated from an extrapolation of the regression line to zero net heat imbalance (Fig. 25b). This procedure results in an ECS of 3.7 K, which can be compared with the value of 2.9 in MPI-ESM-LR. MPI-ESM and ICON-ESM are quite similar in their estimate of the effective forcing (estimated as the crossing of the regression lines with the y-axis in Fig. 25b), but the slopes of the regression lines are considerably different. We note that the change of temperature over time differs for the later part of the experiments. Redoing the ECS estimation excluding the first 20 years in the regression, we find a much higher value of 4.3 K in ICON, whereas there is only a relatively small change to 3.1 K in MPI-ESM. This difference is likely related to different evolution of local or regional feedbacks (Armour et al., 2013). The higher TCR and ECS in ICON-ESM compared to MPI-ESM-LR may be responsible for part of the more pronounced warming in the second half of the 20th century (Fig. 4). However, for the ICON-ESM no effort was made to tune the climate sensitivity in order to better match the historical record as it was done for MPI-ESM1.2 (Mauritsen & Roeckner, 2020).

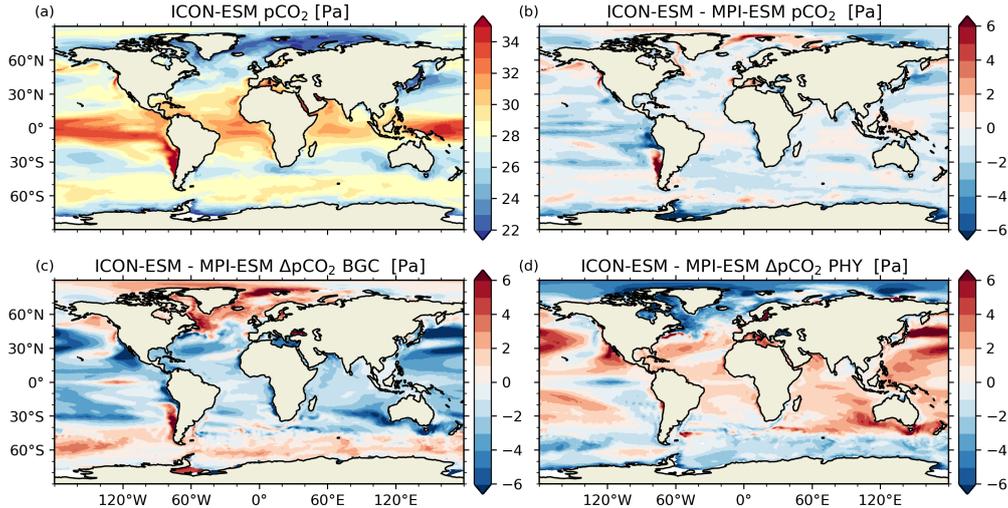

Figure 24. Surface $p\text{CO}_2$ in a) ICON-ESM piControl simulations and b) ICON-ESM minus MPI-ESM piControl simulations. The contribution of biogeochemical factors (alkalinity and DIC) (c) and physical factors (SST and SSS) (d) to the difference in ICON-ESM and MPI-ESM $p\text{CO}_2$ are also shown.

5 Discussion

During the tuning phase we have explored different parameter settings and, in the case of ocean vertical mixing, the choice between two different parameterization schemes (TKE, PP, see section 2.2). We started the coupled experiments using parameter settings inherited from the stand-alone ocean and atmosphere simulations. While these gave good or at least acceptable results in ICON-A (Crueger et al., 2018) and ICON-O (Korn et al., manuscript in preparation), solutions meeting our tuning goals (see Section 3) were much harder to obtain.

Problematic biases increased or became more apparent as feedbacks between the coupled components evolved. For example, the ICON-A AMIP simulation described in Crueger et al. (2018) exhibits relatively good skill scores, but features strong positive sea-level pressure biases in high northern latitudes (their Figure 3). In the coupled simulation, this error is accompanied by too weak winds over the subpolar North Atlantic that could lead to biases in ocean circulation, water mass transformation and, eventually, to a strong reduction or collapse of the AMOC. Changing parameter settings in the SSO parameterization (see Table 1) turned out to be an effective way to reduce the SLP bias. However, for instance, small values of $gkdrag$ reducing SLP biases also led to stronger errors in upper tropospheric and stratospheric zonal wind strength and distribution. Therefore, the results presented here are the results of compromises. Avoiding detrimental effects in some key quantities, such as the collapse of the AMOC or a freeze-over of the Labrador Sea in the ocean, required sometimes parameter settings in the atmosphere that turned out to be sub-optimal in terms of atmospheric performance skill scores (Figure 5).

In general, we found that tuning choices had often complex and unexpected effects in the coupled system. Partly, these were hard to grasp as they required relatively long adjustment times. Moreover, obtaining a tuning target is often dependent on several parameter settings and these may influence each other. We demonstrate this with the ex-

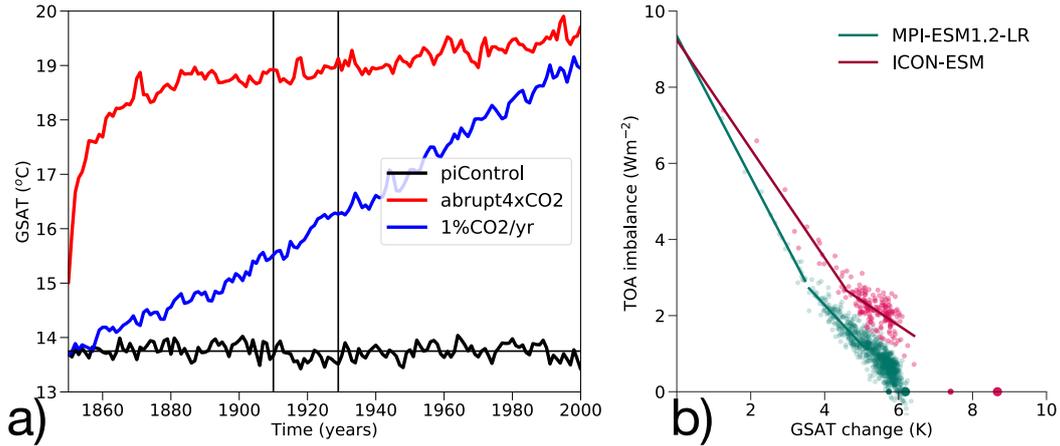

Figure 25. Estimating the Transient Climate Response (TCR) and Equilibrium Climate Sensitivity (ECS) from idealized DECK experiments. a) Evolution of global surface air temperature in the $1pctCO_2$ (blue) and $abrupt4XCO_2$ (red) together with the $piControl$ experiment (black). Vertical lines indicate the period for the TCR calculation, b) Gregory-style regression analyses to estimate ECS in ICON-ESM (dark red) and in the CMIP6 model MPI-ESM1.2.

927 ample of the AMOC strength taken from several experiments with different parameter
 928 settings. ICON-O stand-alone experiments, where only the coefficients for isoneutral dif-
 929 fusion K and eddy-induced diffusion κ have been changed, indicated that larger K and
 930 κ lead to weaker overall AMOC strength, likely due to a stronger flattening of isopyc-
 931 nals (not shown). However, an inspection of the multitude of experiments leads us to con-
 932 clude that it is possible to arrive at any AMOC state even for K and $kappa$ set to zero.
 933 We found fewer solutions with weak overturning at high K and $kappa$, but this may be
 934 due to the smaller number of experiments. It is also difficult to relate the AMOC strength
 935 uniquely to other parameters. For example, the experiments run with $K/kappa$ equal
 936 400 ms^{-2} in Figure 26 come with various settings of the wave drag parameter $gkdrag$ and
 937 an inspection of this column in isolation would lead us to conclude that lower wave drag
 938 parameters produce higher ocean overturning, possibly due to the effect on wind and wind
 939 stress discussed above. But again, looking at all experiments using a moderately low $gk-$
 940 $drag$ of 0.02 we find an AMOC range between 7.6 and almost 25 Sv.

941 It is obvious that another round of tuning and an even more extensive set of sensi-
 942 tivity experiments could have improved some of the shortcomings mentioned above.
 943 We decided, however, to finalize “version 1” at this stage to set a milestone in the model
 944 development. Moreover, model development activities in the component models have con-
 945 tinued in parallel and we prefer to postpone a second round of major tuning efforts un-
 946 til some innovations can be included in the standard model configurations. We mention
 947 here two developments in ICON-O: the z^* vertical coordinate and a newly developed dy-
 948 namical sea-ice model. z^* is designated to replace “z-level” as standard coordinate and
 949 comes together with an improved representation of the bottom topography in the form
 950 of “partial cells”, which was already implemented in MPIOM and its predecessors. The
 951 implementation process includes a slight reorganization of level distribution in the up-
 952 per ocean and we plan to achieve a better representation of the mixed layer processes
 953 and mixing by re-assessing the TKE parameterization. Mehlmann and Korn (2021) have
 954 developed a novel sea-ice dynamics formulation, which is based on an analogue of the
 955 Arakawa-CD grid. The CD-grid placement has appealing resolving properties at high
 956 spatial resolution compared to traditionally used discretizations (Mehlmann et al., 2021).
 957 Furthermore, the development allows a straightforward coupling to the Arakawa C-grid-

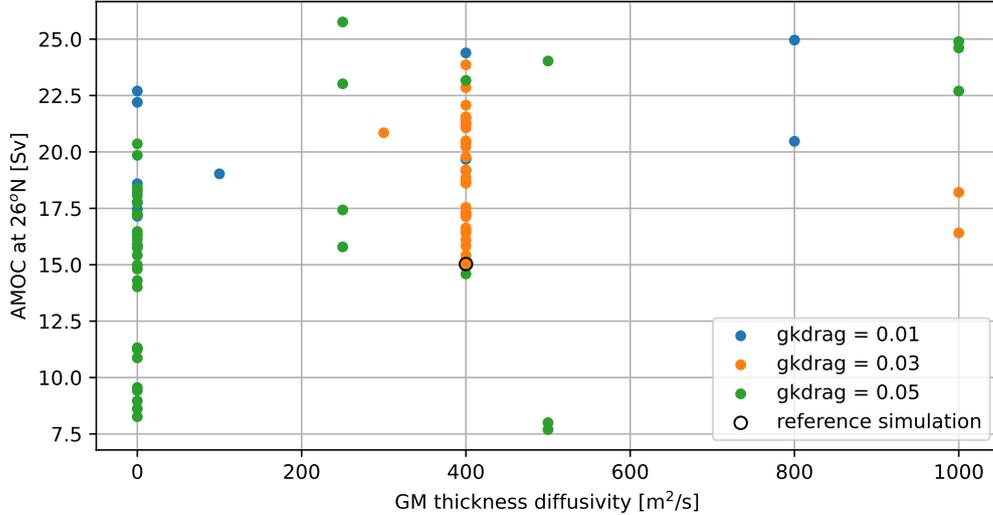

Figure 26. Scatterplot relating the eddy diffusion parameter κ with the strength of the AMOC at 26°N. The black circle indicates the standard experiment (piControl) and colors refer to different choices of the gravity wave drag parameter $gkdrag$.

958 like discretization used in ICON-O. As the new sea ice dynamics are realized on the same
 959 grid as ICON-O the coupling requires no rotations and promises a better representation
 960 of the bathymetry. While the deficits in the simulated sea-ice climatology documented
 961 here may be related to problems in sea-ice thermodynamics, we expect improvement from
 962 the new dynamics, e.g., for the representation of narrow passages and the related ice trans-
 963 ports. By affecting fresh-water exchanges, the latter could lead to improvements in water
 964 mass properties and air-sea exchanges for example in the Labrador Sea.

965 Ongoing development work will further explore ICON-specific opportunities like
 966 grid refinement in ICON-O (Logemann et al., 2021) and nesting in the atmosphere (Jungandreas
 967 et al., 2021). The excellent scaling capabilities of ICON have been documented in the
 968 DYAMOND project with ICON-A setups between 80 and 2.5 km (Stevens et al., 2019;
 969 Hohenegger et al., 2020) and are further explored in very high resolution coupled set-
 970 ups with grid spacing of a few kilometers in the DYAMOND-WINTER project ([https://](https://www.esiwace.eu/services/dyiamond/winter)
 971 www.esiwace.eu/services/dyiamond/winter).

972 While the ICON-A version described herein uses the physical parameterization pack-
 973 age inherited from ECHAM6 (Stevens et al., 2013; Giorgetta et al., 2018), which was de-
 974 signed for “climate” applications at grid sizes from 50 to 350 km, higher-resolution ICON
 975 application will require other choices. At km-scale, some parameterizations may become
 976 obsolete or will be better represented by schemes from the numerical weather-prediction
 977 version of ICON (Zängl et al., 2015). Therefore, a longer-term goal of the ICON com-
 978 munity is the development of a system for “seamless” predictions from weather to cli-
 979 mate scales.

980 6 Summary and conclusions

981 In this paper, we have documented ICON-ESM (V1.0), the first coupled model that
 982 is based on the ICON framework (Zängl et al., 2015) with its isosahedral grid concept.
 983 We have presented the first simulations with the coupled ICON-ESM (Lorenz et al., 2021)
 984 confronting it with the task to deliver reasonable results in a well-defined experimental

985 framework, the CMIP6 DECK simulations. Coupling of the newly developed component
 986 models and the tuning of the coupled model turned out to be more challenging than ex-
 987 pected. Tuning choices that revealed robust results in stand-alone simulations needed
 988 adjustment or reconfiguration in the presence of coupled feedbacks. The performance
 989 of the ICON-ESM reported in this paper can be summarized as follows:

990 1. We were able to fulfil the primary tuning goals: The 500-year long piControl sim-
 991 ulation exhibits little drift in key quantities like GSAT, radiation, sea-ice cover, and the
 992 AMOC TOA radiation is well balanced with little remaining drift. GSAT and other global
 993 quantities are close to observational estimates for the pre-industrial climate.

994 2. A set of five historical simulations reproduces the observed global surface tem-
 995 perature evolution largely in agreement with observational data sets, albeit with some-
 996 what too strong warming in the second half of the 20th century.

997 3. ICON-ESM's climate sensitivities (TCR, ECS) are slightly higher than the cor-
 998 responding values from MPI-ESM, but well in the range of the CMIP6 multi-model en-
 999 semble.

1000 4. The present-day climate simulated for the last decades reproduces largely the
 1001 climatology from observations and reanalyses, but biases are often larger than in ICON-
 1002 ESM's predecessor model MPI-ESM1.2 and other CMIP6 models.

1003 Problematic issues identified in the analyses are: In the atmosphere, the represen-
 1004 tation of both low-level and high-level clouds showed considerable deficits. Bias patterns,
 1005 which were already identified in stand-alone atmosphere simulations became more pro-
 1006 nounced in the coupled system. Counter-tuning that could have improved cloud distri-
 1007 butions had negative side effects on other parts of the climate system. Skill scores based
 1008 on wind and temperature data are worse than in MPI-ESM. In particular zonal wind bi-
 1009 ases remain and there is some indication that the parameterization of sub-grid scale oro-
 1010 graphic effects requires further attention.

1011 Overall, the rather zonal pattern of the LST biases hints to the global atmospheric
 1012 circulation as their major cause. Nevertheless, the land surface temperatures show re-
 1013 gional biases that may be traced to a misrepresentation of surface albedo values. The
 1014 biases over Antarctica and Greenland partly reflect albedo deviations over glaciers. Er-
 1015 rors in land temperatures over Eurasia are substantially caused by a too low snow cover
 1016 and the associated snow-albedo feedback. The biases could be partly improved by changes
 1017 in the near-infrared and visible albedo settings in JSBACH 4, but others are complex
 1018 and related to deficits in snow cover or soil and canopy albedo biases.

1019 In the ocean, SST and SSS climatologies show bias patterns and magnitudes compar-
 1020 able to other coarse-resolution CMIP5 or CMIP6 models, whereas the relatively large
 1021 sub-surface biases are of concern in particular in the tropical oceans. Here, a re-tuning
 1022 of the vertical mixing scheme might alleviate misrepresentation of wind-induced mixing.
 1023 From improvements in the upper-ocean stratification we expect also positive effects on
 1024 ENSO variability and processes in the tropical oceans. Northern hemisphere sea ice con-
 1025 centrations is somewhat too high in winter with too much ice cover, for example in the
 1026 Labrador Sea. On the other hand, the seasonal cycle is too strong leading to too thin
 1027 sea-ice in summer with only half of the Arctic basin being ice-covered in summer. The
 1028 seasonal cycle is also too strong in the southern hemisphere.

1029 ENSO variability in ICON-ESM is less close to observations than MPI-ESM's, but
 1030 similar to many other CMIP5 and CMIP6 models. The spectra derived from Nino3.4 time-
 1031 series of the historical simulations show a too narrow peak at about three years and an
 1032 overly high level of variance. The spatial patterns associated to ENSO variability agree
 1033 with the observed ones, but there are too strong signals in the warm pool and in the In-
 1034 dian Ocean.

1035 We emphasize that the present configuration is the first milestone in establishing
 1036 ICON-ESM as a highly flexible modelling system. ICON-ESM V1 serves as a basis for
 1037 further developments that will take advantage of ICON-specific properties such as spa-
 1038 tially varying resolution, and coupled configurations at resolutions of a few kilometers
 1039 in atmosphere, land, and ocean.

1040 7 Data Availability Statement

1041 The data from the ICON-ESM V1.0 DECK simulations are available at the CMIP6
 1042 repository of the Earth System Grid Federation (Lorenz et al., 2021) and can be accessed
 1043 at <http://esgf-data.dkrz.de/search/cmip6-dkrz/>. The model code of ICON is avail-
 1044 able to individuals under licenses ([https://mpimet.mpg.de/en/science/modeling-with-
 1045 -icon/code-availability](https://mpimet.mpg.de/en/science/modeling-with-icon/code-availability)). By downloading the ICON source code, the user accepts
 1046 the licence agreement. The source code of the ICON-ESM-V1.0 used in this study, pri-
 1047 mary data, and scripts used in the analyses and for producing the figures can be obtained
 1048 from the WDCC Long Term Archive ([http://cera-www.dkrz.de/WDCC/ui/Compact.jsp
 1049 ?acronym=RUBY-0_ICON-ESM_V1.0_Model1](http://cera-www.dkrz.de/WDCC/ui/Compact.jsp?acronym=RUBY-0_ICON-ESM_V1.0_Model1)).

1050 Acknowledgments

1051 We thank the German Climate Computer Centre DKRZ for providing the computational
 1052 resources. TI was supported by the European Union’s Horizon 2020 research and inno-
 1053 vation program under grant agreement No 101003536 (ESM2025 – Earth System Mod-
 1054 els for the Future) and under grant agreement No 820989 (COMFORT)”. TI and FC
 1055 were supported by the Deutsche Forschungsgemeinschaft (DFG, German Research Foun-
 1056 dation) under Germany’s Excellence Strategy - EXC 2037 ‘Climate Climatic Change and
 1057 Society’ (CLICCS) - Project Number: 390683824 and by the European Union’s Hori-
 1058 zon 2020 research and innovation programme under grant agreement number 773421 -
 1059 project ”Nunataryuk”. This paper is a contribution to the project S2 (PIs JJ and NB)
 1060 of the Collaborative Research Centre TRR 181 ”Energy Transfers in Atmosphere and
 1061 Ocean” funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foun-
 1062 dation) - Project nr. 274762653. HP received funding by DWD’s ”Innovation Programme
 1063 for Applied Researches and Developments” (IAFE VH3.5). FZ was supported by the Ger-
 1064 man Federal Ministry of Education and Research (BMBF) as a Research for Sustain-
 1065 ability initiative (FONA) through the project PalMod (FKZ: 01LP1502A) and by the
 1066 European Union’s Horizon 2020 research and innovation programme under grant agree-
 1067 ment No 823988 (ESiWACE2). The CMIP6 participation received funding by the BMBF
 1068 via the project CMIP6-DICAD (FKZ: 01LP1605A).
