Abstract

The magnetohydrodynamics with embedded particle-in-cell (MHD-EPIC) model has been successfully applied to global magnetospheric simulations in recent years. However, the PIC region was restricted to be a box, which is not always feasible for covering the whole physical structure of interest. The FLexible Exascale Kinetic Simulator (FLEKS), which is a new PIC code and allows a PIC region of any shape, is designed to break this restriction. It is usually used as the PIC component of the MHD with adaptively embedded particle-in-cell (MHD-AEPIC) model. FLEKS supports dynamically activating or deactivating cells to fit the regions of interest during a simulation. An adaptive time-stepping scheme is also introduced to improve the accuracy and efficiency of a long simulation. The particle number per cell may increase or decrease significantly and lead to load imbalance and large statistical noise in the cells with fewer particles. A particle splitting scheme and a particle merging algorithm are designed to limit the change of the particle number and hence improve the simulation load balancing. Both particle splitting and particle merging conserve the total mass, momentum, and energy. FLEKS also contains a test-particle module to enable tracking particle trajectories with the time-dependent electromagnetic that is obtained from a global simulation.

FLEKS: A Flexible Particle-in-Cell code for Multi-Scale Plasma Simulations

Abstract

The magnetohydrodynamics with embedded particle-in-cell (MHD-EPIC) model has been successfully applied to global magnetospheric simulations in recent years. However, the PIC region was restricted to be one or more static boxes, which is not always sufficient to cover the whole physical structure of interest efficiently. The FLexible Exascale Kinetic Simulator (FLEKS), which is a new PIC code and allows a dynamic PIC region of any shape, is designed to break this restriction. FLEKS is usually used as the PIC component of the MHD with adaptively embedded particle-in-cell (MHD-AEPIC) model. FLEKS supports dynamically activating or deactivating cells to fit the regions of interest during a simulation. An adaptive time-stepping scheme is also introduced to improve the accuracy and efficiency of a long simulation. The particle number per cell may increase or decrease significantly and lead to load imbalance and large statistical noise in the cells with fewer particles. A particle splitting scheme and a particle merging algorithm are designed to limit the change of the particle number and hence improve the accuracy of the simulation as well as load balancing. Both particle splitting and particle merging conserve the total mass, momentum, and energy. FLEKS also contains a test-particle module to enable tracking particle trajectories due to the time-dependent electromagnetic field that is obtained from a global simulation.

Keywords: particle-in-cell; particle merging; test particle; global kinetic simulation

1 1. Introduction

Multi-scale plasma simulations are challenging due to the limitation of 2 computational resources. Fluid models are efficient for global simulations, 3 but kinetic-scale physics is missing. Fully kinetic codes, such as particle-incell (PIC) codes and Vlasov solvers, contain electron and ion scale physics. 5 However, it is extremely computationally expensive to resolve the global scale and the electron scale at the same time for three-dimensional (3D) 7 global simulations. Traditional hybrid models, which usually treat electrons as a massless fluid and simulate ions with a PIC method or a Vlasov solver, 9 incorporate ion-scale physics into global simulations by sacrificing electron-10 scale kinetic physics. Another class of hybrid methods embeds a kinetic code 11 into a global fluid model so that the kinetic code can resolve the regions 12 where the kinetic physics is important, and the fluid model handles the rest 13 of the domain efficiency. In recent years, independent groups have developed 14 models that couple either a PIC code [1] or a Vlasov solver [2] with a fluid 15 model. 16

Sugivama and Kusano [3] demonstrated the concept of coupling a PIC 17 code with a fluid code. The magnetohydrodynamics (MHD) with embedded 18 particle-in-cell (MHD-EPIC) model developed by Daldorff et al. [1] is the 19 first mature coupled model that is capable of running 3D large-scale simu-20 lations. The MHD-EPIC model usually covers the dayside or/and the tail 21 magnetic reconnection sites with the PIC code when it is applied to simulate 22 the dynamics of magnetospheres [4, 5, 6, 7]. Multiple isolated PIC domains 23 are supported so that a few regions of interest can be covered by the PIC 24 code in one simulation [4]. However, in an MHD-EPIC simulation, each PIC 25 region is restricted to be a static box, which is not always efficient or suitable 26 to cover the whole physical structure of interest due to either the limitation of 27 computational resources or geometric complexity of the physical region. Re-28 cently, Shou et al. [8] developed the magnetohydrodynamics with adaptively 29 embedded particle-in-cell (MHD-AEPIC) model, which allows changing the 30 location of an active PIC region dynamically. 31

In this paper, we introduce a new code, the FLexible Exascale Kinetic Simulator (FLEKS), which is designed and implemented to be the PIC component of the MHD-AEPIC model. FLEKS shares some similarities with the Adaptive Mesh Particle Simulator (AMPS) used in the work by Shou et al. [8], but FLEKS provides a more flexible grid design. FLEKS uses the
parallel data structures provided by the AMReX library [9, 10]. The grid of
FLEKS has to be uniform and Cartesian, but the active PIC region is not
limited to be a box anymore since the PIC cells can be turned off to fit the
region of interest. Furthermore, FLEKS also supports switching on and off
grid cells dynamically for MHD-AEPIC simulations.

FLEKS employs the Gauss's law satisfying energy-conserving semi-implicit 42 method (GL-ECSIM) [11] as the base PIC solver. The time step of the 43 semi-implicit PIC methods is limited by the Courant–Friedrichs–Lewy (CFL) 44 condition based on the macro-particle velocities in order to be accurate [12]. 45 Since the speed of macro-particles may change significantly during a long 46 MHD-AEPIC simulation, the simulation will be either too slow or inaccu-47 rate with a fixed time step. To keep the simulation efficient and accurate 48 at the same time, FLEKS uses an adaptive time-stepping algorithm, which 40 still satisfies the requirement of the energy-conserving semi-implicit method 50 (ECSIM) [13] to keep energy conservation. Section 2 describes the adaptive 51 grid and temporal discretization of FLEKS. 52

The statistical noise of macro-particles is the primary source of numeri-53 cal error in typical PIC simulations. Dozens to hundreds of particles per cell 54 are usually used to achieve a balance between accuracy and computational 55 cost. Since there are much more macro-particles than grid cells in a ki-56 netic PIC simulation, particle-related calculations, such as updating particle 57 positions and velocities, dominate the total computational time. In addi-58 tion, a massively parallel simulation can be significantly slowed down due to 59 the imbalance of macro-particle numbers among the parallel processes. On 60 the other hand, the decrease of the number of macro-particles in some cells 61 increases the statistical noise and reduces the accuracy. A particle resam-62 pling algorithm that is able to control the macro-particle number per cell 63 is crucial for improving both the simulation efficiency and accuracy. More 64 macro-particles need to be added into the cells that contain fewer macro-65 particles than required to represent the plasma velocity-space distribution 66 accurately. This goal is usually achieved by splitting particles. In the cells 67 with more macro-particles than some threshold, a particle merging algorithm 68 needs to be applied to reduce the number of macro-particles and speed up the 69 simulation. A particle resampling algorithm is even more crucial for a PIC 70 code with adaptive mesh refinement, where the motion of macro-particles 71 between the coarse and fine cells alters the macro-particle number per cell 72 dramatically [14, 15]. 73

⁷⁴Both the particle splitting and particle merging processes replace the ⁷⁵original particles with a set of new particles. Lapenta [16] suggested that the ⁷⁶replacement should maintain the following properties:

- 77
- 78 79

1. The plasma moments evaluated on the simulation grid, which are used to update electric and magnetic fields, should not be changed by the replacement.

80 81 2. The replacement should keep the original particle phase space distributions.

It is more challenging to achieve these two goals for a particle merging al-82 gorithm than for a particle splitting algorithm, because it is inevitable to 83 lose information when replacing original particles with fewer particles. A few 84 algorithms have been designed to merge particles. Lapenta [16] introduced 85 two algorithms to merge particles that are close to each other in the phase 86 space. The algorithm C1 merges two particles into one, and the algorithm 87 C2 merges three particles into two. The algorithm C2 conserves the mass, 88 momentum, and energy of the particles, and also the charge densities on 89 the grid, but it is not straightforward to extend to 2D and 3D. Vranic et 90 al. [17] also proposed an algorithm to merge particles into two new particles 91 while conserving the overall mass, momentum, and energy, and the original 92 particles are chosen by binning particles in the momentum space. Instead 93 of merging a few particles into one or two, the algorithms designed by As-94 sous et al. [18], Welch et al. [19], Pfeiffer et al. [20], and Faghihi et al. 95 [21] use a set of particles to replace the old ones. Assous et al. [18] and 96 Welch et al. [19] focused on the conservation of the grid quantities, but the 97 fine structures in the velocity space may not be well preserved. Pfeiffer et 98 al. [20] generated the new particle velocities from a distribution function 99 and adjusted the velocities to conserve energy afterward. Faghihi et al. [21] 100 created new particles with a uniform distribution inside a phase space bin, 101 and adjusted the weights to conserve the moments. As a general rule, the 102 particles selected for merging should be close to each other in the phase space 103 to minimize the error that is introduced by merging. Besides the method of 104 binning the velocity space [17, 21], Teunissen and Ebert [22] applied a k-d 105 tree to find the particles that are closest to each other, and Luu et al. [23] 106 showed how to partition particles with the Voronoi diagram. Our new parti-107 cle merging algorithm implemented into FLEKS searches for 6 particles that 108 are close in phase space and merges them into 5 particles while preserving 109 mass, momentum and energy and also minimizes the change in the phase 110

Figure 1: A schematic shows the improvement of the MHD-AEPIC (right) model from the MHD-EPIC (left) model.

space distribution. The details of the splitting and merging algorithms are described in section 4.

Tracking the motion of macro-particles is useful for investigating the particle trajectories and the energization of particles. FLEKS provides a parallel test particle module to follow the motion of macro-particles and save the particle trajectory data to disk. The test particle module can be used either inside the PIC code, or as an independent component directly coupled to the MHD model. Section 5 describes the implementation details of the test particle module.

The paper is organized as follows. Section 2 describes the grid design of 120 FLEKS. Section 3 introduces the adaptive time-stepping scheme. Section 4 121 focuses on the particle splitting and particle merging algorithms. Section 5 122 discusses the implementation of the test particle module. Section 6 presents 123 numerical tests to demonstrate the capability of the adaptive active PIC 124 regions, the role of the particle resampling algorithms, the parallel efficiency 125 of FLEKS, and examples of global simulations with FLEKS. Finally, section 126 7 presents the conclusions. 127

128 2. Adaptive grid

Since the MHD-EPIC model was developed by Daldorff et al. [1], we have developed new features to make it more flexible to use. It now supports multiple independent PIC domains to cover several regions of interest [4], and it also allows rotating a PIC box domain to align with the features of interest [24]. However, a box is not always suitable or efficient to cover the region of interest. For example, if a PIC box is used to cover the whole dayside

magnetopause, which is close to a paraboloid, the box will cut through the 135 planet and introduce extra difficulties, and the PIC box will also contain 136 a large portion of cells, where the kinetic effects are not important, which 137 slows down the simulation. A flexible grid that allows creating an active PIC 138 domain that approximates the shape of a paraboloid to fit the magnetopause 139 can solve this problems. A dynamically adaptive grid is also useful to improve 140 the efficiency of some simulations. For instance, the near-Earth X-line may 141 move from the inner magnetotail to the middle or even far magnetotail [25], 142 and an adaptive grid that only covers the environment around the X-line is 143 much more efficient than a large PIC box that covers the whole magnetotail. 144 The MHD-AEPIC algorithm is designed to solve these problems and FLEKS 145 is the key component. Figure 1 shows the conceptual difference between the 146 MHD-EPIC and MHD-AEPIC models. 147

FLEKS still requires the shape of the full PIC grid to be a box, and the 148 Cartesian grid has to be uniform (this is a requirement of the GL-ECSIM 149 algorithm). But FLEKS allows switching off part of the cells to approx-150 imately fit a region of any shape. The most straightforward approach is 151 switching on/off each cell independently. However, this approach has several 152 drawbacks, as discussed below, so we make the algorithm a bit more sophis-153 ticated. We divide the whole PIC domain into patches (Figure 2(a)). Each 154 patch contains N cells in each direction, and one can turn on or turn off 155 each patch. The patch size N is required to be larger or equal to 2. We do 156 not allow N = 1 (switching on/off each cell independently) for the follow-157 ing reasons. FLEKS requires two ghost cell layers for coupling with MHD 158 at the PIC region boundary. If N = 1, the boundary ghost cells of an ac-159 tive region may overlap with the physical cells of another active region, and 160 hence introduces more difficulties to handle the boundary ghost cells. A large 161 patch size also benefits the coupling efficiency. In MHD-AEPIC simulations, 162 the fluid model controls the status of the patches based on geometric and 163 physics-based criteria [25]. The fluid model passes the bit-wise patch status 164 array to FLEKS through the Message Passing Interface (MPI), and the size 165 of this array is reduced significantly with a larger patch size (proportional to 166 N^{-3} in 3D). In this paper, we use the word 'active' to describe the patches 167 or cells that are switched on. The active cells do not have to be connected, 168 and the boundary ghost cells of the active regions are filled in with the in-169 formation obtained from the fluid model [1]. Figure 2(a) shows an example 170 that contains two separated active regions. 171

172

FLEKS uses the data structures provided by the AMReX library to store

the fields and also the particles. After the patch status array is obtained from the fluid model, FLEKS uses the functions provided by the AMReX library to divide the active regions into blocks. AMRex does not require all the blocks to have the same size. We note that the patch and the block are two independent concepts. The patches are only used to activate or deactivate cells. For example, the 'L' shape active region in Figure 2(a) consists of 3 patches and it can be divided into 2 blocks (Figure 2(b)).

FLEKS allows activating or deactivating patches during a simulation. If the active regions change, FLEKS will produce a new set of blocks to cover the new active regions. With the function provided by AMReX, FLEKS copies the fields and particles from the old blocks to the new ones for the cells that are already active and deletes the information of the newly deactivated cells. The newly activated cells are filled in with the information obtained from the fluid model as what is done for FLEKS initialization.

FLEKS has two ghost cell layers, but the outer layer is only used to receive 187 and store the magnetic fields, which are necessary for calculating currents on 188 the nodes of the inner ghost cell layer from $\vec{J} = \nabla \times \vec{B}$ in normalized units. 189 The currents are used to generate particles with correct velocities in the inner 190 layer ghost cells. To simplify the description, we ignore the outer layer in 191 Figure 2(c) and also in the rest of the paper unless otherwise specified. The 192 principle of setting boundary conditions of the electromagnetic fields and the 193 particles is still the same as the MHD-EPIC coupling algorithm [1]. However, 194 the non-box shape of an active region introduces some extra implementation 195 difficulties. There are three types of ghost cells for a block: the internal ghost 196 cells (blue cells in Figure 2(c)), the exclusive boundary ghost cells (gray cells 197 in Figure 2(c) and the shared boundary ghost cells (cyan cells in Figure 2(c)). 198 The internal ghost cells are not boundary cells, and there is no need to apply 199 boundary conditions. The exclusive boundary ghost cells are not overlapped 200 with any cells of the neighboring blocks, and they should be filled in with new 201 macro-particles as the particle boundary condition. The shared boundary 202 ghost cells are overlapped with the boundary ghost cells of the neighboring 203 blocks, and only one of these blocks should generate boundary particles. 204 Here is the algorithm to choose the block for populating new particles. The 205 first step is to distinguish the boundary ghost cells from the internal ghost 206 cells. Then, for each boundary ghost cell, either the exclusive type or the 207 shared type, we loop through its at most 26 neighboring cells (3D) in a fixed 208 order (we choose to loop through all the face neighbors first, then the edge 209 neighbors, and finally the corner neighbors), skip the nonexistent cells and 210

find out the first neighboring cell that is either a physical cell or an internal 211 ghost cell. If this neighboring cell is inside the physical domain of this block, 212 this block should generate particles inside this boundary ghost cell. For 213 example, in Figure 2(c), C1 and C3 are overlapped with each other. We 214 loop through the neighboring cells of C1 and find C2 is its first neighboring 215 cell that is either a physical cell or an internal ghost cell (C2 is a physical 216 cell), so block-1 should generate particles in C1 since C2 is inside block-1. We 217 repeat the same procedure for the cell C3, and find C4 is its first neighboring 218 cell that is either a physical cell or an internal ghost cell (C3 is an internal 210 ghost cell), but block-2 should not generate particles in C3 since C4 is outside 220 the physical domain of block-2. 221

The electric fields are node-based in FLEKS. For a node that is shared by multiple blocks, such as the one indicated by a red-cross in Figure 2(c)), only one block should take care of the shared node when solving the linear equations of the electric fields. The aforementioned algorithm is also applied to choose the proper block for a shared node.

227 3. Adaptive time-stepping

The time step of the energy-conserving semi-implicit method (ECSIM) 228 is subject to the accuracy condition $v_{rms}\Delta t/\Delta x < 1$ just as other semi-229 implicit PIC methods [12], where v_{rms} is the maximum root mean square of 230 macro-particle velocities. For a long MHD-AEPIC simulation, v_{rms} may vary 231 significantly, so an adaptive time-stepping algorithm that adjusts time-step 232 accordingly will improve the simulation efficiency and accuracy. However, 233 the energy conservation property of ECSIM is sensitive to the temporal dis-234 cretization scheme, and the adaptive time-stepping algorithm should not 235 break the conservation. 236

Our adaptive time-stepping algorithm is summarized in Figure 3. At the 237 end of one cycle, both the electromagnetic fields and the particle velocities are 238 at time stage t^n , and the particle locations are at the staggered stage $t^{n+1/2}$. 239 The difference between $t^{n+1/2}$ and t^n is $t^{n+1/2} - t^n = \Delta t^n/2$. The maximum 240 speed v_{rms} can be obtained with the particle velocities at t^n , and a new 241 time step Δt^{n+1} can be calculated from $\Delta t^{n+1} = \text{CFL} \cdot \Delta x / v_{rms}$. However, 242 during the next cycle of updating the electromagnetic fields and particle 243 velocities from t^n to t^{n+1} , the time step should be Δt^n instead of Δt^{n+1} , so 244 that the particle location $X^{n+1/2}$ is still at the middle of t^n and t^{n+1} , and 245 the energy conservation property of ECSIM is preserved. In order to adjust 246

Figure 2: The black lines represent the cells of a PIC domain. The red dashed lines in (a) show the patches, and one patch contains 4×4 cells in this example. In (a), the active patches/cells are colored by dark gray, and light gray area represents the ghost cells of the active PIC regions. (b) shows the blocks of the active regions. (c) shows the inner layer of the ghost cells of two blocks, and the red dots represent the macro-particles that are generated in the ghost cells as the particle boundary condition. Blue ghost cells are internal ghost cells, which are overlapped with the physical cells of the neighboring blocks. The gray cells are exclusive boundary ghost cells, and they should be filled in with macro-particles as the boundary condition. The cyan cells are also boundary ghost cells, but they are overlapped with the boundary ghost cells of the neighboring blocks, and only one of the blocks should generate boundary particles. The C1...C4 labels and the two red crosses are used in the main text describing the algorithm.

Figure 3: The adaptive temporal discretization.

the time step for the next cycle, we use the time step $(\Delta t^n + \Delta t^{n+1})/2$ for updating the particle location from $X^{n+1/2}$ to $X^{n+3/2}$. The velocity V^{n+1} at t^{n+1} is not centered exactly between $t^{n+1/2}$ and $t^{n+3/2}$, but the deviation $(\Delta t^{n+1} - \Delta t^n) \propto (\partial \ln v_{rms}/\partial t)(\Delta t^n)^2$ is second order since the v_{rms} used to calculate the time steps changes continuously with time. Therefore the second-order accuracy of updating particle locations is still satisfied.

4. Particle resampling

Particle resampling algorithms are used to control the macro-particle 254 number of each cell. At the end of every computational cycle, a particle 255 splitting (merging) algorithm is applied to generate (remove) macro-particles 256 for the cells that contain fewer (more) particles than the splitting (merging) 257 threshold. The goal of splitting and merging is to stop the number of parti-258 cles per cell (ppc) from dropping or increasing continually. Essentially, the 259 particle resampling algorithms use a new set of particles to replace the old 260 ones. Our guiding principle of designing the algorithms is that the replace-261 ment should preserve the original particle phase space distribution as much as 262 possible. In order to conveniently apply the resampling algorithms, FLEKS 263 stores the particle data cell by cell. 264

265 4.1. Particle splitting

Our particle splitting algorithm is essentially the same as the one introduced by Lapenta [16], in which one particle is split into two children particles. The children particles have the same velocity as their parent particle, but their locations are oppositely displaced slightly along the velocity direction. By displacing the new particles along the velocity direction, the orbits of the new particles are still close to the orbit of the old particle.

The particle splitting will be triggered for the cells with ppc less than the 272 splitting threshold, which is 80% of the initial ppc by default, and we will 273 use this number for all the simulations presented in section 6. Initially, the 274 particles that are close to each other have similar weights, but the weights 275 may become quite different later due to the transport of particles and also the 276 particle splitting and merging. For each cell, we choose to split the heaviest 277 N particles to minimize the particle weight variance, where N is the difference 278 between the current ppc and the splitting threshold. 279

280 4.2. Particle merging

The essence of particle merging is replacing a set of particles with a new 281 set, which contains fewer particles than the old set. Particle merging reduces 282 the particle number in some cells and improves simulation speed. In gen-283 eral, particle merging has a negative impact on the accuracy of a simulation 284 because (1) the replacement introduces errors, and (2) fewer particles lead 285 to larger statistical noise in the subsequent simulation. The statistical noise 286 increasing is inevitable, but the errors caused by the replacement can be 287 minimized with a proper merging algorithm. 288

Our particle merging algorithm consists of two steps: (1) selecting 6 particles that are close to each other in the phase space, and (2) merging these 6 particles into 5. In the following subsections, we will describe the merging step first, and what follows is the selecting step.

293 4.2.1. Merging particles

Once the 6 old particles for merging have been obtained from the select-294 ing step, we use 5 new particles to replace them. The replacement should 295 not alter the original phase space distribution significantly. However, it is 296 not trivial to quantitatively measure the change of the phase space. The 297 conservation of total mass, momentum, and energy can be used as a guid-298 ance and indicator of preserving phase space structure. However, satisfying 290 the conservation property is not good enough, it is still possible that the 300 new particle set occupies a very different velocity space volume than the old 301 set. Previous methods [26, 17] usually generate new particles with velocities 302 that are different from the velocities of the old particles, and extra actions 303

are usually required to ensure the new particles are not too far away from the old ones in the velocity space. To avoid this difficulty, we choose to delete one of the 6 old particles and distribute its mass to the remaining 5 particles under the constraint of conserving total mass, momentum vector, and energy. The weights of these 5 particles change, but their velocities are inherited from the old ones, so the new particle set occupies almost the same phase space volume as the old set.

The total mass, momentum and energy of the old particle set are:

$$w_t = \sum_{i=1}^{N_{old}} w_i, \qquad \mathbf{p}_t = \sum_{i=1}^{N_{old}} w_i \mathbf{v}_i, \qquad e_t = \sum_{i=1}^{N_{old}} \frac{1}{2} w_i v_i^2, \tag{1}$$

where $N_{old} = 6$. From these 6 particles, we find the pair that is closest to each other in the 6D phase space (Figure 4(d)), then remove the lighter one of this pair and adjust the weights of the rest 5 particles to satisfy the conservation requirement:

$$w_t = \sum_{i=1}^{N_{new}} w_{i,new}, \quad \mathbf{p}_t = \sum_{i=1}^{N_{new}} w_{i,new} \mathbf{v}_i, \quad e_t = \sum_{i=1}^{N_{new}} \frac{1}{2} w_{i,new} v_i^2 \qquad (2)$$

$$w_{i,new} > 0 \tag{3}$$

where we choose $N_{new} = 5$ since there are 5 quantities to conserve. The velocities \mathbf{v}_i are known, and the new weights $w_{i,new}$ are the 5 unknowns of the linear equations (2) under the constraint of positivity (3). If the solution does not satisfy the constraint, we skip this merging.

To minimize the impact of the merging on the phase space distribution, we need to quantify a distance in the 6D phase space. The actual definition will be described in the next subsection, here we simply assume that the appropriate distance function exists.

By deleting the lighter particle from a pair that is closest to each other 324 in the phase space, it is likely that its heavier neighbor will gain most of the 325 weight and the other 4 particles adjust their weights relatively slightly. By 326 inheriting the velocities and locations from the old particles, the new particles 327 occupy almost the same phase space volume as the old particles (Figure 4(d)) 328 and (e)), so there is no room for the phase space structure to change dramat-329 ically. Compared to the schemes that allow choosing new particle velocity 330 with fewer restrictions [17], our merging algorithm is less efficient to reduce 331

the particle number because (1) the new particle set still contains 5 particles, and (2) the merging may fail when the constraint $w_{i,new} > 0$ can not be satisfied. If it is required, our algorithm can be easily modified to use a N_{old} that is larger than 6 by deleting $N_{old} - 5$ particles. However, as it can be seen from the following numerical test section, merging 6 particles into 5 is already efficient enough for our typical applications.

338 4.2.2. Selecting particles

To minimize the phase space change, the particles selected for merging 339 should be close to each other in the 6D phase space. Several strategies have 340 been proposed for selecting particles, including binning particles in the phase 341 space [21], partitioning phase space with Voronoi diagram [23], and using k-d 342 tree data structure [22]. For the sake of simplicity, we choose the binning 343 strategy. The dimension of the 6D phase space is so high that even only 344 splitting each direction into 3 pieces leads to $3^6 = 729$ bins in total. Our 345 typical simulations use about 100 particles per cell initially, and it is likely 346 few phase space bins contain enough particles for merging with 3^6 bins. To 347 avoid this problem, we only bin particles in the 3D velocity space and skip the 348 merging if the 6D volume occupied by the selected particles is too large. This 349 approach takes into account the spatial distribution of the selected particles, 350 but also implies reducing the variance in the velocity space is more crucial 351 than controlling the spatial location variance. Because all the particles are 352 already in the same spatial cell, i.e., they can not be too far away from each 353 other in the spatial dimensions. Inside each velocity space bin, we choose 6 354 particles that are closest to each other for merging. 355

The particle merging algorithm needs to calculate the distance between two macro-particles in the 6D phase space. The distance is defined as:

$$d = \frac{\Delta s}{\Delta x} + c_1 \frac{\Delta v}{v_{th}} \tag{4}$$

where Δs is the spatial distance and Δv is the distance in the velocity space between the two particles. The normalization in space is the simulation cell size Δx . The velocity is normalized to the thermal velocity in the cell

$$v_{th} = \frac{1}{N_p} \sum_{i=1}^{N_p} |\mathbf{v}_i - \mathbf{v}|^2 \tag{5}$$

where \mathbf{v} it the bulk velocity of the cell and N_p is the number of particles in the cell. We note that the thermal velocity defined above is used to measure the seperation of particles in the velocity space, so the particle weight is not involved in the calculation. The constant c_1 in (4) determines the relative importance of the spatial distance Δl_{3D} and the velocity distance Δv . We choose $c_1 = 2$ based on our experience with many numerical tests.

At the end of each computational cycle, the following algorithm is performed to select particles for merging if the ppc of a cell is larger than the merging threshold, which is 1.5 times of the initial ppc by default:

1. Bin the particles in the velocity space. For each spatial cell (Fig-370 ure 4(a)), we create a grid in the velocity space ranging from $(v_x - v_y)$ 371 $v_{th}, v_y - v_{th}, v_z - v_{th}$ to $(v_x + v_{th}, v_y + v_{th}, v_z + v_{th})$, and assign par-372 ticles to velocity bins (Figure 4(b)). The velocity grid is divided into 373 $n_{bin} = \left[0.8 N_p^{1/3} \right]$ bins in each direction, where N_p is the current ppc of 374 the cell and the constant 0.8 is chosen based on numerical experiments. 375 We note that each bin contains a buffer region (Figure 4(c)), and the 376 particles in the buffer region may also belong to other bins. We use 377 1/8 of the velocity space bin size as the width of the buffer region (Fig-378 ure 4(c)). Due to the existence of the buffer region, one particle may 379 belong to multiple bins, but it can only be selected for merging at most 380 once during one cycle. 381

2. Select particles from a bin. If there are more than 6 particles inside a bin, including the buffer region, we choose a cluster of 6 particles from them. For each velocity bin, we calculate the velocity center of the associated particles (black cross in Figure 4(c)), and find the 6 particles closest to the center in the 3D velocity space. If a particle in the buffer region has been selected for merging by a neighboring bin, this particle should not be selected again.

389 3. Limit the 6D distance. The previous step selects particles only based 390 on the distance in the velocity space. This step ensures the selected 391 particles are also close to each other in the 6D phase space. We find 392 the 6D center (blue cross in Figure 4(d)) of these 6 particles, and the 393 6D distance d of all the 6 particles to the center should be less than 394 0.6. Again, the constant 0.6 is chosen based on numerical experiments.

³⁹⁵ 4. Merge 6 particles into 5 with the algorithm described in section 4.2.1.

The particle selection method used in step 2 prefers selecting particles in the center of a bin. Without applying the buffer region in step 1, the particles near the edge of a bin are less likely to be chosen for merging. On the other

Figure 4: Schematics of the algorithm of merging macro-particles. See text for details.

hand, it is more likely that a bin extended with a buffer region contains
more than 6 particles, which improves the merging efficiency. Based on
our numerical experiments, applying the buffer region does not improve the
simulation results significantly, but it is still kept by default to avoid the
aforementioned potential issues.

404 5. Test particle module

An independent test particle (TP) module is designed to track the motion of the macro-particles for FLEKS. It can be used either as an auxiliary component of the PIC algorithm or as an independent component. The TP module uses the same algorithm to move particles as the GL-ECSIM algorithm. When the TP module is used with the PIC component together, the

Figure 5: The file structure for storing test particles.

TP module shares the same grid layout as the PIC component and uses the 410 electromagnetic fields calculated by PIC to update test particles. When the 411 PIC component is turned off, FLEKS becomes a pure test particle code, and 412 the TP module can directly obtain the grid structure and electromagnetic 413 fields from the MHD model. Compared to the embedded PIC simulations, 414 the pure test particle simulations are only one-way coupled, i.e., the MHD 415 model provides the electromagnetic fields for FLEKS, but there is not any 416 feedback from FLEKS to the MHD model. 417

In a 3D simulation, it is common to track the motion of millions of test 418 particles, and a few thousand steps of the update will easily produce a few 419 hundred Gigabytes of particle trajectory data. The test particle module 420 should organize the data properly to improve both the IO performance of 421 writing data to disk and also the efficiency of reading the trajectory of a 422 particle for data analysis. To reduce the IO frequency, the TP module of 423 FLEKS saves the particle trajectory data every 100 cycles, and all the pro-424 cessors write to the same file with MPI-IO APIs. We note that if a test 425 particle moves from one processor to another in the middle of two IO op-426 erations, its trajectory data should also be transferred to the destination 427 processor. Besides the particle trajectory data file, a particle ID list file. 428 which maps a particle ID to its data location in the particle data file, is also 429 created. An example of these two files is shown in Figure 5. With this file 430 structure, it is efficient to find all the trajectory data of a particle for data 431 analysis. 432

433 6. Numerical tests

434 6.1. Two-dimensional fast magnetosonic wave propagation with adaptive PIC 435 region

We use a two-dimensional (2D) fast magnetosonic wave propagation test 436 to demonstrate the capability of FLEKS's adaptive grids. The same initial 437 condition as what is described in [1] is applied here to produce a propagat-438 ing fast magnetosonic wave. The simulation domain of the MHD code is 439 -160/3 < x < 160/3 and -40 < y < 40. Two independent PIC domains 440 are used. The left domain in Figure 6 covers the region of -40 < x < 0 and 441 -20 < y < 20 with a grid resolution of $\Delta x = \Delta y = 1/16$. The right domain 442 covers the region of 20 < x < 40 and -10 < y < 10 with a grid resolution 443 of $\Delta x = \Delta y = 1/8$. All cells of the right PIC domain are always switched 444 on during the simulation. For the left domain, only the cells that satisfy the 445 following conditions are switched on: 446

$$r < \frac{L_x}{10}$$
or
$$r < \frac{L_x}{4} + \frac{L_x}{4} \frac{t \mod 200}{200} \quad \text{and} \quad r > \frac{L_x}{8} + \frac{L_x}{10} \frac{t \mod 200}{200},$$
(6)

where r is the distance to the center of the PIC domain, L_x is the length of 447 the PIC domain, which is 40 in this case, and t is the simulate time. The 448 central PIC cells $(r < L_x/10)$ are always switched on, and the outer shell of 449 active PIC cells keep changing during the simulation. A movie that shows 450 the adaptation of the active PIC region is provided as an online supplement. 451 We note that the simulation parameters for these two PIC domains can be 452 specified independently. For example, the cell size is different for these two 453 PIC domains as it is described above, and the ion-electron mass ratio m_i/m_e 454 is 25 for the left domain and it is 100 for the right domain. Both PIC domains 455 use CFL = 0.2, and 900 particles per cell (ppc) per species. 456

Figure 6 shows the plasma velocity U_x and the area of the active PIC cells at the beginning and at t = 400. The interface between the active PIC region and the MHD region is smooth, and there is not any significant artificial effect observed.

461 6.2. One-dimensional non-linear magnetosonic wave evolution

The evolution of the magnetosonic wave is non-linear. The wave may finally evolve into a shock, where the plasma phase space distributions may

Figure 6: The velocity U_x of the 2D fast magnetosonic wave test at the beginning (left) and at t = 400 (right). The black rectangles show the area of the PIC grids. Inside each PIC grid, the semi-transparent area, which is enclosed by red lines, represents the active PIC region. Since all PIC cells are active for the right PIC grid, the black lines and the red lines are overlapped.

⁴⁶⁴ become non-Maxwellian. So the non-linear evolution of the magnetosonic⁴⁶⁵ wave simulation is suitable for testing the particle resampling algorithms.

In section 6.1, the wave vector is perpendicular to the background magnetic field direction. To make the particle phase space distribution further away from Maxwellian and hence more challenging for the particle resampling algorithms, we use a more general setting that the background magnetic field is neither perpendicular nor parallel to the wave vector in this 1D test. The ⁴⁷¹ initial condition of the 1D magnetosonic wave is:

$$B_{x}(x) = B_{0} \cos(\theta)$$

$$B_{y}(x) = B_{0} [\sin(\theta) + \delta \sin(kx - \omega t)]$$

$$B_{z}(x) = 0$$

$$u_{x}(x) = \delta \sin(\theta) \frac{v_{A}^{2} v_{p}}{v_{p}^{2} - v_{s}^{2}} \sin(kx - \omega t)$$

$$u_{y}(x) = \delta \cos(\theta) \frac{v_{A}^{2}}{v_{p}} \sin(kx - \omega t)$$

$$u_{z}(x) = 0$$

$$\rho(x) = \rho_{0} \left[1 + \delta \sin(\theta) \frac{v_{A}^{2}}{v_{p}^{2} - v_{s}^{2}} \sin(kx - \omega t) \right]$$

$$p(x) = p_{0} \left[1 + \gamma \delta \sin(\theta) \frac{v_{A}^{2}}{v_{p}^{2} - v_{s}^{2}} \sin(kx - \omega t) \right],$$
(7)

where γ is the specific heat ratio, $v_A = \frac{B_0}{\sqrt{\rho_0}}$ is the Alfven speed, $v_s = \sqrt{\frac{\gamma p_0}{\rho_0}}$ is the sound speed, and θ is the angle between the wave vector, which is the x-direction here, and the background magnetic field. The phase speed $v_p = \omega/k$ is the fast magnetosonic speed:

$$v_p^2 = \frac{1}{2} \left\{ v_A^2 + v_s^2 + \left[(v_A^2 + v_s^2)^2 - 4v_s^2 v_A^2 \cos^2 \theta \right]^{1/2} \right\},\tag{8}$$

In this paper, we use $\gamma = 5/3$, $B_0 = 0.1$, $\theta = 30^\circ$, $\rho_0 = 1$, $p_0 = 0.0001$, $k = 2\pi/\lambda = 2\pi/64$, and $\delta = 0.5$. We note that the perturbation $\delta = 0.5$ is not small so that the solution will evolve to the nonlinear stage soon. Since the goal of this test is to compare the simulation results with and without particle resampling, it is suitable and acceptable to use such a large perturbation.

The 1D simulation domain is -32 < x < 32 with a cell size $\Delta x = 0.05$. 482 The initial number of particles per cell per species is 900, and CFL = 0.2. 483 The simulation results at t = 200 are presented in Figure 7. To distinguish 484 between the physical density and macro-particle number per cell, we use 485 'mass density' to represent the physical density, and 'number density' is the 486 number of macro-particles per simulation cell or phase space bin. At t = 200, 487 the wave already evolves into a non-linear state, and the velocity shows a 488 sharp gradient near x = 20. The minimum and maximum number of ppc are 489

about 500 and 3140, respectively, for the simulation without applying particle 490 resampling. For the simulation with particle resampling, the minimum ppc 491 is about 750 and the maximum ppc is about 1360, and these numbers are 492 close to the splitting limit 0.8 * 900 = 720 and the merging limit 1.5 * 900 =493 1350. It suggests that the particle resampling algorithms are effective in 494 controlling particle numbers. Except for the particle number, the physical 495 quantities of these two simulations are very similar to each other. The only 496 noticeable difference is that the electric field E_y of the simulation with particle 497 resampling is noisier near x = 20 due to the reduction of particle number. 498 Figure 7(b) shows the ion phase space distribution for particles between 499 x = 21 and x = 21.2. The two mass density distributions are comparable 500 even though the particle number densities are quite different. 501

Figure 8 shows the simulation speed, which represents the number of PIC 502 cells that are updated per second per CPU core. For the first 700 cycles, both 503 simulations become slower and slower due to the imbalance of the particle 504 number per CPU core. Later, the minimum and maximum ppc reach the 505 splitting and merging thresholds and the particle splitting algorithms start 506 controlling the further change of the minimum and maximum ppc, so the 507 simulation speed stops dropping for the simulation with particle resampling. 508 At the end of the simulation, the simulation with particle resampling is almost 509 twice faster than the one without particle resampling. 510

511 6.3. Two-dimensional double-current-sheet magnetic reconnection

Magnetic reconnection is regarded as one of the most important physical 512 processes for energy transfer between magnetic field and plasma in the space 513 plasma environment, so it is also widely used to benchmark the performance 514 of a kinetic plasma modeling code. Here, we use a two-dimensional (2D) 515 asymmetric magnetic reconnection problem to test the particle resampling 516 algorithms, because the particles distributions near the reconnection site can 517 be non-Maxwellian. It is crucial to demonstrate that the particle resampling 518 algorithms preserve the non-Maxwellian distributions. 519

A double current sheet is used to initialize the simulation so that the whole system is symmetric, and periodic boundary conditions can be applied in all directions. The simulation domain is -64 < x < 64 and -16 < y < 16. The background magnetic field is initialized as:

$$B_x(y) = \left(\frac{B_1 + B_2}{2}\right) \left[\tanh\left(\frac{y + L_y/4}{\delta}\right) - \tanh\left(\frac{y - L_y/4}{\delta}\right) \right] - B_2, \quad (9)$$

Figure 7: The 1D magnetosonic wave simulation results at t = 200. (b) shows phase space distributions at x = 21 that is marked with a dashed black line in (a). The upper panel of (b) shows the results without particle resampling, and the lower panel shows the results with particle resampling.

Figure 8: The simulation speed of the 1D magnetosonic wave simulations.

where $B_1 = 1$ and $B_2 = 2$ are the asymptotic magnetic field amplitudes. 524 $L_y = 32$ is the width of the simulation domain, and the centers of the two 525 current sheets are at y = -8 and y = 8, respectively. The plasma pressure 526 is set to balance the magnetic field pressure $p_B = B^2/2$. To mimic the 527 plasma environment of Earth's magnetopause, the asymptotic plasma beta 528 $\beta = (p_i + p_e)/p_B$ are 3.6 and 0.15 on the "1" and "2" sides, respectively. The 529 initial pressure ratio between electrons and ions is $p_i/p_e = 5$ in the whole 530 simulation domain. The ion temperature is: 531

$$T_i(y) = \left(\frac{T_{i,1} + T_{i,2}}{2}\right) \left[\tanh\left(\frac{y + L_y/4}{\delta}\right) - \tanh\left(\frac{y - L_y/4}{\delta}\right) \right] + T_{i,2}.$$
(10)

 $T_{i,1} = 1.33$ and $T_{i,2} = 3.33$ are used in the simulation. With the pressure and temperature given above, the corresponding densities and ion inertial lengths are $n_1 = 1.127$, $n_2 = 0.0736$, $d_{i,1} = 0.942$ and $d_{i,2} = 3.69$. For all the simulations presented in this subsection, the grid resolution is $\Delta x = 1/16$, and the CFL is 0.4.

Figures 9 and 10 show the fields near the reconnection site at t = 20 with 537 100 and 400 initial ppc, respectively. The left (right) columns of Figures 9 538 and 10 are the results without (with) applying particle resampling. Due to 539 the magnetic reconnection plasma flow, the electron ppc around the current 540 sheet increases to about 250 (950), and the minimum ppc in the inflow region 541 reduces to less than 50 (200) in Figure 9 (Figure 10) without applying 542 the particle resampling algorithms. After applying the particle resampling 543 algorithms, the electron ppc becomes more uniform in the whole domain. 544 With the threshold parameters described in section 4, the particle splitting 545 (merging) threshold ppc is 80 (150) and 320 (600) for the simulations with 546 the initial ppc of 100 and 400, respectively. The minimum electron ppc in the 547 right column of Figure 9 (Figure 10) is about 83 (325), and the maximum ppc 548 is about 190 (630). The minimum ppc in the simulate is just a few particles 549 more than the splitting threshold since the splitting algorithm is effective in 550 generating new particles. The difference between the maximum ppc and the 551 merging threshold is larger, but the maximum ppc is still much smaller than 552 that in the simulation without applying particle resampling. 553

Figures 9 and 10 also compare the physical quantities of the simulations. All simulations show essentially the same structures, including the off-diagonal electron tensor. It demonstrates that the particle resampling algorithms do not introduce any significant artificial effect.

Figure 11 shows the electron phase space distributions from three sam-558 pling locations near the reconnection site. These three sampling locations 559 are marked with black rectangles in the first rows of Figures 9 and 10. From 560 top to bottom, we label these three sampling boxes as box-A, box-B, and 561 box-C. In Figure 11, rows (a) and (b) show distributions from box-A, rows 562 (c) and (d) show distributions from box-B, and rows (e) and (f) show dis-563 tributions from box-C. Each column shows the distributions from the same 564 simulation, and the simulation parameters, i.e., the initial ppc and turning 565 on/off the particle resampling algorithms, are described at the top of Fig-566 ure 11. Rows (a), (c) and (e) show the density distributions, and rows (b), 567 (d) and (f) show the macro-particle number distributions in phase space. 568 Figure 11 demonstrates that the particle resampling algorithms preserve the 569 phase space distributions well. The particle resampling does not change the 570 particle number too much at the sampling location box-A (row (b)), and 571 the 'U'-shape density distribution is well preserved (row (a)). From rows 572 (d) and (f), it is clear that the particle resampling significantly reduces the 573 particle number around the distribution centers, so the centers of the density 574 distribution (rows (c) and (e)) with particle resampling are noisier. But the 575 density distribution structure, which consists of a core and a crescent distri-576 bution, is still clearly preserved in the row (c) and also in (e1) and (e2). The 577 distributions of (e3) and (e4) are also very similar to each other. 578

579 6.4. Strong and weak parallel scalings

3D asymmetric magnetic reconnection simulations are used to test the 580 strong and weak scaling of FLEKS. The setup of the 3D test is similar to 581 the 2D simulation in the previous subsection, and it is uniform in the z-582 direction. Since FLEKS uses the parallel field and particle data structures 583 provided by AMReX, the scaling results largely depend on the performance 584 of AMReX [9, 10]. Figure 12 shows the weak scalings. With 8³ cells per core, 585 the performance is still good with up to about 10k cores. With 16^3 cells per 586 CPU core, it reaches good performance even with 28,672 cores. Figure 13 587 shows the strong scalings of two problems. The speedup is not too far away 588 from the ideal scaling up to about 7k (Figure 13(a)) or 14k (Figure 13(b)) 580 CPUs for these problems. 590

⁵⁹¹ 6.5. Magnetospheric simulations

⁵⁹² Magnetospheric simulations represent the most important application of ⁵⁹³ MHD-AEPIC. Here, we show examples of how FLEKS benefits magneto-

Figure 9: 2D magnetic reconnection results with (right column) or without (left column) particle resampling. The initial particle number per cell is 100. The black boxes in the top row indicate where the distribution functions shown in Figure 11 are taken from.

Figure 10: 2D magnetic reconnection results with (right column) or without (left column) particle resampling. The initial particle number per cell is 400 that is 4 times more than in Figure 9. The black boxes in the top row indicate where the distribution functions shown in Figure 11 are taken from.

Figure 11: Each column shows the phase space distributions from the same simulation. The first two rows, middle two rows and the last two rows represent the distributions of box-A, box-B and box-C, respectively. From top to bottom, the black rectangles in Figures 9 and 10 show the locations of box-A, box-B and box-C. Rows (a), (c) and (e) are physical density distributions. Rows (b), (d) and (f) show particle number per phase space bin.

Figure 12: The weak parallel scaling results of FLEKS. The execution time with 112 CPU cores is used as the reference. For perfect scaling the normalized execution time would be 1.0 for all runs.

⁵⁹⁴ sphere modeling. The global MHD magnetosphere model uses the same ⁵⁹⁵ setup as the simulations presented in [5, 24], but the active PIC region is not ⁵⁹⁶ limited to be a box anymore. Figure 14 shows how the active PIC region ⁵⁹⁷ can efficiently cover the dayside magnetopause, including the dawn-side and ⁵⁹⁸ dusk-side flanks, and also the cusp region at the same time.

The test particle module enables us to follow the trajectories of particles in the magnetosphere. Figure 15 shows an example of test particles in Earth's magnetosphere.

602 7. Conclusion

In this paper, we introduce a new kinetic code FLEKS, which is designed 603 as the kinetic component of the MHD-AEPIC model [8, 25]. To support 604 long simulations with varying global configurations, FLEKS allows activating 605 or deactivating cells dynamically during a simulation to fit the regions of 606 interest. This feature was introduced by Shou et al. [8] first, but FLEKS 607 is more flexible since the minimum activation unit is a patch containing N 608 (N > 2) cells in each direction instead of a large block used in [8], and FLEKS 609 supports multiple independent PIC domains in an MHD-AEPIC simulation. 610

Figure 13: The strong scaling of FLEKS. Panels (a) and (b) show the scaling of simulations with 1.835 million and 14.68 million cells, respectively. The red solid lines represent speedup, and the red dashed lines correspond to perfect speedup. The blue lines show the number of PIC cells per CPU core.

Figure 14: An MHD-AEPIC simulation of Earth's magnetosphere with the dayside magnetopause and the cusps covered by FLEKS. The black lines indicate the edge of the active PIC region.

Figure 15: The locations (left) and the example trajectories (right) of test particles.

⁶¹¹ During a long simulation, since the plasma properties inside the active PIC ⁶¹² region may change greatly, we design an adaptive time-stepping algorithm ⁶¹³ to adjust PIC time step accordingly. The adaptive time-stepping scheme ⁶¹⁴ preserves the energy conservation property of the ECSIM algorithm.

Since the number of particles per cell may change dramatically during a 615 long simulation and leads to load imbalance and loss of accuracy in the cells 616 with fewer particles, a particle splitting and a particle merging algorithms are 617 designed to control the change of ppc. The particle merging algorithm selects 618 6 particles that are close to each other in the phase space and combines them 619 into 5 new particles. The merging conserves the total mass, momentum, and 620 energy, and it also preserves the phase space structure as much as possible 621 by inheriting velocities from the old particles. We have presented several 622 non-trivial tests showing that the particle splitting and merging algorithm 623 does not introduce any spurious features. 624

The particle resampling improves the efficiency of FLEKS substantially by not allowing the ppc to drop to very small values or increase to unnecessarily high values. In addition, load balancing the PIC domain becomes much easier with roughly the same number of particles in each grid cell. Indeed, FLEKS shows excellent weak and strong parallel scaling. Finally, the test-particle module expands the capability of FLEKS, and provides a useful tool for
investigating the transport and energization of particles in magnetospheres.
FLEKS improves the quality and efficiency of MHD-AEPIC simulation
results significantly. For example, Wang et. al. [27] use FLEKS inside the
Space Weather Modeling Framework to model a complete magnetospheric
storm with kinetic reconnection in the tail.
