Abstract

There are a large number of tectonic shortening structures distributed across the planet Mercury, which are interpreted as the product of lithospheric deformation mainly attribute to secular cooling of the planetary interior. As the largest single volcanic deposit on Mercury, the northern smooth plains (NSP) is dominated by thrust fault-related landforms, showing particularity in their geomorphic features and requires an assumed weak layer at a shallow depth to account for the thin-rooted deformation in the lithosphere. However, there is a lack of proper mechanical model to account for such layer in the lithosphere beneath the NSP. In this work, we propose a new mechanical model allowing for a mechanically discontinuous lithosphere by introducing the semi-brittle deformation style, with detailed model configurations. Our work simulates a compressive dynamic process to mimic the formation for thrust fault-related landforms in the NSP of 3.8 billion years ago through 2-D numerical simulations. This simulation lasts for 70 million years, resulting in a concentrated and high strain rate region (i.e., weak layer) at shallow depth in the crust and geomorphically consistent surface topography with commonly observed thrust fault-related landforms. Geomorphically steady surface relief suggests that these shortening landforms were formed in a short period of time on geological time scales, and have maintained their basic geomorphic features to present day. The potential influence of the topography at the crust-mantle boundary on the surface relief is also recognized. Additional set of numerical simulations emphasizes that a larger topography facilitates the formation for higher surface relief.

18 Abstract

There are a large number of tectonic shortening structures distributed across the planet 19 Mercury, which are interpreted as the product of lithospheric deformation mainly attribute 20 to secular cooling of the planetary interior. As the largest single volcanic deposit on Mer-21 cury, the northern smooth plains (NSP) is dominated by thrust fault-related landforms, 22 showing particularity in their geomorphic features and requires an assumed weak layer 23 at a shallow depth to account for the thin-rooted deformation in the lithosphere. How-24 ever, there is a lack of proper mechanical model to account for such layer in the litho-25 sphere beneath the NSP. In this work, we propose a new mechanical model allowing for 26 a mechanically discontinuous lithosphere by introducing the semi-brittle deformation style. 27 with detailed model configurations. Our work simulates a compressive dynamic process 28 to mimic the formation for thrust fault-related landforms in the NSP of 3.8 billion years 29 ago through 2-D numerical simulations. This simulation lasts for 70 million years, re-30 sulting in a concentrated and high strain rate region (i.e., weak layer) at shallow depth 31 in the crust and geomorphically consistent surface topography with commonly observed 32 thrust fault-related landforms. Geomorphically steady surface relief suggests that these 33 shortening landforms were formed in a short period of time on geological time scales, and 34 have maintained their basic geomorphic features to present day. The potential influence 35 of the topography at the crust-mantle boundary on the surface relief is also recognized. 36 37 Additional set of numerical simulations emphasizes that a larger topography facilitates the formation for higher surface relief. 38

³⁹ Plain Language Summary

One of the most striking features of Mercury's surface is the global distributed short-40 ening geological landforms. The formation and geomorphic characteristics of these tec-41 tonic features are associated with the mechanical structure of lithosphere. For the sin-42 gle largest volcanically resurfaced smooth terrain termed the northern smooth plains on 43 Mercury, there is neither satisfied lithospheric mechanical model nor numerical simula-44 tions allowing for a mechanically discontinuous lithosphere. In this paper, we propose 45 a new lithospheric mechanical model to mimic a formation process of thrust fault-related 46 landforms of 3.8 billion years ago through 2-D numerical simulation. Our work is tested 47 with an open-source finite element mantle convection code, resulting in an equivalent weak 48 layer and geomorphically consistent surface relief with the observed thrust fault-related 49 landforms. Additional numerical simulations are implemented to investigate the influ-50 ence of the topography at the crust mantle boundary on the surface relief, our results 51 suggest that a larger interface topography facilitates the formation for a higher surface 52 relief. The obtained surface reliefs indicate that these shortening landforms were formed 53 in a short period time and have maintained their basic geomorphic features to present 54 time. 55

56 1 Introduction

Previous studies have shown that there are numerous geometries of shortening tec-57 tonic features distributed across the planet Mercury (e.g., Watters et al., 2009; Solomon 58 et al., 2018). These geological structures are interpreted as one of the products of the 59 shrinkage and failure of the lithosphere, which is mainly attributed to the stress driven 60 by the secular cooling of the planetary interior (Byrne et al., 2014, 2018; Banks et al., 61 2015; Klimczak et al., 2019). Geomorphic works suggest that the most representative 62 geological landforms are lobate scarps, wrinkle ridges and high-relief ridges, which are 63 the surface manifestation of the thrust fault, deforming almost all major geological units on Mercury (e.g., Watters et al., 2009; Banks et al., 2015; Klimczak et al., 2019; Wat-65 ters et al., 2021). Global maps imaged by NASA's MESSENGER mission reveal that 66 about 27% of the Mercury's surface is covered by extensive smooth plains, with the largest 67

single volcanic deposit termed the northern smooth plains (NSP) (Head et al., 2011; Denevi 68 et al., 2013; Ostrach et al., 2015; Du et al., 2020). The NSP is a volcanically resurfaced 69 smooth terrain buried by hundreds to thousands of meters of volcanic deposits (Ostrach 70 et al., 2015), newly estimated thickness of the crust underlying the NSP constrain its value 71 to an average of 19 km by analyzing the relationship between the crustal thickness and 72 mantle melting production (Beuthe et al., 2020). Viewed from the surface, the NSP is 73 abundant in ghost craters and thrust fault-related landforms, where the dominated short-74 ening features are wrinkle ridges and lobate scarps (Byrne et al., 2014). Compared to 75 their counterparts in other geological terrains in Mercury, these landforms show less re-76 lief and shorter length (Byrne et al., 2014; Solomon et al., 2018; Crane & Klimczak, 2019; 77 Peterson et al., 2019). Interpretation of the visible geomorphic characteristics on the sur-78 face provides an opportunity to explore the subsurface architecture and the behind dy-79 namical mechanisms, which can offer important information about the evolutionary his-80 tory of Mercury (e.g., Peterson et al., 2020; Watters, 2021). 81

The principle of initiation of thrust fault requires that the stress imposed by the 82 environment exceeds the limit that the lithosphere can withstand, with the latter being 83 controlled by a variety of factors including the ambient temperature, strain rate and rock's 84 composition and so on (Karato & Wu, 1993; D. Kohlstedt et al., 1995; D. L. Kohlstedt 85 & Mackwell, 2009; Klimczak, 2015; Katayama, 2021). Theoretical calculations rely on 86 87 the lithospheric strength model, in which the most common and classic strength model known as elastic dislocation model has been applied to recur the subsurface mechani-88 cal structure beneath Mercury's intercrater plains (ICP), via the interpretation of the 89 surface shortening landforms (e.g., Watters et al., 2002; Nimmo & Watters, 2004; Egea-90 González et al., 2012). Applications of elastic dislocation model collectively imply that 91 the fault roots at deep depths, forming lithospheric-scale fault, as a result from the de-92 formation in a mechanically homogenous lithosphere under substantial horizontal com-93 pressive stress (Solomon et al., 2018). However, in recent years, detailed tectonic maps drawn by several authors reveal the trends in how thrust fault-related landforms oriented 95 and organized in the NSP, and classify the main deformation style of the lithosphere as 96 thin-rooted by comparison with Earth analogues and patterns acquired by physical mod-97 els, collectively suggest a weal layer (or décollement) at shallow depth beneath the NSP 98 to account for the observed geomorphic characteristics under low strain rate (Byrne et 99 al., 2014; Watters et al., 2015; Crane & Klimczak, 2019; Peterson et al., 2019, 2020; Wat-100 ters et al., 2021). So far, neither the thickness nor the constituent that makes up the weak 101 layer has been well constrained, whereas the only consensus is the possible scenario of 102 the formation for such layer, that is, the burial of impact-induced megaregolith layer by 103 subsequent multi-sequence volcanic eruptions, where faults root and propagate upward 104 (Byrne et al., 2014; Watters et al., 2015). More importantly, the implication deduced from 105 the idea of the presence of weak layer is a mechanically discontinuous crust or lithosphere, 106 which is contradictory to the conclusion suggested by elastic dislocation model used in 107 prior works. Therefore, an appropriate strength model allowing for a mechanically dis-108 continuous lithosphere is still an open issue, in which constantly updated knowledge of 109 Mercury should also be taken into account. 110

In this paper, we propose a new strength model allowing for a mechanically dis-111 continuous lithosphere beneath the northern smooth plains of Mercury, as a result of a 112 comprehensively considered with ambient temperature, strain rate and rheology and other 113 factors. By implementation of 2-D numerical simulation through an open-source finite-114 element mantle convection code - Advanced Solver for Problems in Earth's Convection, 115 ASPECT (Kronbichler et al., 2012; Heister et al., 2017), we obtain a concentrated and 116 high strain rate region equivalent to the weak layer within the crust at shallow depth and 117 well consistent surface topography of thrust fault-related landforms discovered in the NSP. 118 This work is structured as follows. First, we introduce the physical model in section 2, 119 followed by the discussion on model configuration in section 3. Lastly, we present our 120 results, discussion and conclusion in turn. 121

122 2 Physical Model

For the 2-D numerical simulation, we first apply an incompressible, linear Maxwell model to take visco-elasticity of the mantle into account. The constitutive equation for all materials is (e.g., Moresi et al., 2003):

$$\frac{\tau}{2\eta} + \frac{\bar{\tau}}{2\mu} = \hat{D}_v + \hat{D}_e = \hat{D} \tag{1}$$

126

¹²⁷ Where τ is the deviatoric stress tensor, μ is the elastic shear modulus, η is the shear vis-¹²⁸ cosity, and $\bar{\tau}$ is the Jaumann corotational stress rate tensor. \hat{D}_v and \hat{D}_e are the viscous ¹²⁹ part and elastic component of the deviatoric strain rate tensor, respectively. A full dis-¹³⁰ cussion on this equation can be found in, e.g., Moresi et al. (2003).

Incorporating the elastic force term, the basic equations set describing the conser vation of mass, momentum and energy is given by (Moresi et al., 2003):

$$\nabla \cdot u = 0 \tag{2}$$

$$\tau_{ij,j}^{t+\Delta t^e} - \nabla P + f_i + F_i^{e,t} = 0 \tag{3}$$

$$\rho c \frac{\partial T}{\partial t} = \frac{\partial}{\partial x_i} \left(k \frac{\partial T}{\partial x_i} \right) + H_R + H_D \tag{4}$$

¹³⁸ Where u is the velocity, P is the pressure, and f_i is the specific body force, $F_i^{e,t}$ is the ¹³⁹ elastic force term. In Eq.(4), ρ is the density, c is the specific heat capacity, and the last ¹⁴⁰ three terms on the right side represent the conductive heat, radiogenic heat and viscous ¹⁴¹ dissipation, respectively.

142

143

150

The radiogenic heat term in W/m^3 has the following form (e.g., Michel et al., 2013):

$$H_R(x,t) = \rho_x \sum_i Q_i^0 0.5^{t/\mu_i}$$
(5)

¹⁴⁴ Where ρ is the average density, x is the index used to indicate different geological lay-¹⁴⁵ ers (e.g., the crust). Q^0 is the initial radiogenic heating rate in W/kg, i is the index de-¹⁴⁶ noting radiogenic heating elements (RHEs), including the element potassium (K), tho-¹⁴⁷ rium (Th) and uranium (U) (Peplowski et al., 2011). μ and t are half-decay time and ¹⁴⁸ time, respectively.

¹⁴⁹ For the viscous dissipation, it is given by (e.g., Thielmann & Kaus, 2012):

$$H_D = \zeta \tau : \dot{\epsilon}^v \tag{6}$$

¹⁵¹ Where ζ is the heat conversion efficiency, it depends on whether other deformational mech-¹⁵² anisms are taken into account. In this work, ζ is set to 1, meaning that we assume that ¹⁵³ all dissipation energy is converted into heat (e.g., Schmalholz et al., 2018). τ is the de-¹⁵⁴ viatoric stress tensor and $\dot{\epsilon}^v$ is the visco-plastic component of the deviatoric strain rate ¹⁵⁵ tensor.

3 Model Configuration

The implementation of numerical simulation via ASPECT requires specific configuration of the model when initializing. This step is necessary, because the initial state of any numerical simulations has great impact on the final results. In this section, we primarily concentrate on key configurations, including the initial conditions (initial temperature profile plus the background bulk strain rate), rheology and lithology of the research domain.

¹⁶³ 3.1 Initial Conditions

The discussions on the initial conditions focus on the initial temperature profile and the applied background bulk strain rate of the research domain. We first assume that the research domain only covers the crust and the lithosphere-mantle rather than the whole outer silicate shell of Mercury. The main reasons are two-fold. Firstly, the average penetration depth of most thrust faults in the NSP is shallow (e.g., Crane & Klimczak, 2019), a full-scale geometry (i.e., a silicate shell with thickness of around 400 km) may affect the display of result. Secondly, the solution to the profile of temperature is easier to solve in the lithosphere.

In order to obtain a representative initial temperature profile, following our pre-172 vious work (Xie et al., 2022), we carry out a 1-D parametric global evolution model of 173 Mercury (refer to Appendix A). The 1-D model radially divides the planet into several 174 layers (e.g., the crust, thermal boundaries, convecting mantle), with the descriptions of 175 energy-related equations of each layer. The model will iterate until self-consistent results 176 are obtained, providing an outline of the evolutionary picture of Mercury. One additional 177 advantage of this model is the flexibility to specify the truncation time of the model runs. 178 Studies on the timing of the shortening tectonic features suggest that most thrust fault-179 ing underway at 3.8 ± 0.2 Ga before present (b.p) (e.g., Giacomini et al., 2015, 2020; Crane 180 & Klimczak, 2017), which is the time of our interest. Therefore, the results given below 181 are all at 3.8 Ga b.p. 182

After the 1-D parametric model running done (Fig A2), we have crust and lithosphere-183 mantle with the thickness of around 19.1 km and 110.8 km, respectively. The first re-184 sult is close to the value of the crustal thickness beneath the NSP of 19 ± 3 km (Beuthe 185 et al., 2020). Correspondingly, the radiogenic heating production rate (RHPR) are about 186 9.37×10^{-11} W/kg and 9.37×10^{-12} W/kg at 3.8 Ga b.p. The value of the crustal RHPR 187 is in line with the result calculated by the Gamma-Ray Spectrometer measured data (Peplowski 188 et al., 2011). In the end, the initial temperature profile over time derived from Eq.(A1-189 2) is shown in Fig 2, where the temperature at the crust-mantle boundary (T_{CrMB}) and 190 the bottom of the lithosphere-mantle (T_l) are about 754 K and 1435 K at the time of 191 3.8 Ga b.p. 192

The second point is about the background bulk strain rate (hereinafter referred to 193 as strain rate). For Mercury, favored values adopted by strength models are of the or-194 der of 10^{-17} s⁻¹ (e.g., Zuber et al., 2010; Egea-González et al., 2012). However, recent 195 study on the stratigraphic relationships of thrust fault-related landforms with craters lim-196 ited the strain rate at the onset of faulting to the order of $10^{-20} \sim 10^{-21} \text{ s}^{-1}$ (Crane & 197 Klimczak, 2017). Moreover, if the elastic properties of the rock are taken into account, 198 the strain rate during the lithospheric elastic deformation processes is probably between 199 the order of 10^{-19} and 10^{-20} s⁻¹(Klimczak, 2015). In other words, in either case, the 200 strain rate is much smaller than the commonly used one in previous studies, although 201 it does not preclude a larger strain rate when lithosphere breaks. Finally, considering 202 that faults may have occurred during the Calorian (i.e., one of the five defined time-stratigraphic 203 systems of Mercury, $3.9 \sim 3.5$ to 3 Ga b.p.), we choose the strain rate in the range of $4.1 \pm 1.6 \times 10^{-20}$ 204 s^{-1} as same as Crane and Klimczak (2017). 205

The data of the initial temperature profile over depth at the time of 3.8 Ga b.p. is saved in a formatted text file, which can be accessed on Zenodo through the link we provide, and part of the major basic parameters are listed in Table 1.

3.2 Rheology

209

Regarding the rheology of Mercury's lithosphere. Given the fact that no evidence 210 of plate motion has been found on the surface, it is common to apply power laws (e.g., 211 the dislocation creep) to characterize the rheology of Mercury's outer silicate shell in pre-212 vious parametric/numerical simulations (e.g., Egea-González et al., 2012; Thiriet et al., 213 2019). Using this type of rheological law facilitates the planet's silicate shell becoming 214 strong in a short period of time, which helps to produce a large viscosity contrast be-215 tween the planetary surface and interior, resulting in a complete global plate (Stern et 216 al., 2018; Tosi & Padovan, 2021). However, since we focus on what happened 3.8 billion 217 year ago, should other creep laws be taken into account? 218

Table 1. Basic Parameters

Ref.:1.Knibbe and van Westrenen (2018); 2.Thiriet et al. (2019)

Ref.:3.Crane and Klimczak (2019); 4.:Xie et al. (2022)

Laboratory studies show that temperature, pressure and strain rate are the main 219 factors controlling the rheology of rocky planets (e.g., Karato & Wu, 1993; Mei et al., 220 2010; Burov, 2011). Experiments suggest that for lower temperatures (approximately 221 lower than 800 K) and high strain rate, restrictions to glide of dislocations limits rates 222 of straining, the deformation processes abide by Peierls creep, while for higher temper-223 atures region, diffusion creep and power-law play the key role due to their strong sen-224 sitivity of temperature and strain rate (e.g., Kameyama et al., 1999; Mei et al., 2010; Mol-225 nar, 2020; Pleus et al., 2020). Prior numerical studies targeting at the formation of shear 226 zone suggested that the mechanical discontinuity tends to induce strain localization un-227 der lithospheric conditions, resulting in the formation of local region with high effective 228 strain rate (e.g., Schmalholz & Duretz, 2015; Auzemery et al., 2020), which is indicative 229 of the research on the thrust fault-related landforms on Mercury. Combing with the ini-230 tial temperature profile (i.e., 440 K to 1435 K), the involvement of creep laws like Peierls 231 creep in both the crust and part of the lithosphere-mantle seems to be reasonable. In 232 the end, we apply a composite rheological model that incorporates the rheological laws 233 of Peierls, diffusion and dislocation, assuming that the viscosity is expressed as the pseudo-234 harmonic average of those three rheologies under isotropic applied stress. 235 236

The Peierls creep is given by (e.g., McCarthy et al., 2020):

$$\eta_p = \frac{\gamma \sigma p}{2(A(\gamma \sigma_p)^n)^{1/(s+n)}} exp(\frac{H}{RT} \cdot \frac{(1-\gamma^p)^q}{s+n}) \dot{\epsilon}_{II}^{\frac{1}{s+n}-1}$$
(7)

with 238

237

239

249

$$s = \left(\frac{H}{RT}\right)pq(1-\gamma^p)^{q-1}\gamma^p \tag{8}$$

Where γ is the fitting parameters, σ_p is the Peierls stress. A is the pre-factor and n is 240 the stress exponent. p and q are the Peierls glide parameters that depend on the geom-241 etry of obstacles that limit the dislocation motion. Theoretical considerations suggest 242 that $0 \le p \le 1$ and $1 \le q \le 2$ (Chowdhury et al., 2017; Jain et al., 2017). $\dot{\epsilon}$ is the ef-243 fective strain rate, and H = E + PV, where E is the activation energy, V is the acti-244 vation volume, R is the universal gas constant. P and T are pressure and temperature, 245 respectively. 246

The generic form of dislocation creep law and diffusion creep law can be expressed 247 as (e.g., Billen & Hirth, 2007): 248

$$\eta_d = f A^{\frac{-1}{n}} d^{\frac{m_1}{n}} (\dot{\epsilon}_{II}^v)^{\frac{1-n}{n}} exp(\frac{E+PV}{nRT})$$
(9)

Where f is a scaling factor that used to decrease the effective viscosity relative to the 250

viscosity resulting from rock deformation experiments. A is the pre-factor, n is the power-251

law stress component, d is the grain size, m_1 is the grain size exponent, and $\dot{\epsilon}_{II}^v$ is the second invariant of the viscous part of the deviatoric stress tensor. E, P and V have the same definition as mentioned above. For diffusion creep, $n = 1, m_1 \neq 0$, while for dislocation creep, $n > 1, m_1 = 0$.

Finally, the viscosity can be expressed as (e.g., O'Neill & Zhang, 2019):

$$\eta = (\sum_{i} \eta_i^{-1})^{-1} \tag{10}$$

Where i is the index indicating the above three rheological laws.

We also apply the Drcuker-Prager criterion (DP) to limit all the materials that undergo frictional/plastic deformation (Alejano & Bobet, 2015). It has the following form:

$$\tau_{dp} = C_0 \cdot \cos(\phi) + P \cdot \sin(\phi) \tag{11}$$

Where τ_{dp} is the yield stress of DP in MPa, C_0 is the cohesion, ϕ is the internal friction angle and P is the pressure in MPa.

In case of yielding, the effective viscosity is iteratively reduced until the corresponding stress is equal to the yield stress, resulting in the effective viscosity with the following form (e.g., Schmalholz & Duretz, 2015):

$$\begin{cases} \eta_{eff} = \eta & \tau < \tau_{dp} \\ \eta_{eff} = \frac{\tau_d}{2E_{II}} & \tau > \tau_{dp} \end{cases}$$
(12)

Where η_{eff} is the effective viscosity, E_{II} is the square root of the second invariant of the strain rate tensor, with $E_{II} = \sqrt{\left(\frac{\partial u_1}{\partial x_1}\right)^2 + \frac{1}{4}\left(\frac{\partial u_1}{\partial x_2} + \frac{\partial u_2}{\partial x_1}\right)^2}$.

3.3 Lithology

256

257

261

267

270

In addition to the rheology, lithology is another major factor determining the plas-271 tic strength of the lithosphere, because the plastic strength is generally controlled by the 272 weakest constituent that makes up the rock (e.g., Azuma et al., 2014; Katayama, 2021). 273 Recent geochemical works constrained the major surface potential mineralogy of Mer-274 cury to plagioclase, pyroxene and olivine. Particularly, in the NSP, it is plagioclase dom-275 inated (e.g., Namur & Charlier, 2017; Kaaden et al., 2017). As for the composition of 276 the lithosphere-mantle of Mercury, an olivine-rich mantle is suggested (Namur et al., 2016; 277 Beuthe et al., 2020). Similarly, we assume that a dried olivine enriched lithosphere-mantle 278 is covered by a dried Columbia diabase (mainly composed of plagioclase) enriched crust 279 (Kay & Dombard, 2019; Katayama, 2021), although the precise constituents of Mercury's 280 lithosphere are still poorly constrained. 281

Lastly, due to the lack of experiments on the diffusion creep of Maryland/Columbia diabase, we use the diffusion creep of plagioclase instead. For the same reason, we apply the same Peierls creep of dry olivine to both the crust and lithosphere-mantle (Mei et al., 2010; Katayama, 2021). The parameters of rheology and lithology (collectively named material model parameters in ASPECT) are given in Table 2 and 3.

3.4 Mechanical structure

Given the initial temperature profile, strain rate and rheological laws, we can cal-288 culate the strength profile of the lithosphere through the parameters given in Table 1 289 to 3. Laboratory studies suggest that there can be three deformation styles of rocks un-290 der lithospheric conditions, namely the brittle, semi-brittle and viscous deformation (D. Kohlst-291 edt et al., 1995; Mei et al., 2010). However, the condition under which the transition from 292 brittle to semi-brittle occurs is still poorly understood. Following previous works (e.g., 293 D. Kohlstedt et al., 1995; D. L. Kohlstedt & Mackwell, 2009), we use an empirical rule 294 that the transition is identified once the brittle strength is approximately equal to one-295 fifth of the plastic strength. Additionally, the Goetze criterion determining the transi-296

tion from semi-brittle to viscous deformation is applied (e.g., D. L. Kohlstedt & Mackwell, 2009; Mei et al., 2010; Zhong & Watts, 2013; Bellas et al., 2020), given by (Goetze
& Evans, 1979):

300

316

320

334

339

340

341

 $\tau_g = \frac{1}{2}(\rho g z - P_p) \tag{13}$

Where τ_g is the shear stress of Goetze criterion in MPa, ρ is the density, g is the surface gravitational acceleration and z is the depth. P_p is the pore pressure, which is ignored in this work.

Finally, the results calculated from Eq.(11-13) and the empirical rule mentioned 304 above will be used to divide the mechanical structure of the lithosphere (see below). How-305 ever, one can easily notice that the pressure term in Eq.(11) is the total pressure rather 306 than the lithospheric pressure P_l (i.e., under compression condition: $P_l = \rho g z$), rais-307 ing the question of how to compute the Eq.(11) without knowing the total pressure when 308 model initializing. In recent years, multiple works have been devoted to revealing the 309 relationship between the total and lithospheric pressure (e.g., Gerya, 2015; Marques et 310 al., 2018; Zuza et al., 2020). A rough estimate is that when the internal friction angle 311 (i.e., ϕ) is around 30°, which is commonly applied to studies on Mercury's lithosphere 312 (e.g., Klimczak, 2015), the total pressure can be equivalent to twice the lithospheric pres-313 sure under lithospheric conditions (e.g., Zuza et al., 2020). Therefore, the Eq.(11) can 314 be recast as: 315

$$\tau_{dp} \approx C_0 \cdot \cos(\phi) + 2\rho gz \cdot \sin(\phi) \tag{14}$$

In order to evaluate the result calculated by Eq.(14), we additionally introduce the Byerlee intermediate-high pressure law (hereinafter referred to as Byerlee law), with the following form (Klimczak, 2015):

$$\begin{cases} \tau_b = 2\rho gz & \rho gz < 110 \text{MPa} \\ \tau_b = \frac{1}{2}(2.1\rho gz + 210) & \rho gz > 110 \text{MPa} \end{cases}$$
(15)

Where τ_b is the shear stress of Byerlee law in MPa, the rest of parameters are the same as in Eq.(13).

The results computed by Eq.(14-15) are shown in Fig 1, and it can found that the deviation between them is not too significant to accept. Given that the total pressure may be more than twice the lithospheric pressure in most scenarios, it would make the deviation smaller (e.g., Gerya, 2015). Therefore, the application of Eq.(14) is reasonable. Nevertheless, it should be noted that the use of Eq.(14) is only valid when model initializing, while we still apply Eq.(11) to subsequent numerical simulation.

Fig 1 illustrates the strength profile of the crust and lithosphere-mantle at the strain rate of 4.1×10^{-20} s⁻¹, via $\tau = 2\eta \dot{\epsilon}$, where $\dot{\epsilon}$ is the effective strain rate, η is the viscosity. Fig 1.A depicts the strength profile of the crust, where CD20 represents the shear strength of Columbia diabase. Correspondingly, CD20/5 represents the one-fifth of the value of CD20.

It can be figured out that,

- the brittle strength calculated from the Drucker-Prager criterion (red line) inter sects with the profile of CD20/5 (purple line) at point A (the corresponding depth is about 8.5 km), indicating that the deformation type in segment OA is brittle,
 while the deformation type changes to semi-brittle from point A.
 - 2. the Goetze criterion (dashed black line) and the profile of CD20 (orange line) have no intersection, suggesting that there is no transition from semi-brittle to viscous deformation in the crust.

Accordingly, the crust can be divided into the upper crust that undergoes brittle deformation (segment OA) and the semi-brittle region (segment AB). Similarly, Fig1.B shows the strength profile of the lithosphere-mantle. OL20 (orange line) represents the shear strength of Olivine, and OL20/5 (purple line) is one-fifth of that. It is obviously to find out that OL20/5 is always smaller than DP in the lithosphere-mantle (green line), while

Figure 1. The strength profile of the crust and lithosphere-mantle at the strain rate of 4.1×10^{-20} s⁻¹. In both subplots, the label Drucker and Byerlee respectively indicates the strength profile calculated from Drucker-Prager criterion and Byerlee law. A) In the crust, CD represents the strength profile of Columbia diabase, and CD/5 is one-fifth of that. B) In the lithosphere-mantle, OL represents the strength profile of olivine, and OL/5 is one-fifth of that.

OL20 and Goetze criterion (dashed black line) intersects at point C (the corresponding depth is about 30.85 km). Hence, we can treat the lithosphere-mantle as being made of the semi-brittle region and the rest part (named mantle in this paper).

As a result, the research domain, which initially consisted of the homogenous crust 350 and lithosphere-mantle, is subdivided into four mechanical discontinuous layers (Fig 2). 351 From shallow to deep, they are: the upper crust (z: 0-8.5 km), the semi-brittle region 352 of the crust (z: 8.5-19.1 km), the semi-brittle region of the lithosphere-mantle (z: 19.1-353 30.85 km) and mantle (z: 30.85-130 km). For those layers with semi-brittle deformation, 354 we can distinguish them by specifying a smaller internal friction coefficient (i.e., a smaller 355 internal friction angle) from other layers when performing numerical simulations (Pleus 356 et al., 2020). 357

3.5 Geometry configuration

358

Regarding the model configuration, a cartesian geometry with dimensions of $800 \times$ 359 130 km is applied, where 130 km is the sum of the thickness of the crust and lithosphere-360 mantle. The mesh of our geometry has a resolution of 125×125 m above the depth of 361 60 km and $250 \times 250 \text{ m}$ below. A topography at the CrMB of 1.5 km (indicator: point 362 U, see Fig 2) is set to account for the lateral heterogenous (Beuthe et al., 2020), which 363 also breaks the symmetry of the model and helps to initialize the convection. This model 364 is heated from the bottom and cooled from the top, while the left and right boundaries 365 are insulated. The top and bottom boundary are free surface and free slip, respectively. 366 A constant strain rate of 4.1×10^{-20} s⁻¹ is generated by the horizontal velocity applied 367 on the two lateral boundaries. Fig 2 gives the disproportionate schematic diagram of the 368 geometry model. 369

Figure 2. The disproportionate schematic diagram of the geometry model with dimensions of 800×130 km, where the surface temperature (T_s) is 440 K, the temperature at the crust-mantle boundary (T_{CrMB}) is 754 K and the bottom temperature (T_b) is 1435 K. The geometry is composed of a dried Columbia diabase enriched crust and olivine enriched lithosphere-mantle, where the geometry is vertically subdivided into four layers: the upper crust (z: 0-8.5 km) and the crustal semi-brittle region (z: 8.5-19.1 km), lithosphere-mantle semi-brittle region (z: 19.1-30.85 km) and mantle (z: 30.85-130 km). We set up topography (point U as an indicator, its corresponding x-coordinate is 480 km) at the crust-mantle boundary of 1.5 km. This model is heated from the bottom and cooled from the top, while the left and right boundaries are insulated. The top and the bottom boundary are free surface and free slip, respectively. A constant background bulk strain rate of 4.1×10^{-20} s⁻¹ is generated by the horizontal velocity applied on the two lateral boundaries. CCD: crustal Columbia diabase. MOL: mantle olivine.

370 4 Results

Our 2-D numerical simulation starts at 3.8 Ga b.p and lasts for 70 Myr. Fig 3 shows a set of representative results of the square root of the second invariant of the shear strain rate tensor (hereinafter referred to as SRI), which is regarded as the effective strain rate (e.g., Gerya, 2019), at 10 Myr, 40 Myr and 70 Myr with the topography at CrMB of 1.5 km (see Fig 2).

In general, the SRI exhibits a clear spatial distribution pattern. According to the 376 distance from the topography indicator at CrMB (i.e., point U), we divide the high-SRI 377 regions into three sections, namely the section H, section T (framed by black line) and 378 section F. Among them, neither the value nor the concentration of the SRI in the sec-379 tion H has changed much over time, which provides a stable and highly concentrated high-380 SRI region with an average depth of 10 km, corresponding to the semi-brittle deforma-381 tion region within the crust. Similarly, we can observe high-SRI region in the section F, 382 but the overall intensity is lower in comparison to section H, and most notably, it is the 383 most sensitive to time. One can notice that the SRI decreases rapidly along with time, 384 and the relative high-SRI region gradually moves into the lithosphere-mantle, correspond-385 ing to the semi-brittle region in the lithosphere-mantle. The strain status in section T 386 is the most complicated, where the strain localization occurs due to the proximity to the 387 topography at the CrMB. Although we can find out that the localization seems to ex-388 tend throughout the crust (i.e., shear zone), both the magnitude and intensity are smaller 389 than those of works concerning with the formation of shear zones on Earth (e.g., Thiel-390 mann & Kaus, 2012; Schmalholz & Duretz, 2015), for which we attribute to the much 391 lower strain rate we applied (refer to section 3.1). In addition, the high-SRI region is pro-392 gressively concentrated near the surface over time in section T, suggesting that the sur-393 face is prone to break. It therefore seems to indicate that these shortening features can 394 be formed in the early stage of the simulation. 395

Furthermore, we calculate the corresponding surface topography and draw the cross section of the surface topography in Fig 4. In Fig 4, we mark some characteristic points, among which the black point U is used to indicate the relative position of the topogra-

Figure 3. The snapshots of the square root of the second invariant of the shear strain rate (SRI) at A) 10 Myr, B) 40 Myr and C) 70 Myr. The vertical axis represents the y-extension in km, the horizontal axis represents the x-direction extension in km. The high SRI concentrated regions are divided into three sections, from left to right, which are section H, section T (framed by black line) and section F.

phy at the CrMB. The precise values of these markers are listed in Table 4. Geomorpho-399 logically, our simulation results in a commonly observed characteristic surface topogra-400 phy on Mercury. Referring to previous geological works (e.g., Byrne et al., 2018; Crane 401 & Klimczak, 2019; Peterson et al., 2020), we also respectively define the segment LS_1A 402 and AS_2B in Fig 4 as the forelimb and the backlimb, in which we can figure out a steep 403 forelimb and a gently sloping backlimb. For comparison, we reference to the morpholog-404 ical profiles of a stack of shortening features in the NSP plotted in Fig2.b from Peterson 405 et al. (2020) and insert it into the Fig 4, the result clearly shows that a well consistent 406 surface topography with the characteristic geomorphic cross section of lobate scarps is 407 obtained (e.g., Watters et al., 2009; Byrne et al., 2018; Klimczak et al., 2019). 408

According to the data listed in Table 4, the surface topography gradually relaxes 409 but the rate of relaxation is decreasing over the simulation time. we owe the cause of this 410 phenomenon to the change in the strain state within the lithosphere with time. An ob-411 vious example is the fading away of the crustal high-SRI regions in section T and F, mak-412 ing the backlimb more gentle along over time. Although the relaxation of the topogra-413 phy is observed, the basic geomorphic features of the surface relief remain stable. The 414 main reason is that, theoretically, we apply the Drucker-Prager criterion to limit all the 415 materials that undergo plastic deformation, in case of yielding, the effective viscosity is 416 iteratively reduced until the corresponding stress is equal to the yield stress. Thus, af-417 ter the break occurs, the imposed background effective compressive stress is equal to the 418 yield stress, so that makes the surface relief stable in absence of other geological activ-419 ities like erosion. In addition, for cold rocky planet like Mercury, the gradually increased 420

Figure 4. The cross section of the corresponding surface topography (red line) at A) 10 Myr, B) 40 Myr and C) 70 Myr with the topography at CrMB of 1.5 km. The black point U is used to indicate the relative position of the topography at the CrMB. The insertion shows the stacked profiles of several shortening features in the northern smooth plains, which is referenced to the Fig2.b in Peterson et al. (2020).

effective viscosity of Mercury's interior also ensures the maintenance of the surface relief (Hemingway & Matsuyama, 2017).

423 5 Discussion

For numerical simulation, it is sensitive to the input parameters. In this regard, 424 we spend a lot of contents on selection and calculation of the parameters that may have 425 great impact in section 3. Given that our goal of this paper is to propose a new mechan-426 ical model allowing for a mechanically discontinuous lithosphere as well as to obtain a 427 geomorphic consistent surface topography with thrust fault-related landforms in the NSP, 428 and the fact that the information like burial depth or thickness of the weak layer is poorly 429 constrained. As a result, this paper achieves this goal, we therefore do not give more dis-430 cussions to account for the parameters' uncertainties. Nevertheless, we are still aware 431 of the potential influence of the topography at crust-mantle boundary on the surface re-432 lief, as it may be related to which mechanism the surface topography is compensated by 433 (e.g., Watts, 2001). However, a detailed investigation into the compensation state of the 434 crust is obviously beyond the scope of this paper, we hence simply compare the results 435 by adjusting the topography at the CrMB to explore the relationship between surface 436 relief and the interface topography, in which the topography at the CrMB ranges from 437

Figure 5. The cross section of the surface topography (red line) at A) 10 Myr, B) 40 Myr and C) 70 Myr with the topography at CrMB of 1 km. The black point U is used to indicate the relative position of the topography at the CrMB.

0.5 to 1.5 km. We present the result with the topography of 1 km in Fig 5, while the rest 438 of the results are shown in supporting information (FigS1 to FigS3). Overall, with the 439 increase of the topography at the CrMB, the surface relief is closer to what is shown in 440 Fig 4. For the areas of interest, such as the areas framed by the black frame in Fig 5, 441 it can be seen that the surface relief is gentler and it shows more tectonic patterns of short-442 ening features compared to that of Fig 4. We owe the main reason to that a larger to-443 pography is more likely to induce dramatic strain localization as well as the formation 444 for higher surface relief. According to the detailed tectonic maps drawn by several prior 445 works, the dominated thrust fault-related landforms in the NSP show complex patterns 446 in terms of relief, orientation and extension (e.g., Crane & Klimczak, 2019). Our results 447 suggest that the surface relief may be closely related to the topography at the CrMB, 448 which also stresses that high resolution gravity and topography maps are urgently needed, 449 as they can be used to recur the subsurface architecture (Wieczorek & Phillips, 1997). 450 Another interesting phenomena is that these features appear to be formed in a short pe-451 riod of time on geological time scales (i.e., 10 million years). Stratigraphic studies show 452 that the formation of most of Mercury's shortening landforms are concentrated in spe-453 cific geological period, and the compressive stress driving the shortening tectonic activ-454 ities decreases along with time (e.g., Giacomini et al., 2015; Crane & Klimczak, 2017). 455 Collectively, our simulation is able to capture the key features of the process of the for-456 mation for thrust fault-related landforms. 457

458 So far, the driven forces that make the current landforms have not been fully iden-459 tified. If the compressive stress were derived solely from Mercury's contraction, the faults

 Table 4.
 The precise values of surface topographical indicators over time

should be uniformly distributed across the planet, which is contradictory to observations 460 (e.g., Watters et al., 2009, 2015). Candidate participants including the tidal force (Klimczak 461 et al., 2015), insolation (Williams et al., 2011) and mantle downwelling (Watters et al., 462 2021) have been suggested to have contribution to the distribution of the observed fea-463 tures. As the name suggested, the most significant feature of the smooth plains is the 464 volcanically resurfaced surface, with large-volume volcanism being suggested to had ceased 465 around 3.5 billion years ago, younger than the most observed shortening features in smooth 466 plains (e.g., Byrne et al., 2016; Thomas & Rothery, 2019). Surface thick volcanic deposits 467 are thought to have contributions to the formation for thrust faults in the NSP (e.g., Pe-468 terson et al., 2019, 2020). Moreover, there are studies suggesting that the volcanic ac-469 tivities play a role especially in regionally or locally tectonic actives (Crane & Klimczak, 470 2019; Peterson et al., 2020), one evidence is the increased frequency of thrust fault-related 471 landforms within volcanically filled basins suggested by Watters et al. (2009). Therefore, 472 the influence of the long-standing volcanism as well as other tectonic activities and outer-473 source events like impact on the formation (e.g., Marchi et al., 2013), distribution and 474 orientation of thrust fault-related landforms in the NSP remains to be revealed. Like-475 wise, the contribution from the topography at the crust-mantle boundary deserves fur-476 ther investigation. 477

Lastly, for the weak layer itself. As mentioned earlier, neither the thickness nor the 478 constituent of this structure is well constrained. But it is most likely made up of an im-479 pact product named megaregolith that was buried by subsequence volcanic activities (e.g., 480 Byrne et al., 2014; Watters et al., 2015). As being defined as a highly fragmented struc-481 ture with low thermal conductivity, megaregolith shows excellent insulation performance 482 (Xie et al., 2022). Therefore, in addition to the fragility of the weak layer, its influence 483 on the thermal dynamic process should also be concerned. For example, the retention 484 of interior heat could facilitate a low degree of contraction (Watters, 2021) or prolon-485 gation of volcanism (Byrne et al., 2016). 486

487 6 Conclusion

In this paper, we propose a new mechanical model allowing for a mechanically dis-488 continuous lithosphere beneath the northern smooth plains of Mercury. This work is tested 489 with open-source finite-element mantle convection code, resulting in high strain rate re-490 gion equivalent to weak layer at shallow depth and geomorphic consistent surface topog-491 raphy with typical thrust fault-related landforms. Geomorphically steady surface relief 492 suggests that these shortening features were formed in a short period of time on geolog-493 ical time scales. Mechanically, our model divides the lithosphere into several discontin-494 uous layers by introducing the deformation style of semi-brittle, filling the blank between 495 the brittle and viscous deformation zone (e.g., Zuber et al., 2010; Egea-González et al., 496 2012). Although the properties and dynamics of semi-brittle deformation are still poorly 497 constrained, the application of such deformation zone to planetary science is still promising, especially thin-rooted tectonic landforms are also reported on other terrestrial plan-499 ets (e.g., Andrews-Hanna, 2020). We are also aware of the potential influence of the in-500 terface at the crust-mantle boundary and volcanism on the formation, distribution, re-501

Figure A1. The disproportionate schematic diagram of the 1-D global parametric model of Mercury. This model radially divides the planet into several layers: the crust, lithosphere-mantle, upper/lower thermal boundary, convecting mantle and the outer/inner core (not displayed).

lief and orientation of the shortening features. Additional set of numerical simulations
reveals that larger topography at the crust-mantle boundary facilitates the formation
for higher surface relief, which also emphasizes that high resolution of gravity and topography maps are urgently needed, as they can be used to recur the subsurface architecture. Because of that, we are looking forward to the upcoming BepiColombo era (Benkhoff
et al., 2010).

518 Appendix A The 1-D parametric model

The 1-D parametric global evolution model Mercury radially divides the planet into several layers (refer to Fig A1), where the evolutionary process over time of each layer is controlled by its own energy-related equation. By inputting initial parameters, these equations can be literately solved until stable, self-consistent results are obtained. In this appendix, we list the set of major equations describing the energy exchange in Mercury's silicate shell. Detailed description of this model can be found in Xie et al. (2022).

The heat transfer in the crust is controlled by the 1-D steady conduction equation with radiogenic heat production, which is given by:

$$\frac{d}{dr}(r^2k_{cr}\frac{dT}{dr}) = -r^2H_{cr} \tag{A1}$$

Figure A2. Output of the 1-D global parametric model of Mercury for the first billion years. The vertical dashed purple line indicates the time at 700 million years (i.e., 3.8 Ga b.p), and its four intersections with other curves (i.e., A, B, C and D) respectively represent: A. The temperature at the bottom of the lithosphere-mantle (T_l) , B. crust (T_{cr}) . C. The thickness of the lithosphere-mantle (D_l) , D. crust (D_{cr}) .

Where r is radius, k_{cr} is the thermal conductivity of the crust, H_{cr} is the radiogenic heating source in the crust.

For the lithosphere-mantle, its thickness variation depends on the energy equation at the base of the lithosphere-mantle, it can be expressed as (e.g., Morschhauser et al., 2011):

$$\rho_m c_m (T_m - T_l) \frac{dD_l}{dt} + k_m \frac{T_l - T_m}{\delta_u} + k_m \frac{T_c - T_b}{\delta_c} = (\rho_{cr} L_{cr} + \rho_{cr} c_{cr} (T_m - T_l)) \frac{dD_{cr}}{dt}$$
(A2)

⁵³⁴ Where ρ_m and c_m are the average density and specific heat capacity of the mantle, re-⁵³⁵ spectively. T_m is the temperature at the upper convecting mantle and T_l is the temper-⁵³⁶ ature at the base of the lithosphere-mantle. k_m is the mantle's thermal conductivity, T_c ⁵³⁷ is the temperature at the core-mantle boundary and T_b is the temperature at the lower ⁵³⁸ convecting mantle. δ_u and δ_c respectively represent the thickness of the upper and lower ⁵³⁹ thermal boundary. ρ_{cr} is the average density of the crust, L_{cr} is the latent heat of fu-⁵⁴⁰ sion and c_{cr} is the specific heat capacity of the crust.

541

The energy equation of the convecting mantle is (e.g., Morschhauser et al., 2011):

$$\epsilon_m V_{cm} \rho_m c_m (1+st) \frac{dT_m}{dt} + (\rho_{cr} L_{cr} + \rho_{cr} c_{cr} (T_m - T_l) \frac{dD_{cr}}{dt}) A_{cm} = k_m \frac{T_c - T_b}{\delta_c} + V_{cm} Q_m$$
(A3)

Where ϵ_m is the ratio of the convecting mantle's temperature to the average temperature of the convecting mantle, V_{cm} and A_{cm} are the volume and the surface area of this layer. Q_m is the radiogenic heat production rate in the convecting mantle. st is the stefan number that accounts for the consumption and release of latent heat during crystallization and melting of mantle rock.

The results for the first 1 billion years are shown in Fig A2, including the temperature at the bottom of the crust (T_{cr}) and lithosphere-mantle (T_l) over time, the thickness of the crust (D_{cr}) and lithosphere-mantle (D_l) over time. In both subfigures, the purple vertical dashed line indicates the time at 7 million years, i.e., 3.8 Ga b.p.
