Abstract

Bowen ratio reflects the partitioning between sensible and latent heat fluxes and plays a crucial role in land-atmosphere interaction. In this study, the spatiotemporal variations of Bowen ratio among 12 vegetation types were analyzed using observations from 203 FLUXNET sites worldwide and compared against Community Land Model. Results showed that the annual mean Bowen ratio across all sites was 1.48 ± 1.20 (mean \pm SD). Sites with Bowen ratios less than 1 (39%, 80 sites) were found across all continents, and the ones with higher Bowen ratios (>3)(7%, 14 sites) appeared in dry and warm areas. Open shrublands showed the highest Bowen ratio (3.04 ± 0.58), whereas wetlands showed the lowest (0.74 ± 0.09). In terms of seasonality, Bowen ratio showed a U-curve with lower values in local summer and higher in spring and autumn in the northern hemisphere; the opposite occurred in the southern hemisphere. The spatiotemporal variations in Bowen ratio increased under higher VPD (R = 0.45) and hotter (R=0.14) conditions with more shortwave radiation (R=0.39), and decreased with higher precipitation (R=-0.34), albedo (R=-0.16), and leaf area index (R=-0.25). CLM well reproduced the global annual mean Bowen ratio, but showed larger differences for certain vegetations types such as open shrublands (-1.51), woody savannas (+0.98). Our results could enhance our understanding of biotic and environmental controls on land surface energy fluxes and help improve land surface and climate models.

22 Abstract

23 Bowen ratio reflects the partitioning between sensible and latent heat fluxes and plays a crucial 24 role in land-atmosphere interaction. In this study, the spatiotemporal variations of Bowen ratio 25 among 12 vegetation types were analyzed using observations from 203 FLUXNET sites 26 worldwide and compared against Community Land Model. Results showed that the annual mean 27 Bowen ratio across all sites was 1.48 ± 1.20 (mean \pm SD). Sites with Bowen ratios less than 1 28 (39%, 80 sites) were found across all continents, and the ones with higher Bowen ratios (>3)(7%, 29 14 sites) appeared in dry and warm areas. Open shrublands showed the highest Bowen ratio (3.04 30 \pm 0.58), whereas wetlands showed the lowest (0.74 \pm 0.09). In terms of seasonality, Bowen 31 ratio showed a U-curve with lower values in local summer and higher in spring and autumn in the 32 northern hemisphere; the opposite occurred in the southern hemisphere. The spatiotemporal 33 variations in Bowen ratio can be explained by climatic, geographical, and biological factors, with 34 climate factors having the greatest impact. Bowen ratio increased under higher VPD (R = 0.45) 35 and hotter (R=0.14) conditions with more shortwave radiation (R=0.39), and decreased with 36 higher precipitation (R=-0.34), albedo (R=-0.16), and leaf area index (R=-0.25). CLM well 37 reproduced the global annual mean Bowen ratio, but showed larger differences for certain 38 vegetations types such as open shrublands (-1.51), woody savannas (+0.98). Our results could 39 enhance our understanding of biotic and environmental controls on land surface energy fluxes 40 and help improve land surface and climate models.

Keywords: Bowen ratio, sensible heat, latent heat, vegetation, FLUXNET, Community Land
Model

43 1. Introduction

The energy exchange between the land and the atmosphere plays an important role in the
biogeochemical cycle, water cycle, and climate change (Zeng et al., 2020; Qiu et al., 2021; Foley

46 et al., 2003). In particular, vegetation covering 70% of the earth's land surface modulates how 47 net radiation at the land surface is balanced by sensible heat, latent heat, and soil heat flux and 48 thus has a strong impact on land-atmosphere interaction (Zhang et al., 2019; Su et al., 2021; Gray 49 et al., 2018; van Heerwaarden and Teuling, 2014). Vegetation differences in type, structure, and 50 density affect surface energy partitioning (Burakowski et al., 2018; Nicholls and Carey, 2021; 51 Cho et al., 2011; Jo et al., 2004). In terms of radiative processes, vegetation coverage could 52 increase land surface roughness and decrease albedo (Pang et al., 2022), leading to an increase in 53 net radiation. In terms of non-radiative processes, vegetation could increase evapotranspiration, 54 leading to an increase in latent heat and a decrease in sensible heat (Duveiller et al., 2018). Both 55 radiative and non-radiative changes associated with vegetation can influence land-atmosphere 56 interaction and the climate (Bonan, 2008).

57 Bowen ratio, defined as the ratio of sensible to latent heat fluxes at a certain interface, is often 58 used to characterize their partitioning (Bowen, 1926). A large Bowen ratio indicates the turbulent 59 heat flux is dominated by sensible heat, whereas a small ratio suggests the dominance of latent 60 heat. Bowen ratio and aerodynamic resistance jointly affect surface temperature through the non-61 radiative process (Rigden and Li, 2017; Su et al., 2021; Lee et al., 2011). The greater sensible 62 heat associated with a higher Bowen ratio leads to increased land surface temperature and 63 aggravated drought (McGloin et al., 2019). Moreover, Bowen ratio is strongly regulated by 64 climate and vegetation conditions (Ping et al., 2018; Tang et al., 2014; Gholz and Clark, 2002). 65 For example, it is reported that grassland could decrease Bowen ratio through increased latent 66 heat to suppress heatwave compared to forests, but this process accelerated soil moisture 67 depletion and induced a critical shift in the regional climate system that leads to increased heating 68 (Teuling et al., 2010). Given the importance of vegetation modulation, it is meaningful to 69 investigate how Bowen ratio differs among different vegetation types and explore its controlling 70 factors.

71	Bown ratio and its climatic effects were primarily studied through site measurement and
72	modeling (Wang and Dickinson, 2012; Lee et al., 2011). It is found that Bowen ratio was
73	generally high in drier areas (e.g., > 5 in desert and semi-arid areas), and low in moist areas (e.g.,
74	0.5~0.2 in tropical rain forests and irrigated croplands) (Oke and Cleugh, 1987; Morwal et al.,
75	2016; Ryu et al., 2008; Juang et al., 2007). Vegetation changes are often accompanied by surface
76	energy fluxes and Bowen ratio changes. Deforestation tended to elevate Bowen ratio and warm
77	the land surface since forests had a lower Bowen ratio (Yuan et al., 2021; Lee et al., 2011).
78	However, most of these observation-based assessments focused on a certain geographic region
79	with relatively few global-scale studies (Wilson et al., 2002). In addition, surface fluxes are
80	routinely simulated by land surface and climate models, but models have known biases in their
81	energy partitioning between sensible and latent heat that affect their performance (Boisier et al.,
82	2012; Meier et al., 2018; Chen et al., 2018). The latent heat partitioning within different land-
83	cover types was diagnosed to be a major uncertainty source for the different climate responses to
84	land cover change in a model comparison project (Boisier et al., 2012). In another study, the
85	biases of Community Land Model (CLM) in simulating daily minimum land surface temperature
86	were linked to underestimated latent heat for broadleaf deciduous trees and crops while
87	overestimated for non-arctic grasses and broadleaf evergreen trees (Meier et al., 2018). Given the
88	essential role of latent/sensible heat fluxes in heat and water cycling, it is also necessary to
89	evaluate their partitioning in land surface/climate models based on the most updated observation
90	data.
91	In this study, we quantified the Bowen ratio of 12 vegetation types based on the up-to-date

observations from 203 FLUXNET sites, and analyzed the factors that drive the spatiotemporal
variations of Bowen ratio. We further compared the CLM modeled Bowen ratio with these
FLUXNET observations to evaluate the model performance. This work provides a basis for

95	understanding the important role of vegetation in land-atmosphere interaction and climate
96	through a focus on energy partitioning.

97 2. Methods and data

98 2.1 Fluxnet and satellite data

99 The flux data from FLUXNET, a global network of flux observation sites (Fig 1 and

100 Supplementary Table 1) (https://fluxnet.org/) were used in this study. The FLUXNET2015

101 Dataset (accessed by 2021.1.30) provides continuous measurements of carbon and energy fluxes

102 at half-hourly to hourly time intervals by eddy covariance method (Baldocchi et al., 2001; Ma et

al., 2021). Flux sites can be classified into 12 vegetation types based on the MODIS IGBP

104 (International Geosphere Biosphere Programme) land cover classification (Fig 1a), including

105 evergreen needleleaf forests (ENF, N=44), evergreen broadleaf forests (EBF, N=15), deciduous

106 needleleaf forests (DNF, N=1), deciduous broadleaf forests (DBF, N=25), mixed forests (MF,

107 N=9), closed shrublands (CSH, N=3), open shrublands (OSH, N=11), woody savannas (WSA,

108 N=6), savannas (SAV, N=9), grasslands (GRA, N=39), wetlands (WET, N=21), and croplands

109 (CRO, N=20). These sites are distributed across major climate regions (tropical, subtropical,

temperate, and cold zones) and continents (Asia, Africa, North America, South America, and

111 Oceania, especially Europe and North America). Fig 1b shows the distribution of 203 flux sites

112 with their site temperature and precipitation in the climate space of the land surface (the shading

area). Most of the climate space of earth's land was covered by the FLUXNET sites, indicating

114 good representativeness of the world's vegetation.

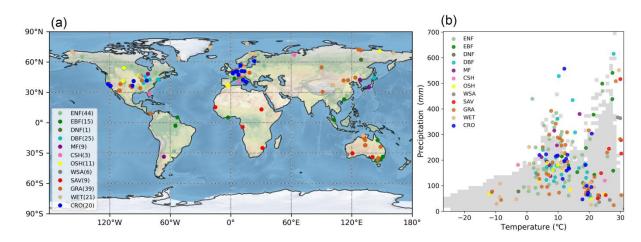

Figure 1. (a) Spatial distribution of global FLUXNET sites with their corresponding vegetation types. Numbers in parentheses denote the number of sites for different vegetation types; (b) The 203 sites in the climate space defined by their annual mean temperature and precipitation. The gray areas denote the climate space over the land (data source: CRU TS Version 4.05).

120 We used sensible heat (H_F_MDS) and latent heat (LE_F_MDS) from FLUXNET to estimate

121 Bowen ratio at each site and obtained environmental factors including precipitation (P_F),

122 temperature (TA F), vapor pressure deficit (VPD F), incoming shortwave radiation (SW IN F),

123 and incoming longwave radiation (LW_IN_F). Albedo was calculated as the outgoing shortwave

radiation (SW_OUT) divided by the incoming shortwave radiation (SW_IN_F). Since fluxes

125 measured by eddy covariance at night have missing data and large errors (Mahrt, 1999; Yuan et

- al., 2021), we used the gap-filled half-hourly data of these variables and extracted only the
- daytime data. Daytime was defined as the local time from 9:00 to 16:00 (McGloin et al., 2019;

128 Yuan et al., 2021). Then we removed data values below 5% and above 95% for sensible and

129 latent heat fluxes to reduce the influence of outliers on the half-hourly scale. At each site, only the

130 site years with available data more than 35% of all the daytime half-hour periods were kept for

- 131 further analysis (Wilson et al., 2002). Finally, 203 sites were retained. These half-hourly data
- 132 (e.g., sensible and latent heat) were averaged to monthly scale, and the multi-year mean Bowen
- 133 ratio was calculated by dividing sensible heat by latent heat at either monthly or annual scales.

134 Leaf area index (LAI) data of each site were obtained from MODIS LAI product

135 (MCD15A3H.006 MODIS Leaf Area Index/FPAR 4-Day Global 500m) from 2000 to 2020 via

136 Google Earth Engine. The multi-year annual mean LAI was extracted at each site location.

137 To analyze the factors influencing spatiotemporal variations in Bowne ratio, we conducted linear

138 regression analyses between Bowen ratio and climatic (precipitation, vapor pressure deficit,

temperature, shortwave radiation, longwave radiation, and albedo), geographical (latitude and

140 longitude), and biological factors (LAI).

141 **2.2 Model simulation data from CLM**

142 Community Land Surface Model 5.0 (CLM 5.0) is the most recent part of the land surface

143 component of the Community Earth System Model, and has been widely used in climate,

144 hydrology, and ecology research (Lawrence et al., 2019). In this study, an offline simulation by

145 CLM 5.0 with prescribed satellite phenology and the separate soil column configuration (Meier et

al., 2018; Schultz et al., 2016) was conducted at the spatial resolution of 0.5° from 2001 to 2015,

driven by a revised climatology GSWP3 (the Global Soil Wetness Project Phase3) as the

148 atmospheric forcing (http://hydro.iis.utokyo.ac.jp/GSWP3/). The years 2001 to 2005 were treated

as spinup periods, and only years from 2006 to 2015 were used in our analysis. The hourly

150 subgrid output data from CLM were processed in the same way as the FLUXNET data, including

extracting daytime data (9:00-16:00) and removing outliers (5% and 95%) in each plant

152 functional types (PFT). Because CLM5.0 model uses PFT to classify vegetation, while

153 FLUXNET uses IGBP, we created a look-up table to convert them (Supplementary Table 2).

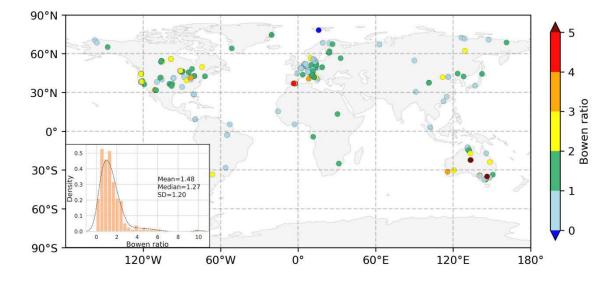

154 When comparing with FLUXNET, we extracted CLM subgrid output based on the location (by

155 longitude and latitude) and PFT of 203 sites, and then calculated Bowen ratio. In order to explore

the relationship between Bowen ratio and environmental factors, regression analyses were

157 conducted with environmental data of CLM5.0.

3. Results

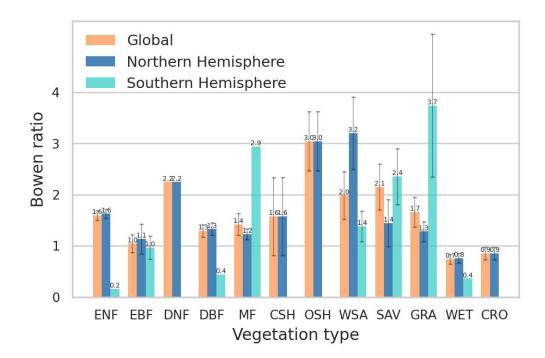

159 **3.1 Spatial variations of Bowen ratio**

Figure 2. Spatial distribution of multi-year annual mean Bowen ratio across 203 FLUXNET sitesand their frequency distribution (inset).

163 At the annual scale, the multi-year mean Bowen ratio of all sites was averaged to be 1.48 ± 1.20 164 $(mean \pm SD)$ (Fig 2). Such a larger-than-one Bowen ratio indicated that globally, sensible heat 165 dominated the turbulent fluxes exchanged between the land and the atmosphere. Of all 203 sites, 166 about 61% sites (123) had Bowen ratio greater than 1. Higher Bowen ratio (>3)(7%, 14 sites) 167 appeared in middle latitude sites, especially in North America and Australia (Fig 2). The 39% 168 sites (80) with Bowen ratio below 1 were found on all continents ranging from about 30°S to 169 70°N (except Antarctica with no site). From the Köppen climate classification (Peel et al., 2007), 170 sites with high Bowen ratios (>1) usually appeared in the arid desert (BW) and arid steppe (Bs) 171 climate (Fig S1), and those sites with smaller Bowen ratio (<1) were usually located in warm 172 temperate and humid climate (Cf). Despite this general pattern, Bowen ratio showed considerable 173 differences within similar climate regimes (e.g., in warm temperate and fully humid climate), 174 reflecting the modulation role of vegetation.

175

Figure 3. The multi-year annual mean Bowen ratio of different vegetation types based on
FLUXNET across the globe, in the northern and southern hemispheres. The error bar on each bar
represents standard error.

- 179 We found that Bowen ratio was significantly different among different vegetation types (Fig 3).
- 180 Globally, open shrublands (3.04 ± 0.58) and savannas (2.15 ± 0.45 for SAV, 1.98 ± 0.46 for WSA)
- 181 had the highest Bowen ratio among all vegetation types. This was followed by forest vegetation
- types including deciduous needleleaf forests (2.25), evergreen needleleaf forests (1.59±0.09), and
- 183 mixed forests (1.42 ± 0.21). Croplands (0.85 ± 0.13) and Wetlands (0.74 ± 0.09) had the smallest
- 184 Bowen ratio among all vegetation types.
- 185 We noticed that even for the same vegetation type, Bowen ratio varied substantially in the
- 186 northern (NH) and southern hemispheres (SH). This reflected the environmental differences in
- 187 their climate, radiation, topography, and other aspects (Fig 3and Fig S2). For example, Bowen
- 188 ratio of most vegetation types was greater than 1; however, evergreen needleleaf forests,
- deciduous broadleaf forests, and wetlands in the SH with high precipitation (Fig S2) had Bowen

190 ratio <1. There were also considerable differences in Bowen ratio of grassland between

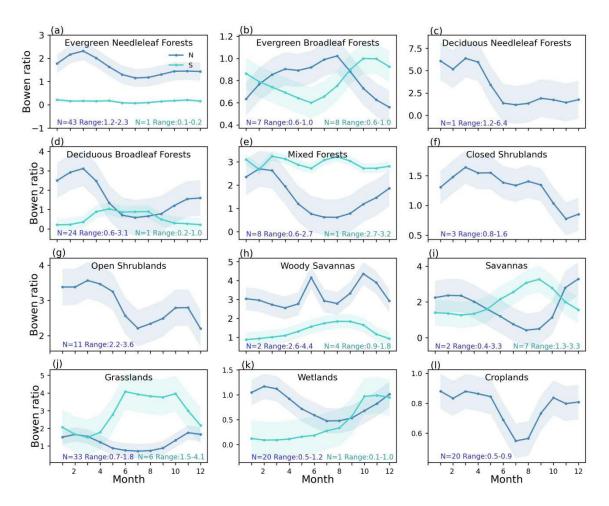

191 hemispheres $(3.74\pm1.34 \text{ in SH vs.} 1.28\pm0.19 \text{ in NH})$ (Fig S2). This could be explained by the

192 fact that grassland sites in the SH were mainly located in arid steppe areas, characterized by high

temperature, VPD, and radiation, while grassland sites in the NH were found in low temperature

- and high precipitation areas (Fig S2).
- 195 **3.2 Seasonal variations of Bowen ratio**

196 Bowen ratio of different vegetation types had distinct seasonal variations in the NH and SH. Most 197 vegetation in the NH showed U-shaped seasonal variations in Bowen ratio (Fig 4), with small 198 values in local summer and large values in local spring and autumn. However, in the SH, many 199 vegetation types including deciduous broadleaf forests, mixed forests, woody savannas, savannas, 200 and grasslands showed an inverted U-curve, with larger Bowen ratios in local summer but lower 201 in spring and autumn. These patterns might be related to their different climate seasonalities. The 202 high temperature and high precipitation typically coincided in summer in the NH, during which 203 vegetation growth peaked with the largest evapotranspiration (ET), thereby leading to the lowest 204 Bowen ratio. By contrast, most sites in the SH experienced less precipitation at local summer for 205 SH, which limited ET and increased Bowen ratio (Fig S3). It is worth noting that Bowen ratio 206 values had a larger bias in winter. This was caused by the FLUXNET data uncertainty in winter 207 when the energy balance closure issues occurred, especially for evergreen needleleaf forests, 208 mixed forests, deciduous broadleaf forests, and wetlands (Cui and Chui, 2019).

209

Figure 4. Seasonal variations of Bowen ratio of different vegetation types in the northern (blue) and southern (cyan) hemisphere based on FLUXNET. The seasonality of SH was shifted by 6 months to align it with NH. The shading area represents one standard deviation. Note that the display ranges of the Y-axis are different in each panel to highlight fluctuation.

214 **3.3** Climatic, geographical, and biological drivers for Bowen ratio

215 In order to explore the factors influencing the spatial variations of Bowen ratio, we conducted

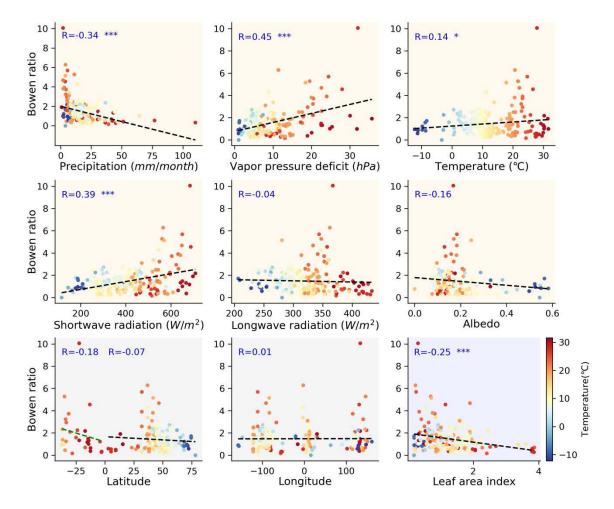

216 regression analyses between annual mean Bowen ratio and several climatic, geographical, and

- 217 biological factors (Fig 5 and Fig S2). Among them, climate factors had the largest impact on
- Bowen ratio. Vapor pressure deficit (R=0.45, p<0.001), incoming shortwave radiation (R=0.39,
- 219 p<0.001), and temperature (R=0.14, p<0.05) showed positive correlations with Bowen ratios,

220 whereas precipitation (R=-0.34, p<0.001), albedo (R=-0.16), and incoming longwave radiation 221 (R=-0.04) showed negative correlations. These results suggested that Bowen ratio became higher 222 under dry/drought and hot conditions (e.g., high VPD, temperature, and less precipitation). 223 Since temperature and precipitation are compounded, we made regressions separately for dry 224 (precipitation<10mm/month) and wet sites (precipitation>30mm/month) to explore the central 225 role of precipitation/moisture in determining energy partitioning because they modulate the 226 temperature effects (Fig S4). The high Bowen in dry sites reflected that sensible heat is the 227 preferred way of heat transfer when evaporation is limited. In this case, Bowen ratio increased 228 with temperature due to a sharp increase of sensible heat with temperature (Fig S4 a). At wet sites 229 with sufficient precipitation/moisture, heat tended to be transferred in the form of latent heat. 230 Therefore, Bowen ratio decreased with the temperature increase due to promoted latent heat with 231 increased temperature (Fig S4 b). 232 In terms of geographical factors, longitude showed no apparent correlations with Bowen ratio. 233 For latitude, Bowen ratio increased with the increasing latitude in the SH (R= -0.18) but not in the 234 NH (R=-0.07). As for the biological factor, there was a significant negative relationship between 235 LAI and Bowen ratio (R=-0.25, p<0.001), revealing the important pathway by which vegetation 236 regulates Bowen ratio. A larger LAI of vegetation effectively increased latent heat through higher 237 ET (Fig S5), while sensible heat remained stable (Fig S6), leading to decreased Bowen ratio. It is 238 worth noting that although sensible heat (Fig S6) and latent heat (Fig S5) showed significant 239 relationships with almost all environmental factors, their strong relationships with environmental

240 factors were weakened in Bowen ratio, reflecting the different responses of sensible and latent

241 heat fluxes to environment factors.

242

Figure 5. The spatial relationship between Bowen ratio and different climatic (orange

background), geographical (gray), and biological factors (blue) based on FLUXNET data. Each
dot represents a site and the dashed lines show the regression line. R is Pearson correlation
coefficient with asterisks denoting significance levels (*for p<0.05; **p<0.01, and ***for
p<0.001). The color of data points shows the mean temperature.

248 **3.4 Comparing Bowen ratio between FLUXNET observations and CLM simulation**

249 We extracted sensible and latent heat fluxes from the subgrid output CLM simulation at the

- 250 location of flux sites with the same PFT (plant functional types) to enable comparison with
- 251 FLUXNET observations (Fig 6). Globally, CLM had relatively good performance in simulating
- sensible heat (R=0.69, P<0.001), latent heat (R=0.69, P<0.001), and to a less extent for Bowen

ratio (R=0.42, P<0.001)(Fig 6 a-c). The simulated sensible heat and latent heat from CLM were
106.18 W/m2 and 88.14 W/m2 averaged at flux site locations, respectively, resulting in a global
mean Bowen ratio of 1.42. In comparison, the corresponding values from FLUXNET data were
110.03 W/m2, 88.60 W/m2, and 1.54, respectively. Therefore, CLM showed a smaller global
mean Bowen ratio by 0.12 relative to FLUXNET observations.

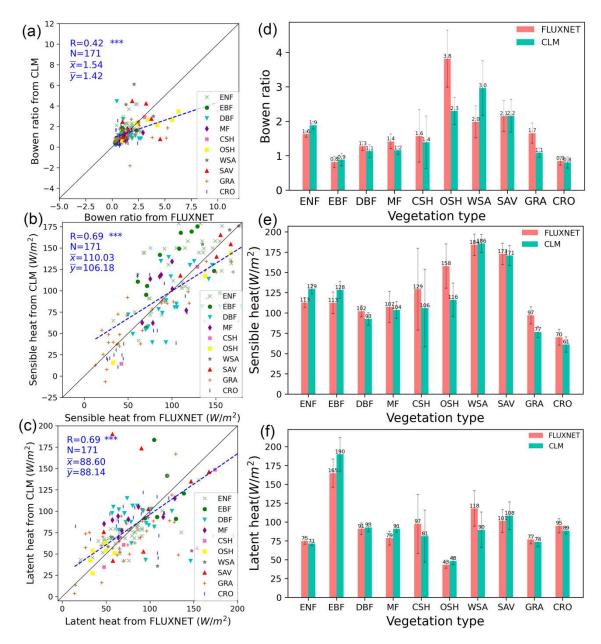

Figure 6. Comparison of annual mean (a) Bowen ratio, (b) sensible heat (H) and (c) latent

258

the 1:1 line. The right column shows the comparison of (d)Bowen ratio,(e)sensible heat (H), and

262 (f)latent heat (LE) between CLM simulation and FLUXNET data in different vegetation types.

263 Since there is no DNF (1) and WET (21) in the model, they were excluded. The H and LE values

of some sites in CLM were missing, so the number of points used for analysis is 171. Note: DNF

- and WET were excluded due to null values in CLM simulation results.
- Although CLM can well simulate the annual mean Bowen ratio at the global scale, there were
- 267 large discrepancies when compared with FLUXNET for different vegetation types (Fig 6d). The
- largest differences appeared in open shrublands where CLM (2.30±0.39) simulated a much
- smaller Bowen ratio than in FLUXNET (3.81±0.83), yielding an underestimation of 1.51. Similar
- underestimation was found for grasslands (GRA, 1.09±0.14 for CLM vs 1.65±0.08 for
- FLUXNET). However, woody savannas (WSA, 2.96±0.79 for CLM vs. 1.98±0.46 for
- FLUXNET) and evergreen needleleaf forests (ENF, 1.88±0.11 for FLUXNET vs. 1.62± 0.08 for
- 273 FLUXNET) from CLM showed a strong overestimated Bowen ratio than observations. The
- differences in Bowen ratio for the rest vegetation types ranged from 0.3 to 0.1. These differences
- 275 in Bowen ratio between CLM and FLUXNET originated from multiple combinations of the
- 276 differences between simulated sensible and latent heat fluxes. For example, a lower simulated
- 277 Bowen ratio could be caused by either a much smaller sensible heat (e.g., GRA and
- 278 croplands/CRO), or a larger latent heat relative to the other (e.g., open shrublands/OSH,
- 279 deciduous broadleaf forests/DBF, and mix forests/MF). A larger simulated Bowen ratio could be
- 280 caused by the opposite combination with a higher sensible heat (e.g., evergreen needleleaf
- 281 forests/ENF). Therefore, Bowen ratio with small differences could reflect the canceling of biases
- in sensible and latent heat if their biases went to the same direction.

283 4. Discussion

284 In this study, the updated data of 203 FLUXNET sites were used to estimate Bowen ratio to 285 analyze the partitioning of surface turbulent heat fluxes. We found that Bowen ratio was 286 positively correlated with vapor pressure deficit, temperature, and incoming shortwave radiation 287 and negatively correlated with precipitation, albedo, and leaf area index. This verifies that Bowen 288 ratio depends on the differences in heat and water exchanges between land and atmosphere. 289 Under climate conditions with high temperatures and sufficient precipitation, heat prefers to exist 290 as latent heat. When water is limited (ET is limited), heat can only exist as sensible heat, leading 291 to a higher Bowen ratio (Fig S5 and Fig S6). Therefore, Bowen ratio is generally high in arid and 292 hot areas but low in humid regions (Bateni and Entekhabi, 2012; Zhao et al., 2018). Among 293 vegetation types, forests have larger LAI and lower albedo and thus absorb more solar radiation. 294 Also, more developed roots of forests enable absorbing deep water to maintain ET, especially 295 during dry periods. Therefore, forests have high efficiency to move water from the land surface to 296 the atmosphere via ET/latent heat (Lawrence et al., 2022). In contrast, grassland has smaller LAI 297 and shallow roots, which limits the ET, leading to greater sensible heat and a larger Bowen ratio. 298 The multi-year annual mean Bowen ratio in grasslands (1.66 ± 0.29) was higher than most forest 299 types (Fig 3), and it also showed large seasonal variations of 1.50-4.07 in the southern 300 hemisphere (Fig 4j). As for wetlands and croplands, the former is usually located in humid areas, 301 while the latter is under intensive human management which might be affected by irrigation. For 302 these reasons, they had the lowest Bowen ratios among all vegetation types and showed small 303 seasonal variations (0.28-1.08 for wetlands and 0.55-0.88 for croplands) (Fig 4). 304 The FLUXNET data provide observations for analyzing the spatiotemporal variations in Bowen 305 ratio of all vegetation types and a useful benchmark for evaluating the accuracy of the model. 306 However, the differences between FLUXNET and CLM of different vegetation types could be 307 linked to several other factors. First, FLUXNET site data are measured by the eddy covariance 308 method. The measurement error and the energy closure problem could influence the estimation of 309 Bowen ratio (Wilson et al., 2002). Second, there is a scale mismatch between FLUXNET site and 310 CLM model grid. The CLM model grid of 0.5° resolution is too coarse to represent the 311 heterogeneous FLUXNET site conditions. Besides, different time periods between FLUXNET 312 (varying across sites, Supplementary Table 1) and CLM data (10 years, from 2006 to 2015) also 313 contribute to the differences in Bowen ratio. Third, the land cover classification of CLM is 314 different from FLUXNET, which might introduce inconsistency as each PFT has its own 315 parameters in the model. Finally, CLM itself has uncertainty in the representations of the energy 316 and hydrological processes, causing biases in ET and soil moisture (Deng et al., 2020; Gao et al., 317 2021). In our study, we focused on assessing the performance of CLM 5.0 but did not investigate 318 the specific causes in the modeling processes. More improvements in land surface models are 319 needed to resolve this difference in the future.

320 We acknowledge limitations in our analyses of data sampling and calculation. Although selected 321 flux sites are distributed in most climate regions (Fig 1b), not all lands are equally sampled (e.g., 322 extremely dry and cold regions are undersampled). To further investigate the spatial sampling 323 issues, we used CLM5.0 data covering all land grids to repeat the regression analyses between 324 Bowen ratio and influencing factors (Fig S7). It can be found that most fitting relationships in 325 CLM were consistent with FLUXNET results in sign, which confirms the general reliability of 326 regression analyses at the site level. However, albedo showed a positive correlation with Bowen 327 ratio (R=0.45, p<0.001), in contrast to the negative correlation obtained with FLUXNET (R=-328 0.16, p>0.05). When we restricted the regression analyses of the CLM results to flux site 329 locations only (Fig S8), a negative relationship between albedo and Bowen ratio appeared and 330 was in line with the FLUXNET results (Fig 5). This demonstrated that the uneven spatial 331 sampling of FLUXNET data might bias the analyses for spatiotemporal variations in Bowen ratio. 332 In addition, we found that the estimation of Bowen ratio was highly sensitive to specific choices 333 in the data processing procedures. For example, the treatment of outliers, the different ways to

define daytime (local time or incoming shortwave radiation threshold), and the time scale at
which the ratio was calculated would lead to slightly different Bowen ratio values. Therefore, we
should pay attention to data processing when estimating Bowen ratio in the future. This will serve
as the basis for a fair comparison between observations and models since both are critical
measures to better understand the sensible heat and latent heat partitioning.

339 In conclusion, this analysis provides evidence for the global variations of Bowen ratios among 340 vegetation types and deepens our understanding of energy partitioning which has far-reaching 341 consequences on land and atmosphere interactions. A decrease in Bowen ratio indicates an 342 increasing dominance of latent heat, which could mitigate land surface warming and affect cloud 343 and precipitation processes in the atmosphere (Stoy, 2018; Xu et al., 2020). An increase in Bowen 344 ratio indicates an enhanced surface heating effect, which may aggravate the drought (Schumacher 345 et al., 2019). The spatiotemporal variation of Bowen ratio is the result of both vegetation 346 characteristics and environmental factors (especially climate factors). With global warming, the 347 response of vegetation would play a more important role in modulating energy redistribution 348 (Forzieri et al., 2020). The different vegetation types with their effects on energy partitioning 349 provide the basis for nature-based solutions to mitigate warming. Finally, our data-model 350 comparison emphasizes the importance of accurately representing energy partitioning of 351 vegetation changes in the model, which is critical for studying the climate impacts of land cover 352 change. Therefore, high-quality flux observations are essential for model improvement. In the 353 future, more flux sites are welcome to improve the spatial sampling of the FLUXNET, especially 354 underrepresented vegetation (e.g., deciduous needleleaf forests) and climate types (e.g., 355 extremely dry and cold regions). This combined knowledge from observations and advances in 356 land surface and climate modeling will enhance the credibility of climate predictions and promote 357 better climate policy.

555

556 Supplementary Table 2 Conversion of vegetation types between CLM model and IGBP. Due to 557 the lack of wetlands (WET) and deciduous needleleaf forests (DNF) data in the CLM model, no 558 conversion is made. Note: CLM land classification scheme: 1 needleleaf evergreen temperate 559 tree, 2 needleleaf evergreen boreal tree, 3 needleleaf deciduous boreal tree, 4 broadleaf evergreen 560 tropical tree, 5 broadleaf evergreen temperate tree, 6 broadleaf deciduous tropical tree, 7 561 broadleaf deciduous temperate tree, 8 broadleaf deciduous boreal tree, 9 broadleaf evergreen 562 temperate shrub, 10 broadleaf deciduous temperate shrub, 11 broadleaf deciduous boreal shrub, 563 12 arctic c3 grass, 13 cool c3 grass, 14 warm c4 grass, 15 crop.

PFT	IGBP
1-2	Evergreen needleleaf forests (ENF)
4-5	Evergreen broadleaf forests (EBF)
6-8	Deciduous broadleaf forests (DBF)
1-8	Mixed forests (MF)
9-11	Closed shrublands (CSH)
9-11	Open shrublands (OSH)
1-11	Woody savannas (WSA)
1-11	Savannas (SAV)
12-14	Grasslands (GRA)
15	Croplands (CRO)

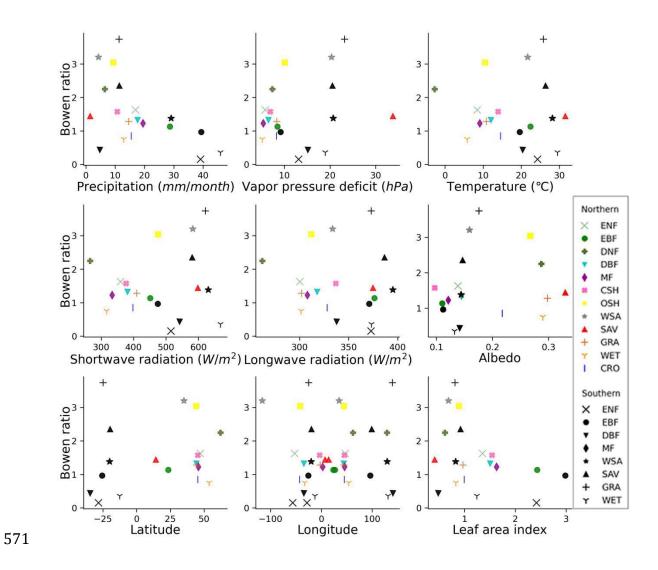

564

571 Supplementary Fig 1 Spatial distribution of multi-year annual mean Bowen ratio across

572 203 FLUXNET sites. Different circles represent FLUXNET sites, colors represent

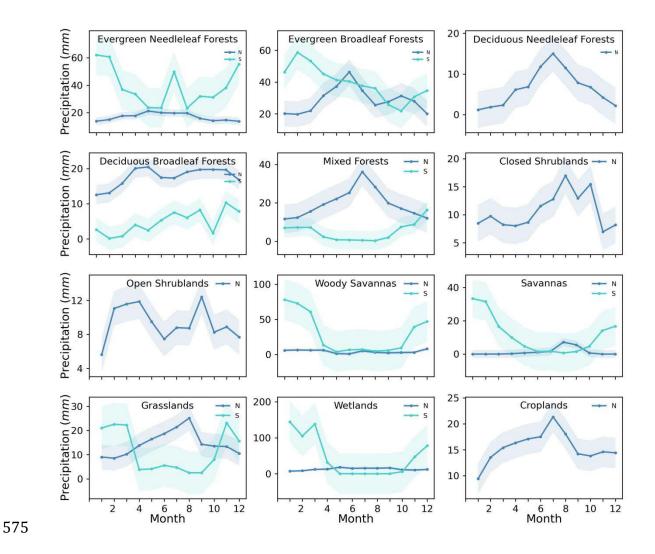

- 573 different Bowen ratio, and background colors represent the Köppen climate classification.
- 574 Take the grassland as an example, the squares are the grassland sites in the northern
- 575 hemisphere, and the stars are sites in the southern hemisphere.

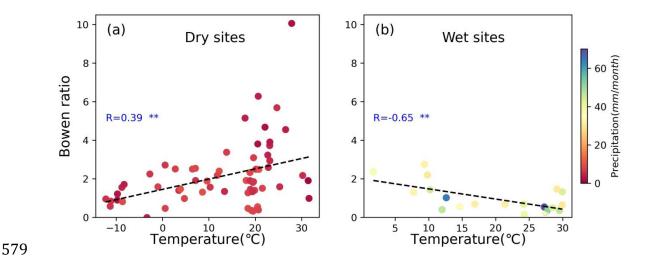

572 Supplementary Fig 2 Relationship of Bowen ratio and influencing factors among

573 different vegetation types. Due to data limitations, DNF, CSH, OSH and CRO only have

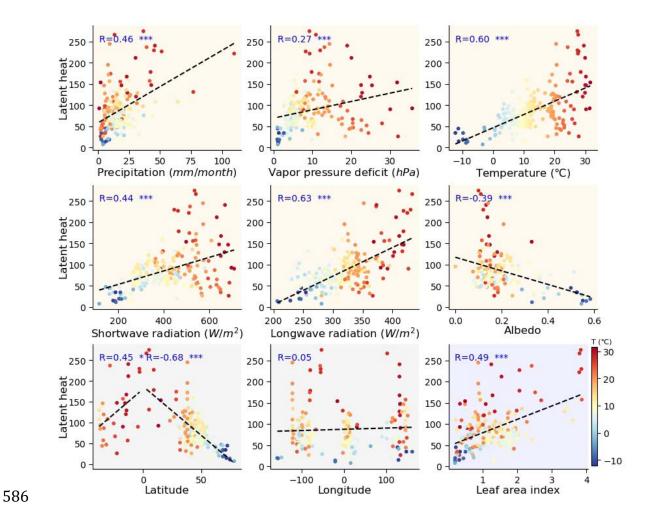

574 sites in the northern hemisphere.

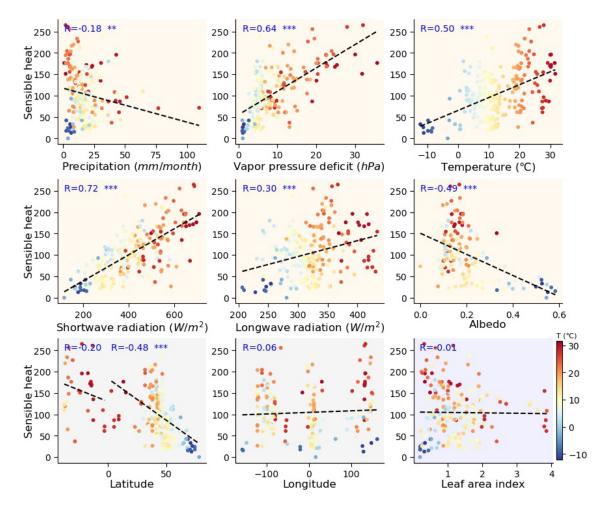

Supplementary Fig 3 Seasonal variations of precipitation of different vegetation types in
the northern (blue) and southern (cyan) hemisphere. The seasonality of SH was shifted by
6 months to align it with NH. The shading area represents one standard deviation.

Supplementary Fig 4 The spatial relationship between Bowen ratio and temperature for
dry (precipitation<10mm/month) and wet sites (precipitation>30mm/month) based on
FLUXNET data. Each dot represents a site and the dashed lines show the regression line.
R is Pearson correlation coefficient with asterisks denoting significance levels (*for
p<0.05; **p<0.01, and ***for p<0.001). The color of data points shows the mean
precipitation.

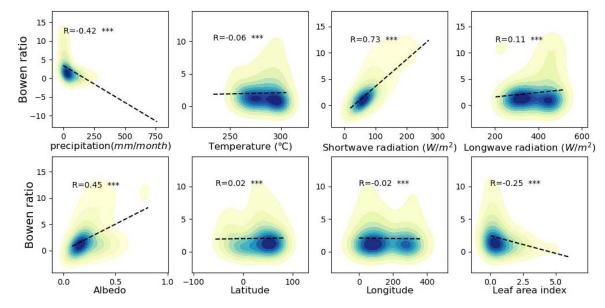

Supplementary Fig 5 Regression analysis of latent heat flux and different influencing
factors. Orange, gray, blue background represent climatic, geography and biological
factors. The dashed line shows the regression line. R is Pearson correlation coefficient
(*:p<0.05, **: p<0.01, ***: p<0.001). The color of data points shows the mean
temperature.

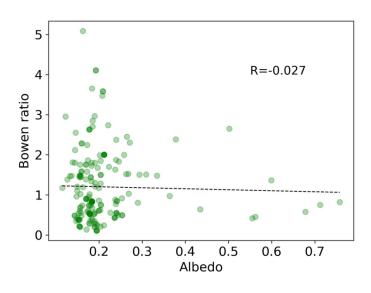

592

Supplementary Fig 6 Regression analysis of sensible heat flux and different influencing
factors. Orange, gray, blue background represent climatic, geography and biological
factors. The dashed line shows the regression line. R is Pearson correlation coefficient
(*:p<0.05, **: p<0.01, ***: p<0.001). The color of data points shows the mean
temperature.

Supplementary Fig 7 Regression analysis of Bowen ratio and different influencing factors
of all grid points in CLM results. The dashed line shows the regression line. R is Pearson
correlation coefficient (*:p<0.05, **: p<0.01, ***: p<0.001). Color represents the density
of points.

603

598

604 Supplementary Fig 8 Regression analysis of Bowen ratio and albedo from CLM

according to the site locations. P>0.05, implying that there was no significant difference.
