Abstract

A three-dimensional physical-biogeochemical ocean numerical model with eddy-permitting horizontal resolution was applied to simulate upper-ocean carbon cycle variabilities in the Tropical Maritime Continent (TMC) over the last decade (2010–2019). Forced by atmospheric and oceanic reanalysis products with high temporal resolution, the model showed robust consistency with the observed seasonality of pCO2 and atmospheric CO2 sink/source characteristics across the modeling domain. Within the TMC, the model results indicated strong CO2 degassing along the west of Sumatra-south of Java associated with the seasonal cycle of the upwelling system in the area. While acting as a full-year atmospheric CO2 source, the TMC exhibited pronounced interannual modulation in both pCO2 and sea-air CO2 flux over the last decade. Large-scale anomalous strong CO2 degassing from 2015 to 2016 in response to the evolution of the 2015/2016 El Niño was observed from the simulation results. Modulations related to the Indian Ocean Dipole (IOD), on the other hand, were confined along the west of Sumatra-south of Java with a higher magnitude compared with anomalies related to El Niño/La Niña. Simulation results also captured the asymmetric response of the upper-ocean carbon cycle to the IOD over the last decade, where anomalies during negative IOD (nIOD) were notably strong despite being indicated as weak nIOD events by the Dipole Mode Index.

12   **Key Points:**

13   • The Tropical Maritime Continent Sea surface acted as a full-year atmospheric CO_2 source

14   with average flux of 0.08 PgC per year

15   • Strong pCO_2 and CO_2 degassing during Boreal Summer-Boreal Autumn around the West

16   of Sumatra-South of Java was related to upwelling cycle

17   • Large-scale stronger-than-usual CO_2 degassing from Tropical Maritime Continent Sea

18   surface during the development of the 2015/2016 El Niño

19 **Abstract**

20 A three-dimensional physical-biogeochemical ocean numerical model with eddy-permitting

21 horizontal resolution was applied to simulate upper-ocean carbon cycle variabilities in the Tropical

22 Maritime Continent (TMC) over the last decade (2010–2019). Forced by atmospheric and oceanic

23 reanalysis products with high temporal resolution, the model showed robust consistency with the

24 observed seasonality of pCO_2 and atmospheric CO_2 sink/source characteristics across the modeling

25 domain. Within the TMC, the model results indicated strong CO_2 degassing along the west of

26 Sumatra-south of Java associated with the seasonal cycle of the upwelling system in the area.

27 While acting as a full-year atmospheric CO_2 source, the TMC exhibited pronounced interannual

28 modulation in both pCO_2 and sea-air CO_2 flux over the last decade. Large-scale anomalous strong

29 CO_2 degassing from 2015 to 2016 in response to the evolution of the 2015/2016 El Niño was

30 observed from the simulation results. Modulations related to the Indian Ocean Dipole (IOD), on

31 the other hand, were confined along the west of Sumatra-south of Java with a higher magnitude

32 compared with anomalies related to El Niño/La Niña. Simulation results also captured the

33 asymmetric response of the upper-ocean carbon cycle to the IOD over the last decade, where

34 anomalies during negative IOD (nIOD) were notably strong despite being indicated as weak nIOD

35 events by the Dipole Mode Index.

36 **Plain Language Summary**

37 The lack of long-term observational data has limited research on sea-air CO_2 exchange variabilities

38 in the Tropical Maritime Continent (TMC). In this study, we provide results of the initial effort in

39 modeling sea-air CO_2 exchange across the region over the last decade (2010-2019). The simulation

40 results suggest that while the sea surface across the area acts as a CO_2 source to the atmosphere,

41 some periods like 2015-2016 were associated with stronger-than-usual degassing. Such anomalies

42 are related to large-scale changes in the Pacific and Indian oceans.

43 **1 Introduction**

44 The Tropical Maritime Continent (TMC) region acts as a water passage that allows Pacific Ocean

45 water to be transported to the Indian Ocean as part of thermohaline circulation, which modulates

46 the global climate system (Gordon, 1986; Wyrtki, 1961). Located between the Indian and Pacific

47 Ocean, the TMC area is subject to modulation caused by variabilities occurring in these two ocean

48 basins, including the El Niño-Southern Oscillation (ENSO) in the tropical Pacific Ocean, and

49 Indian Ocean Dipole (IOD) in the Indian Ocean (Ashok et al., 2003; Saji and Yamagata, 2003;

50 Sprintall et al., 2014). Recent studies have confirmed that these climate modes influence the TMC

51 area through sea-air interaction perturbation, which affects the rainfall rate and oceanic properties

52 such as sea surface temperature, sea surface height, and circulation pattern (Delman et al., 2016;

53 Pujiana et al., 2019, 2020; Saji and Yamagata, 2003; Siswanto et al., 2020; Sprintall et al., 2014;

54 Susanto et al., 2001; Syamsudin et al., 2004).

55 Despite the progress, studies on oceanic carbon cycle dynamics in the area remain very limited

56 compared to the number of oceanic carbon-related studies that are growing globally (Bakker et al.,

57 2016; Key et al., 2004; Takahashi et al., 2002, 2009). Although one of the latest observation-based

58 studies by Kartadikaria et al. (2015) on the compilation of sea surface CO_2 partial pressure (pCO_2)

59 across the Indonesian seas could provide a general view of the atmospheric CO_2 sink/source

60 characteristics, it still could not represent the actual seasonal cycle and response of the seawater

61 CO_2 system to large-scale climate variabilities. Typical pCO_2 underway measurements conducted

62 in a short period are not reliable in capturing the low-frequency variabilities that usually develop

63 within an interannual time scale or longer (Sutton et al., 2017b). A study by Hamzah et al. (2020)

64   in western Indonesian seas later confirmed this issue by highlighting the possible variation in the

65   carbonate system over seasonal and interannual timescales in the undersampled area. The recent

66   development of the pCO_2 empirical model (Iida et al., 2015) or machine learning in estimating

67   pCO_2 is unfortunately still inadequate and produces a relatively coarse resolution for resolving the

68   complex island configuration within the TMC. These constraints make it challenging to apprehend

69   TMC oceanic carbon cycle variabilities at various time scales.

70   Several modeling studies have indicated that the pCO_2 and sea-air CO_2 flux exhibit apparent

71   modulation related to climate variability. A modeling study by Chai et al. (2009) in the South

72   China Sea showed that pCO_2 followed the seasonal variations of net primary productivity, which

73   was inversely correlated with the sea surface temperature (SST) anomaly in the Eastern Tropical

74   Pacific region (NINO 3). Global scale modeling by Obata and Kitamura (2003) emphasized the

75   Tropical Pacific Ocean region's sea-air CO_2 flux, where the variability in the region related to

76   ENSO contributed approximately 70% to the global variability. Similar global-scale modeling was

77   conducted by Valsala et al. (2014); despite indicating differences in the contribution of Tropical

78   Pacific CO_2 flux variabilities to global variabilities, the study still agrees to the extent that Tropical

79   Pacific Ocean variability has a significant influence on global carbon cycle modulation. They

80   further suggested a stronger influence of El Niño-Modoki (Ashok et al., 2007) on carbon cycle

81   variability in the western part of the Tropical Pacific, adjacent to the TMC. In their modeling study,

82   Xiu and Chai (2014) also addressed the significance of the Pacific Decadal Oscillation and North

83   Pacific Gyre Oscillation in modulating the sea-air CO_2 flux across the North Pacific region,

84   highlighting the variabilities in much lower frequency domains. These studies partly confirm the

85   hypothesis about the possible low-frequency modulation of the oceanic carbon cycle, considering

86   the proximity of the TMC to the area studied previously. One of the remaining questions concerns

87   the modulation pattern related to the Indo-Pacific climate variability in the area, which this study

88   attempts to address.

89   A newly developed low-trophic ecosystem model was employed to further resolve the issue of

90   elucidating the upper-ocean carbon cycle variability across the TMC. The model was forced by

91   realistic high-temporal resolution atmospheric forcings to approach the actual ocean-atmosphere

92   dynamics that occurred during the simulation period that took place from December 2007 to

93   January 2020. We further focused the analysis between 2010 and 2019 to examine the interannual

94   changes in pCO_2 and sea-air CO_2 flux in the region. The analysis period included extreme events,

95   such as the 2015/2016 El Niño and the 2019 positive IOD (pIOD). Previous studies have indicated

96   that unprecedented anomalies occur around the TMC associated with these extreme climate events

97   (e.g., Lu and Ren, 2020; Pujiana et al., 2019) and thus, have become an interesting period to

98   examine the sensitivity of the upper-ocean carbon cycle in the area to such anomalous climate

99   events.

100   **2 Model and datasets**

101   **2.1. Model description and configuration**

102   The newly developed ecosystem model employed here was carbon (C) and nutrient (phosphate,

103   nitrate, ammonium) tracing, low-trophic ecosystem model developed by Nakamura et al. (2018).

104   The model was embedded in the Coupled Ocean-Atmosphere-Wave and Sediment Transport

105   (COAWST) modeling environment (Warner et al., 2010) with the Regional Ocean Modeling

106   System (ROMS; Shchepetkin and McWilliams, 2005) as the ocean general circulation model

107   (OGCM). The ecosystem model developed here includes three phytoplankton functional types

108   (PFT) in terms of carbon biomass, comprising diatoms, dinoflagellates, and coccolithophores.

109   These PFTs utilize nutrients and dissolved inorganic carbon (DIC) for photosynthesis and

110   assimilation. Additionally, coccolithophores further use total alkalinity (TA) for the calcification

111   process to produce $CaCO_3$ shells.

112   The material excreted by PFTs following the assimilation process immediately enters the labile

113   dissolved organic matter (labile-DOM) pool. All dead phytoplankton biomass enters the

114   particulate organic matter pool as detritus (detritus-POM) and sinks into a deeper layer in the water

115   column. As for the dead coccolithophore biomass, the previously produced $CaCO_3$ from the

116   calcification process enters the particulate inorganic matter ($CaCO_3$-PIM) pool and sinks into a

117   deeper layer, like the detritus-POM. Estimated produced $CaCO_3$-PIM from coccolithophore dead

118   biomass was adapted from Krumhardt et al. (2017, 2019). In this modified version, we have added

119   an inorganic nitrogen compound (nitrate and ammonium) compartment to calculate the effect of

120   nutrient limitation on calcification. Additional sinking velocities for all PFTs in this modified

121   version were applied, following Gregg et al. (2007). One type of zooplankton in terms of carbon

122   biomass was assigned in this model which grazed on phytoplankton, labile-DOM, and detritus-

123   POM. As in the phytoplankton, the dead bodies of zooplankton also entered the detritus-POM

124   pool, with a small part entering the $CaCO_3$-PIM pool. The $CaCO_3$-PIM from zooplankton dead

125   biomass was based on Ishizu et al. (2019, 2020).

126   The decomposition process takes place in the labile-DOM pool to resupply the inorganic carbon,

127   nitrogen (as ammonium), and phosphorus (as phosphate) needed by phytoplankton. The

128   decomposition of detritus-POM transforms POM into DOM and dissolved inorganic compounds

129   (carbon, nitrogen, and phosphorus) simultaneously. Nitrate in this model was recovered through

130   the nitrification of ammonium. We applied the first order dissolution reaction equation for the

131   dissolution process of $CaCO_3$-PIM with a seawater $CaCO_3$ saturation state that varied within the

132   water column (Jansen et al., 2002; Sarmiento and Gruber, 2006). Here, the $CaCO_3$-PIM saturation

133   state was approximated as the calcite saturation state, given that the main $CaCO_3$ produced in this

134   model came from coccolithophores.

135   The pCO_2 was calculated in multiple steps, starting from the estimation of sea surface pH and the

136   concentration of $CO_{2(aq)}$ in the same surface layer. Both pH and $CO_{2(aq)}$ are functions of DIC, TA,

137   water temperature, and salinity, and DIC and TA are generated in the ecosystem module. The sea-

138   air CO_2 flux was calculated based on Wanninkhof (1992), with the CO_2 solubility parameterization

139   adapted from Weiss (1974).

140   We set the model domain to span from the Southeast Tropical Indian Ocean (SETIO) to the

141   Northwest Pacific Ocean (90º E-164º E; 18º S-29º N). The domain was gridded uniformly with a

142   horizontal resolution of $1/6° \times 1/6°$ while the water column was transformed into 30-layers of non-

143   uniform, terrain-following s-coordinates. Generic length scale (GLS) mixing parameterizations of

144   the k–ε configuration were utilized in this model for vertical mixing combined with the Kantha-

145   Clayson stability function (CPP options KANTHA_CLAYSON) and horizontal smoothing of

146   buoyancy/shear (CPP options N2S2_HORAVG). Smagorinsky-like diffusion (CPP option

147   UV_SMAGORINSKY and TS_SMAGORINSKY) was activated in this simulation for the

148   horizontal diffusion and viscosity for both momentum and tracer variables.

149   Lateral boundary condition was set to be mixed radiation-nudging for the 3D momentum and tracer

150   variables. The inflow nudging timescale for the temperature/salinity and biogeochemical tracers

151   were set to 100 days and 180 days respectively. In this simulation, some types of material

152   compounds, such as coarse particulate organic matter and refractory dissolved organic matter,

153   were deactivated by setting the value to zero for both the initial and boundary conditions. River

154 discharge across the model domain was also not implemented; thus, the indicated results of pCO$_2$

155 and sea-air CO$_2$ flux were caused solely by the ocean-atmosphere interaction dynamics.

2.2. Datasets

157 The Global Ocean Forecasting system (GOFS) analysis/reanalysis product from the hybrid

158 coordinate ocean model (HYCOM; Chassignet et al., 2006) were used as the ocean circulation

159 model initial and boundary conditions in this simulation. Both versions 3.0 and 3.1 of the GOFS

160 output were utilized owing to the difference in the coverage period. We used a three-hourly 55-

161 year Japan reanalysis (JRA-55) product (Kobayashi et al., 2015) as atmospheric forcings in the

162 simulation, which included the atmospheric pressure, air temperature, humidity, wind speed, and

163 cloud fraction. The bulk fluxes (shortwave radiation and longwave radiation) were calculated

164 internally in the model as a function of the sea surface temperature, air temperature, humidity, and

165 cloud fraction. For tidal forcing, Oregon State University Tidal Prediction Software (OTPS)

166 product consisting of 12 tidal components was used.

167 The initial and boundary conditions for the ecosystem model were generated analytically because

168 of the limitation of seawater carbonate chemistry-related data across the study area. The Global

169 Data Analysis Project (GLODAP) product (Key et al., 2004) which stores scientific cruise data of

170 necessary inorganic carbon parameters such as TA, DIC, and dissolved oxygen (DO), was used

171 and paired with the water temperature data record to create a polynomial equation. This approach

172 allowed us to create a vertically stratified profile for both TA and DIC parameters, which play a

173 crucial role in near-boundary areas. We also estimated the nutrient concentrations for the initial

174 and boundary conditions of the ecosystem model by utilizing the calculated TA, DIC, and salinity

175 data from the GOFS. The equation established here was based on the gradient between the salinity-

176 normalized DIC (nDIC) and the corresponding nutrient (N, P) from the GLODAP datasets. We

177 found nDIC:P and nDIC:N ratios of 141.23 and 9.76, respectively; hence, this ratio was used for

178 the simulation. The observed nDIC:P and nDIC:N ratios were within the results of previous studies

179 (Martiny et al., 2014; Redfield, 1934; Sarmiento and Gruber, 2006). More details of the analytical

180 equations used to create the initial and boundary conditions of the ecosystem model are provided

181 in Table 1.

182 **Table 1**. Analytical equations used to estimate necessary parameters for the ecosystem model

183 simulation in initial and boundary conditions. The equations stated here are functions of water

184 temperature (T), salinity (S), depth (z), and dissolved inorganic carbon (DIC)

Parameter (unit)	Equation
Dissolved inorganic carbon (μmol. kg^{-1})	$2312.12 + (10.68 \cdot T) - (3.50 \cdot T^2) + (0.16 \cdot T^3) - (2.42 \times 10^{-3} \cdot T^4)$
Total alkalinity (μmol. kg^{-1})	$2444.73 - (22.29 \cdot T) + (0.09 \cdot T^2) + (1.28 \times 10^{-3} \cdot T^3) + (4.60 \times 10^{-4} \cdot T^4)$
Dissolved oxygen (μmol. L^{-1})	$245.85 - (52.01 \cdot T) + (6.46 \cdot T^2) - (0.28 \cdot T^3) + (3.84 \times 10^{-3} \cdot T^4)$
Phytoplankton (μmolC. L^{-1})	For z < 155 m $$\frac{10.5 - 0.00095 \cdot (z + 50)^2}{6}$$
Zooplankton (μmolC. L^{-1})	$0.1 \cdot$ Phytoplankton
Nitrate (μmolN. L^{-1})	$0.98 \cdot \dfrac{\left(\dfrac{(DIC \cdot 35)}{S} - 1977.4\right)}{9.765}$
Ammonium (μmolN. L^{-1})	$0.02 \cdot \dfrac{\left(\dfrac{(DIC \cdot 35)}{S} - 1977.4\right)}{9.765}$

Phosphate (μmolP. L^{-1})	$\dfrac{\left(\dfrac{(DIC \cdot 35)}{S} - 1961.3\right)}{141.23}$

185

186   Annual global-averaged atmospheric CO_2 concentration data from 2007 to 2019 recorded by the

187   Earth System Research Laboratory of the National Oceanic and Atmospheric Administration

188   (ESRL NOAA) was used to generate the carbon exchange between the sea surface and atmosphere

189   in the model (https://www.esrl.noaa.gov/gmd/ccgg/trends/global.html). Underway measurement

190   records of seawater CO_2 fugacity (fCO$_2$) archived in the Surface Ocean CO_2 Atlas (SOCAT)

191   version 2020 (Bakker et al., 2016) were employed for comparison with modeled pCO$_2$, especially

192   around the Western Pacific Region given its frequent observation. For further simplicity, we

193   regarded both the global-averaged CO_2 concentration and the measured fCO$_2$ in SOCATv2020 as

194   atmospheric pCO$_2$ (pCO$_{2atm}$) and pCO$_2$ respectively, because of the generally negligible difference

195   between these two parameters and the actual pCO$_2$ value.

196   Considering the lack of continuous observation data inside the TMC, we only utilized the

197   underway pCO$_2$ measurements and pCO$_2$ flux estimation results from several expeditions that

198   were also used by Kartadikaria et al. (2015). The pCO$_2$ and CO_2 flux data from these expeditions

199   were processed further to remove possible outliers. Outliers were defined as any data below

200   (exceed) the 10th (90th) percentile. Lastly, we calculated both NINO3.4 SSTA and DMI (See Saji

201   et al. 1999 for DMI calculation details) using HadI SST1.1 (Rayner et al. 2003) and the 1961–

202   1990 mean seasonal cycle as the baseline. ENSO events (El Niño/La Niña) were defined whenever

203   the five-month moving average of the NINO3.4 SSTA exceeded the assigned threshold of $\pm$ 0.5

204   ºC for at least three consecutive months within the November-March period. A summary of the

205   datasets utilized for this simulation is presented in Table 2.

206 **Table 2.** Summary of datasets utilized for simulation and necessary data analysis

208 **3 Results and discussion**

209 **3.1 Comparison with available observations**

210 We separated the SOCAT v2020 data around the Western Pacific Ocean into six longitudinal

211 transect lines from 135° E to 160° E in the following latitudes 0° N, 5° N, 10° N, 15° N, 20° N, 25°

212 N (Figure 1). The monthly value of pCO_2 in each transect line was calculated by averaging all

213 measurement records across the line in the corresponding month. Using this method, we obtained

214 line-averaged monthly pCO_2 data from 2010 to September 2019. For further analysis, we treated

215 the missing value of the area-averaged monthly pCO_2 that did not exceed two consecutive months

216 by using piecewise cubic spline interpolation.

217 A strong seasonal pattern was exhibited by the Northwestern Pacific Ocean (15° N-25° N) where

218 both model results and observations indicated that high and low pCO_2 occurred in the summer

219 (June-August) and winter (December-February), respectively, which closely follows the seasonal

220 cycle of SST. This implies strong water temperature modulation on pCO_2 in the subtropical Pacific

221 region. However, the seasonal magnitude of pCO_2 weakened around the tropical area from 10° N

222 to 0° N (Figure 1b, lower panel), as the temperature remained relatively stable throughout the year.

223 Long-term linear trend analysis of modeled and observed pCO_2 from 2010 to 2019 showed that

224 the annual increase in pCO_2 also varied with latitude, where the subtropical region experienced

225 faster pCO_2 growth compared with the equatorial area (Table 3). Varying long-term trends across

226   latitudes were related to atmospheric CO_2 uptake capability, which tends to be stronger in high-

227   latitude areas (Xiu and Chai, 2014).

228   To examine atmospheric CO_2 sink/source characteristics from observed pCO_2 in the Western

229   Pacific Ocean, we utilized atmospheric pCO_2 (pCO_{2atm}) data from Chuuk Lagoon maintained by

230   the Pacific Marine Environmental Laboratory (PMEL) NOAA Carbon Program (Sutton et al.,

231   2017). The three-hourly recorded pCO_{2atm} from November 2011 to October 2018 was averaged to

232   obtain the monthly average value of pCO_{2atm}. The obtained monthly pCO_{2atm} was then used to

233   calculate the pCO_2 difference between the sea surface and atmosphere ($dpCO_2$), which further

234   dictated the direction of the CO_2 flux at each latitude. A similar procedure was performed for the

235   modeled pCO_2 but using the employed annual global-averaged atmospheric pCO_2 instead. The

236   modeled $dpCO_2$ was in general consistent with the observed $dpCO_2$ with robust correlation (r =

237   0.72; $p < 0.01$) and a bias of 8.70 µatm.

238

Figure 1. (a) The whole model domain and longitudinal transect lines in the Western Pacific Ocean

where SOCATv2020 data was processed and compared with simulation results. (b) Time series of

monthly pCO_2 from simulation (blue solid line) and observed (red scatter dots) pCO_2 in the

Western Pacific Ocean from equator (0° N) to 25° N latitude. (c) Scatter plot between modeled

$dpCO_2$ and observed $dpCO_2$. Dashed black line in (c) indicates the 1:1 line where perfect agreement

lies.

Table 3. Linear trend analysis results from both observed and modeled pCO_2 across the Western

Pacific. Showed trend values were significant at $p < 0.01$.

Annual pCO$_2$ trend (µatm/year)	25°N	20°N	15°N	10°N	5°N	0°N
SOCAT	3.35	3.51	2.96	2.83	2.69	1.49
Model	2.74	2.47	1.25	1.71	1.26	n/a

248

249 The comparison between model results and underway measurements in Indonesian seas also

250 agreed to the extent that the area generally acted as an atmospheric CO$_2$ source (Table 4).

251 Compared with model results, measured pCO$_2$ and CO$_2$ flux by Kartadikaria et al. (2015) showed

252 a higher standard deviation. This emphasizes the urgency of a reliable long-term upper-ocean

253 carbonate chemistry observation system in the area to reduce uncertainty regarding the atmosphere

254 CO$_2$ sink/source characteristic.

255 The differences in the modeled pCO$_2$ with the measured value could be attributed to the spatial

256 variations in biogeochemical dynamics that were not fully resolved by the single-value

257 parameterization approach in the current model configuration. The selection of atmospheric pCO$_2$

258 used for the simulation also possibly contributed to this difference. This is based on a comparison

259 between the global-averaged pCO$_{2atm}$, Chuuk Lagoon monitoring site pCO$_{2atm}$ record (Sutton et

260 al., 2017a), and observed pCO$_{2atm}$ in the study by Kartadikaria et al. (2015), where the global-

261 average pCO$_{2atm}$ was higher than the other measurements.

262

267 **3.2. Simulated mean seasonal cycle of the upper-ocean carbon cycle in the Tropical**

268 **Maritime Continent**

269 Figure 2a shows the simulated pCO$_2$ with contrasting seasonal cycles between the western and

270 eastern parts of the TMC, consistent with the segregation suggested by Kartadikaria et al. (2015).

271 The western part of the TMC showed a higher pCO$_2$ than the eastern part during the summer.

272 Conversely, the pattern was reversed during winter, with higher pCO$_2$ in the eastern part. Large-

273 scale high pCO$_2$ was observed during spring (March-May), as most of the area across the TMC

274 showed its annual warmest SST, which is a two–three months lag from the peak of winter (Figure

275 2b). In the succeeding season of the summer-autumn (September-November), an apparent

276 upwelling signature of low SST from along west of Sumatra-south of Java was observed but was

277 associated with high pCO$_2$ in the area. This further suggests that the effect of SST drop on pCO$_2$

278 due to upwelling could be suppressed by the increase in inorganic carbon content, resulting in a
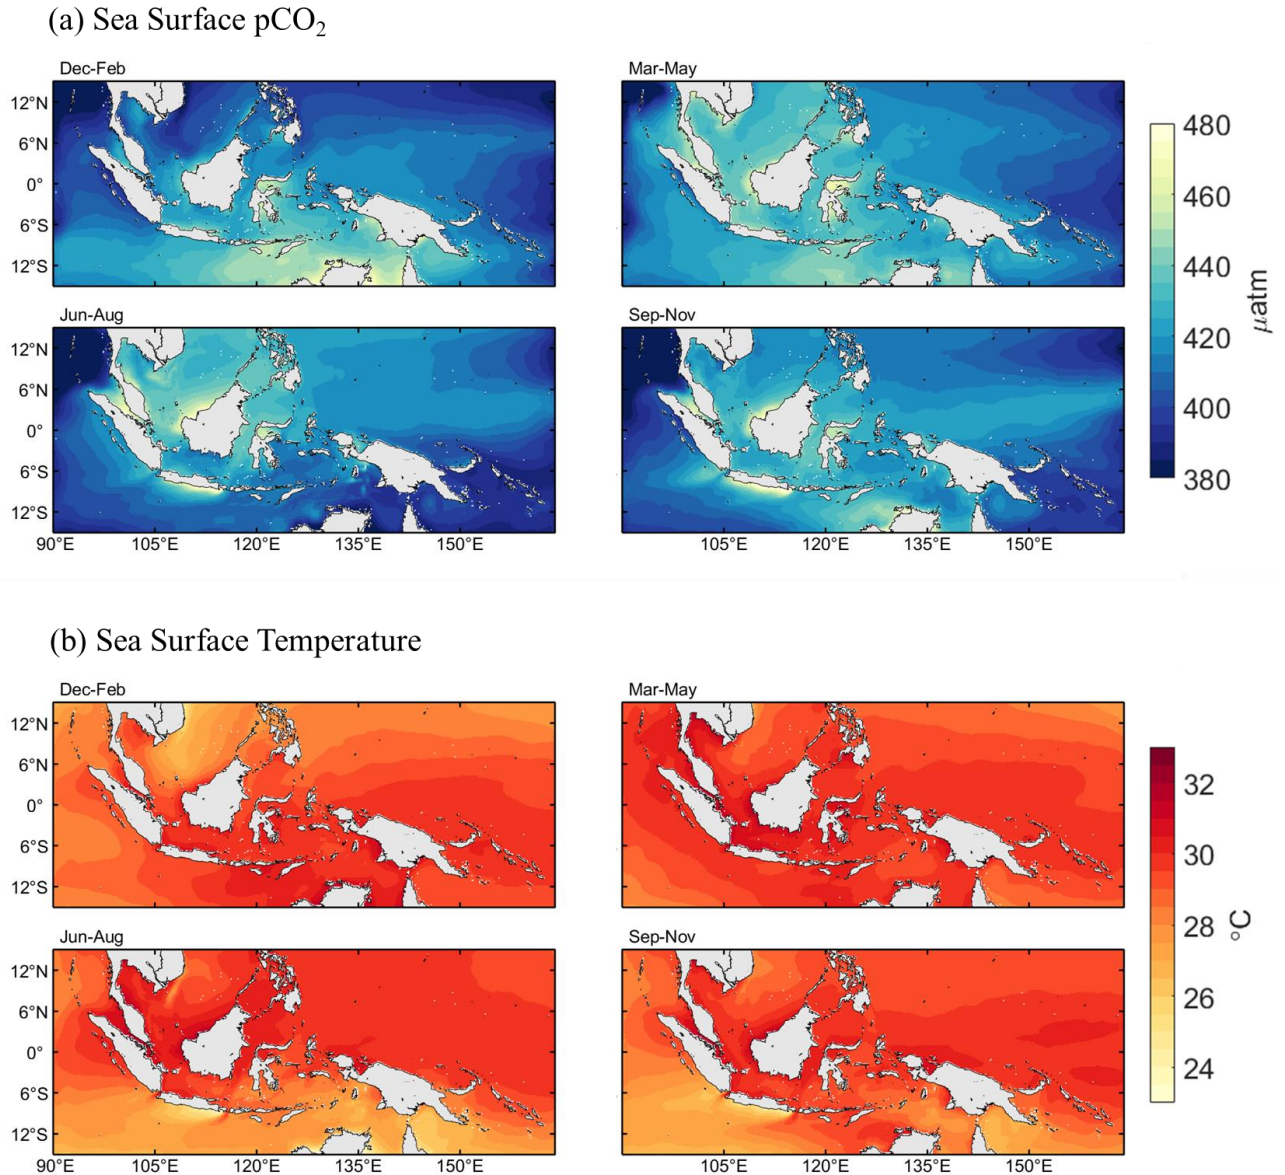

279 net increase in pCO$_2$.

(a) Sea Surface pCO$_2$

(b) Sea Surface Temperature

280

281 **Figure 2**. Mean seasonal cycle of modeled (a) sea surface pCO$_2$ partial pressure (in μatm) and (b)

282 sea surface temperature (in $^\circ$C) over the 2010-2019 period.

283

284 The sea-air CO$_2$ flux seasonal cycle showed that the TMC acted as a full-year atmospheric CO$_2$

285 source from sea surface water (Figure 3). Despite the relatively high pCO$_2$ in spring, the model

286 results suggested weak CO$_2$ degassing related to the wind speed around the TMC, which was in its

287   weakest state. Strong CO_2 degassing occurred during the summer, where many areas, such as the

288   southern South China Sea, south of Java, and Southern Makassar Strait, indicate their annual

289   maximum CO_2 flux. In contrast to the other areas, strong CO_2 degassing along the south of Java

290   was further maintained up to the autumn, while in the west of Sumatra, CO_2 degassing peaked at

291   the same time. This made the area the strongest CO_2 source within the TMC according to the
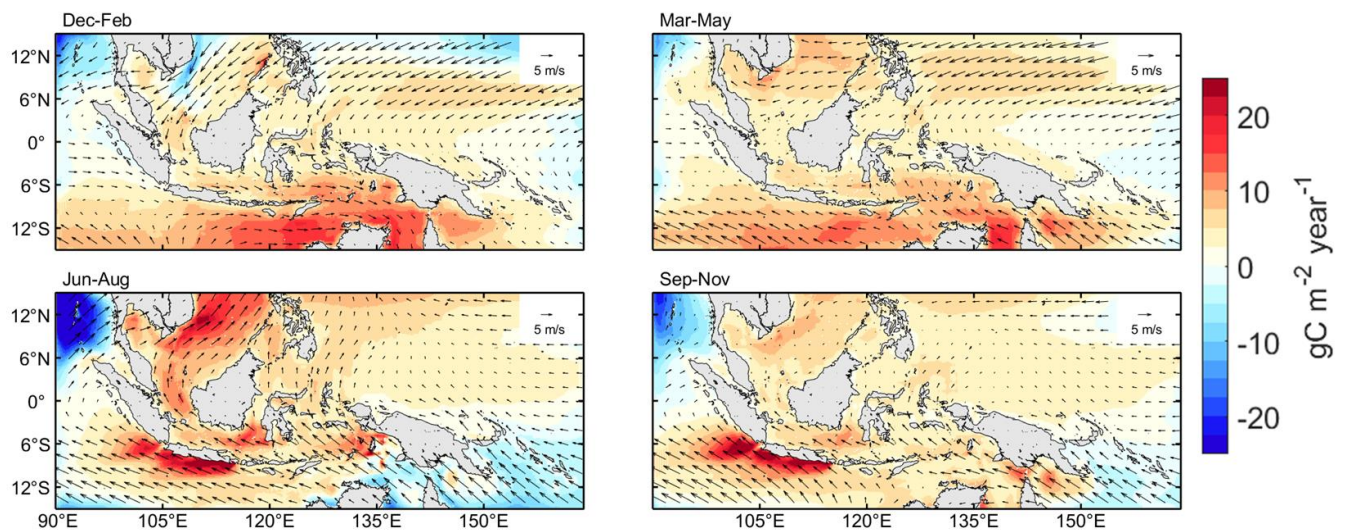

292   simulation results.

293

294   **Figure 3.** Simulated mean seasonal cycle of sea-air CO_2 flux (**s**haded color; in gC. m^{-2}. $year^{-1}$)

295   across the Tropical Maritime Continent and the corresponding wind speed pattern (vector arrows;

296   in m. s^{-1}) according to the JRA-55 product over the 2010-2019 period. Positive and negative values

297   in the sea-air CO_2 flux indicates atmospheric CO_2 source and sink signature**s**, respectively.

298

299   Persisting CO_2 degassing in the south of Java during the summer-autumn could be attributed to

300   the combination of atmospheric forcing and the biogeochemical response of the area to the forcing.

301   Strong wind speeds in the summer created favorable conditions for strong CO_2 degassing in the

302   area through accelerated gas exchange (Figure 4a) and, at the same time, increased the inorganic

303 carbon content in the sea surface during upwelling onset. However, the upwelling itself reached

304 its peak in early autumn, a month after the annual wind stress maxima. This left the area with high

305 inorganic carbon surface water, which further maintained the strong CO_2 degassing condition due

306 to high pCO_2 in the succeeding season.

307 Persisting CO_2 degassing was not apparent through model simulation in the west of Sumatra,

308 despite the similar upwelling seasonality with south of Java (Figure 4b). Instead, our simulation

309 suggested that the peak of CO_2 degassing occurred only in the early autumn, which coincided with

310 peak upwelling. The relatively weaker wind speed compared to south of Java was presumed to be

311 one of the contributing factors to weaker upwelling, both during the onset and peak. The angle of

312 the coast on Sumatra Island and the Coriolis parameter gradient toward latitude, as pointed out by

313 Susanto et al. (2001), further provided additional constraints for the wind to generate coastal

314 upwelling as strong as in the south of Java. We used chlorophyll-a concentration observed by the

315 Moderate Resolution Imaging Spectrometer (MODIS Aqua; Hu et al., 2012) as a proxy for

316 upwelling processes in both west of Sumatra and south of Java. We also calculated the annual

317 average value of Chl:C ratio in the two upwelling areas and found a ratio of 0.02, which was still

318 within the range suggested by Arteaga et al. (2016).

(a) South of Java
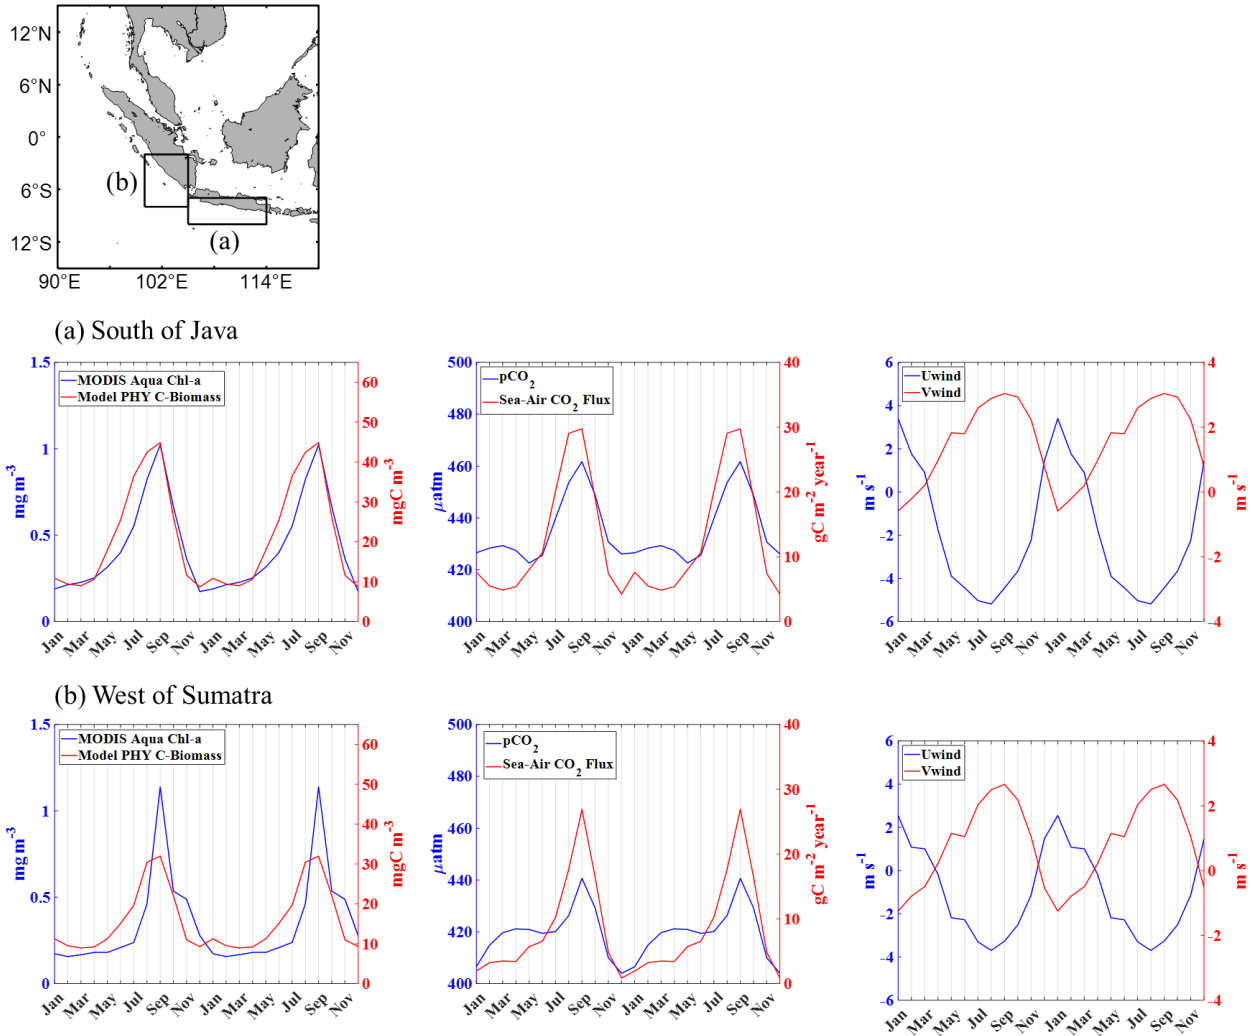

(b) West of Sumatra

319

Figure 4. Two full repeated annual cycles of the upwelling system in (a) south of Java and (b) west of Sumatra. Figures include the Chlorophyll-a concentration and simulated phytoplankton carbon biomass (left figures), simulated pCO_2 / sea-air CO_2 flux (middle figures), and wind speed from JRA-55 product (right figures).

3.3 Upper-ocean carbon cycle interannual variability in the Tropical Maritime Continent

The interannual variability was examined by removing the mean seasonal cycle of simulated pCO_2, CO_2 flux, and wind speed from JRA-55 over the 2010–2019 period. As a typical ENSO mature phase occurs within the November-March period, while the IOD occurs in July-November, we

328   focused on the analysis of both pCO_2 and CO_2 flux anomalies in those two periods. Aside from

329   the 2015/2016 El Niño and the 2019 pIOD, there were other ENSO and IOD events reported over

330   the last decade, which can be seen in Table 5.

331

332   **Table 5.** List of Indo-Pacific climatic forcings (ENSO and IOD) over the last decade (2010-2019)

333   according to the NINO3.4 and DMI time series employed in this study

ENSO	IOD
El Niño: 2014/2015, 2015/2016, 2018/2019	pIOD: 2011, 2012, 2015, 2017, 2018, 2019
La Niña: 2010/2011, 2011/2012, 2017/2018	nIOD: 2010, 2013, 2016

334

335   Composited pCO_2 and CO_2 flux anomalies during ENSO years (Figure 5) showed that El Niño

336   was associated with anomalously higher pCO_2 around the TMC. In contrast, La Niña was

337   associated with lower pCO_2. In agreement with the suggestion by Kartadikaria et al. (2015), the

338   anomalous lower pCO_2 during La Niña here corresponded to weaker CO_2 degassing. Our model

339   results further indicated a strong large-scale pCO_2 enhancement during the extreme 2015/2016 El

340   Niño, which corresponded to increased CO_2 degassing within the TMC. The composite analysis

341   provided in Figure 5 also suggested an out-of-phase modulation pattern between the Western

342   Pacific Ocean and TMC during ENSO events over the last decade. This further implied that

343   examination of ENSO influence on the TMC upper-ocean carbon cycle based on the Western

344   Pacific condition should be considered with more caution.
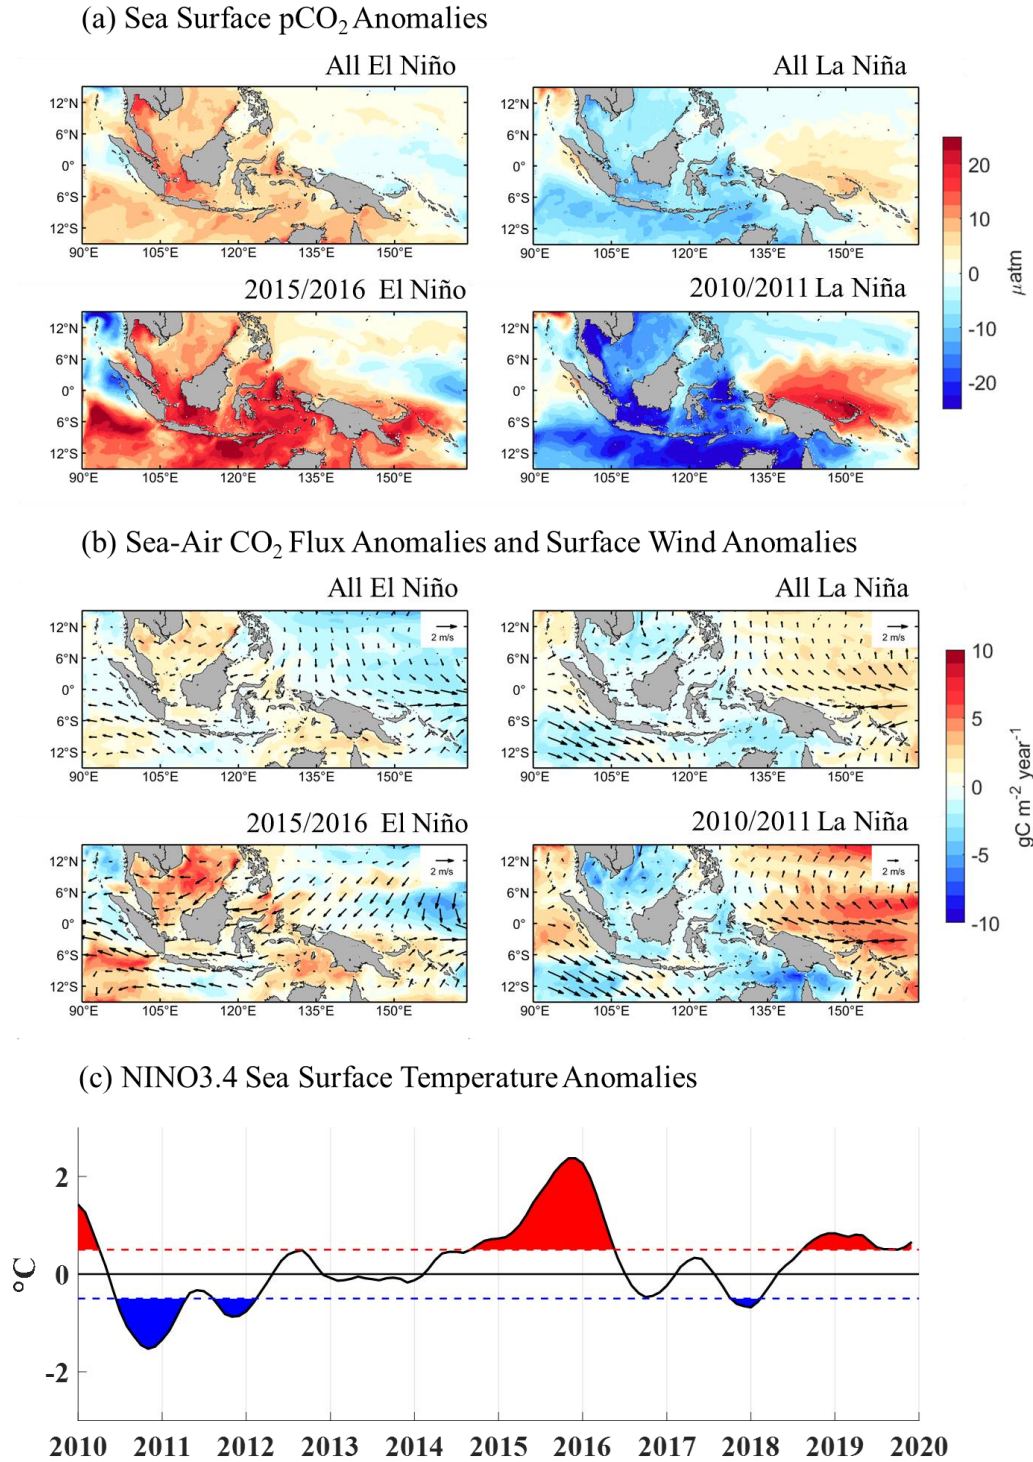

Figure 5. November-March composite average of (a) modeled pCO_2 anomalies (in µatm); (b) modeled sea-air CO_2 flux anomalies (in gC. m^{-2}. year^{-1}) with corresponding surface wind anomalies (vector arrows, in m/s) according to the JRA-55 product; and (c) five months moving

349   average of NINO3.4 sea surface temperature anomalies (SSTA). Shaded red and blue color in (c)

350   indicates the period when the SSTA value exceeded/below the $+0.5$ ℃/-0.5 ℃ threshold.

351   Composite average during periods with strong El Niño (2015/2016) and La Niña (2010/2011) were

352   also presented for comparison.

353

354   Apparent anomalous pCO_2 and CO_2 fluxes were observed during IOD event periods, particularly

355   around the west of Sumatra-south of Java (Figure 6). The pIOD was associated with strong pCO_2

356   enhancement and increased CO_2 degassing, whereas under negative IOD (nIOD) conditions, the

357   upper-ocean carbon cycle along the upwelling region showed the opposite modulation pattern.

358   Compared to the composite figures associated with ENSO events, the pCO_2 and CO_2 flux

359   anomalies around West Sumatra-South of Java during IOD events showed more pronounced

360   linearity, where strong anomalies in pCO_2 translated into strong anomalies in CO_2 flux. This could

361   be related to the different pattern of oceanic and atmospheric conditions perturbation caused by

362   these two large-scale climate variabilities, which in IOD cases, are more favorable for stronger

363   CO_2 flux modulation.

364   In addition, to modulation along the west of Sumatra-south of Java, the IOD was also associated

365   with upper-ocean carbon cycle variabilities in the inner part of the TMC, as shown by the

366   composite figure (Figure 6). The model results suggested an anomalous pCO_2 decrease (increase)

367   in the Indonesian seas and northwestern Australia during the pIOD (nIOD). However, a notable

368   decrease (increase) in CO_2 degassing was observed only around northwestern Australia.

369   Contrasting anomaly patterns between the west of Sumatra-south of Java and other areas during

370   IOD events implied different mechanisms controlling the upper-ocean carbon cycle variabilities.

371   Considering the composite analysis provided here, it could be inferred that the 2015-2016 Indo-

372   Pacific climatic forcings (2015 pIOD, 2015/2016 El Niño, and 2016 nIOD) resulted in

373   unprecedented pCO_2 modulation across the TMC over the last decade.

(a) Sea Surface pCO_2 Anomalies

(b) Sea-Air CO_2 Flux Anomalies and Surface Wind Anomalies

(c) Dipole Mode Index

374

375   **Figure 6.** July-November composite average of IOD events. (a) Modeled pCO_2 anomalies (in

376   µatm); (b) modeled sea-air CO_2 flux anomalies (in gC. m^{-2}. year^{-1}) with corresponding surface

377   wind anomalies (vector arrows, in m/s) according to the JRA-55 product; and (c) five months

378   moving average of NINO3.4 sea surface temperature anomalies (SSTA). Shaded red and blue color

379   in (c) indicates the period when the DMI value exceed/below the one-standard deviation (+1σ/-

380   1σ) threshold. Composite average during the period with strong positive IOD (2019) and negative

381   IOD (2016) were also presented for comparison.

382

383   Weaker (stronger) northwest monsoon circulation within the TMC during El Niño (La Niña) due

384   to anomalous divergence (convergence) could weaken (strengthen) the gas exchange between the

385   sea surface and the atmosphere. However, shifts in the Walker circulation caused by the same

386   anomalous divergence (convergence) also altered the cloud distribution across the tropics,

387   including the TMC itself, and affected SST. Decreased (increased) cloud cover around the TMC

388   during El Niño (La Niña) can increase (decrease) SST through an increase (decrease) in incoming

389   solar radiation. This mechanism could increase (decrease) pCO_2 and ultimately strengthen

390   (weaken) CO_2 degassing. The opposite modulation tendencies between atmospheric and oceanic

391   conditions in response to ENSO forcing made the CO_2 flux anomalies magnitude associated with

392   ENSO less pronounced, despite the strong pCO_2 anomalies during the 2015/2016 El Niño or

393   2010/2011 La Niña.

394   Conversely, the IOD did not exhibit such opposite tendencies, which resulted in the strong linearity

395   between the pCO_2 anomalies and the CO_2 flux anomalies. Typical IOD events occur between late

396   summer-autumn, where seasonal upwelling occurs (Delman et al., 2016; 2018; Susanto et al.,

397   2001). Anomalous southeasterly (northwesterly) winds during the pIOD (nIOD) around SETIO

398   can directly modulate upwelling around the west of Sumatra-south of Java. Enhanced (suppressed)

399   upwelling in response to stronger (weaker) wind forcing during pIOD (nIOD) then result in higher

400   (lower)-than-usual pCO_2 from the ocean side and accelerated (decelerated) gas exchange on the

401   atmospheric side.

402   Furthermore, our model results suggested an asymmetric response of the upper-ocean carbon cycle

403   to IOD over the last decade. The 2016 nIOD, which was not as intense as the preceding 2015 pIOD

404   and far weaker than the 2019 pIOD from the DMI magnitude perspective, showed a comparable

405   modulation in pCO_2 and CO_2 degassing. Scatter plots of pCO_2 anomalies, CO_2 flux anomalies, and

406   phytoplankton carbon biomass concentration anomalies against the DMI showed y-intercept

407   values that fell within the $y < 0$ territory (Figure 7) which depict the asymmetry. Asymmetry

408   response to the IOD was also observed from MODIS observations, implying the robustness of our

409   model in capturing the TMC physical-biogeochemical variabilities associated with the Indo-
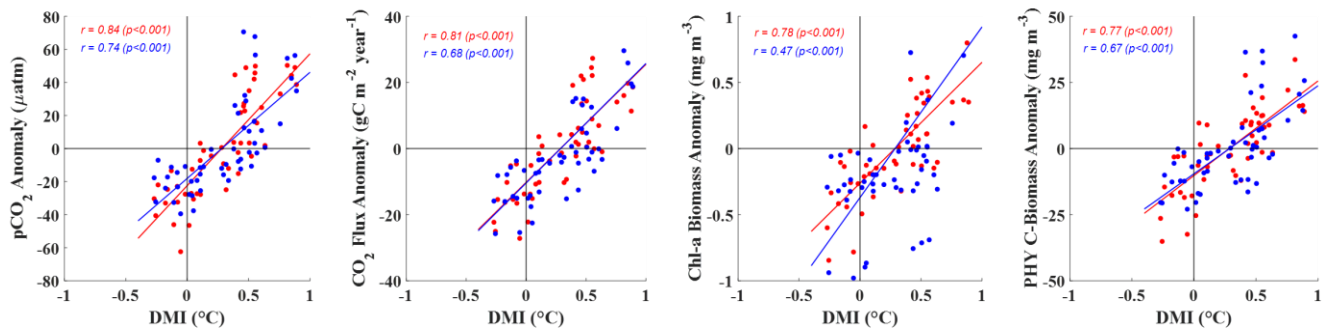

410   Pacific climate variabilities.

411

Figure 7. Scatter plot of Chl-a anomaly (in mg. m^{-3}), phytoplankton biomass anomaly (in mgC.

413   m^{-3}), pCO_2 anomaly (in µatm), and CO_2 flux anomaly (in gC. m^{-2}. $year^{-1}$) against DMI around west

414   of Sumatra (blue) and south of Java (red) in July-November over the 2010-2019 period. The red

415   solid line and blue solid line in each scatter graph show the regression model line for south of Java

416   and west of Sumatra, respectively.

417

418 The strong asymmetry response to the IOD around the west of Sumatra-south of Java, which was

419 apparent in both simulation results and observations (Chl-a from MODIS Aqua), emphasized the

420 peculiarity of nIOD events over the last decade. Zhang et al. (2018) suggested the contribution of

421 low-frequency thermocline dynamics around the equatorial Indian Ocean to this unusualness,

422 which was most likely captured by the ocean reanalysis product used in this experiment.

423 Anomalous pCO_2 enhancement during nIOD events, especially the 2010 and 2016 nIOD, which

424 extended up to the interior of the Indonesian seas, implied the possibility of another ocean-

425 atmosphere interaction that took place around the TMC. Strong sea surface warming anomalies

426 around the SETIO in the 2010 and 2016 summer, which were also captured by the simulation (not

427 shown), coincided with the demise years of the 2009/2010 and 2015/2016 El Niño. The seasonal

428 timescale difference between the El Niño demise and the appearance of SETIO warming here was

429 in line with Alexander et al. (2002) on the ENSO SST teleconnection pattern, with the Indian

430 Ocean lagging the central Pacific by 3–6 months. A recent review by Cai et al. (2019) further

431 emphasized that such summer warming following El Niño events became prevalent after the

432 1970s. We presume that while the low-frequency thermocline variabilities may affect upwelling

433 modulation along the west of Sumatra-south of Java during the IOD, the pCO_2 modulation beyond

434 the region during the nIOD was still closely related to the preceding El Niño events.

435

436 **3.4 Separating the ENSO and IOD influence on the upper-ocean carbon cycle variabilities**

437 **around the TMC**

438 Since ENSO and IOD showed a statistically significant correlation over 2010-2019 (Pujiana et al.,

439 2019), we further separated the effect of ENSO on IOD and vice versa by performing partial

440 correlation analysis for pCO_2 anomalies, CO_2 flux anomalies, and wind anomalies against DMI

441 and NINO3.4 following the methods of Saji and Yamagata (2003). Regression analysis was

442 conducted to evaluate the extent of each Indo-Pacific climatic forcing in modulating the upper

443 carbon cycle across the TMC over the study period. For uniformity reasoning, we regressed the

444 pCO_2 anomalies, CO_2 flux anomalies, and wind anomalies against the one-standard deviation ($\pm$

445 1σ) of the NINO3.4 ($\sigma_{NINO3.4} = 0.80$ ${}^{o}C$) and DMI ($\sigma_{DMI} = 0.26$ ${}^{o}C$) over the 2010-2019 period.

446 Regressed pCO_2 anomalies and CO_2 flux anomalies against one-standard deviation ($\pm$ 1σ) of

447 NINO3.4 and DMI revealed distinguishable spatial extents of modulation (Figures 8 and 9).

448 Anomalies associated with ENSO during the November-March period tended to have a larger

449 spatial extent, which could reach the SETIO region, compared with IOD during July-November,

450 which was confined along west of Sumatra-south of Java. Results from the regression analysis also

451 showed an extended minor influence of IOD on the carbon cycle variabilities up to the lesser Sunda

452 Island water area and inside the Indonesian seas. Regressed pCO_2 anomalies and CO_2 flux

453 anomalies against the DMI bolster our presumption that IOD alone could not explain notable

454 anomalous pCO_2 enhancement beyond the west of Sumatra-south of Java during recent nIOD

455 events.

456 Despite regressed pCO_2 anomalies against DMI, which showed a magnitude comparable to the

457 NINO3.4-regressed value, the regressed CO_2 flux anomalies against DMI showed a much higher

458   value. Removing the 2019 pIOD events from the regression analysis (Figure 9, second column)

459   resulted in only slight changes in both pCO_2 anomalies and CO_2 flux anomalies. This implied that

460   even a typical IOD event (after the ENSO influence has been removed) could trigger strong

461   anomalies in the CO_2 flux, especially along the west of Sumatra-south of Java.

462   Regressed pCO_2 anomalies against NINO3.4 further suggested a stronger sensitivity of the TMC

463   to ENSO forcing compared with the adjacent Western Pacific Ocean. The smaller extent of

464   regressed CO_2 flux anomalies against NINO3.4 supported our hypothesis about the apparent

465   nonlinearity between pCO_2 anomalies and CO_2 flux anomalies under the same ENSO events. The

466   exclusion of the 2015/2016 El Niño event in the regression analysis (Figure 8, second column)

467   decreased the magnitude of the pCO_2 anomalies and significantly reduced the spatial extent of the

468   CO_2 flux anomalies. This further suggests that the double-dip La Niña in 2010/2011 and 2011/2012

469   induced less-pronounced CO_2 flux modulation within the TMC. To put into perspective, the 2010–

470   2012 La Niña event occurred for a maximum of 22 months while the 2015–2016 El Niño occurred

471   for 13 months. Both events also showed comparable magnitudes according to the Multivariate

472   ENSO Index v2 (MEIv2; Zhang et al., 2019) in addition to the NINO3.4 SSTA used in this study.

473   It is possible that the Pacific decadal climatic shift in the 2010s modified the ENSO flavor, as

474   pointed out by Newman et al. (2016), including its influence on the TMC, so that CO_2 flux

475   modulation related to the 2015/2016 El Niño showed substantially different characteristics. Further

476   modeling studies across the TMC over a longer time scale will be needed to confirm this possible

477   upper-ocean carbon cycle decadal variation. Note that although removing the extreme events

478   conducted here obviously reduced the standard deviation of NINO3.4 and DMI, the regressed

479   modulation pattern and magnitude against reduced standard deviation did not show significant
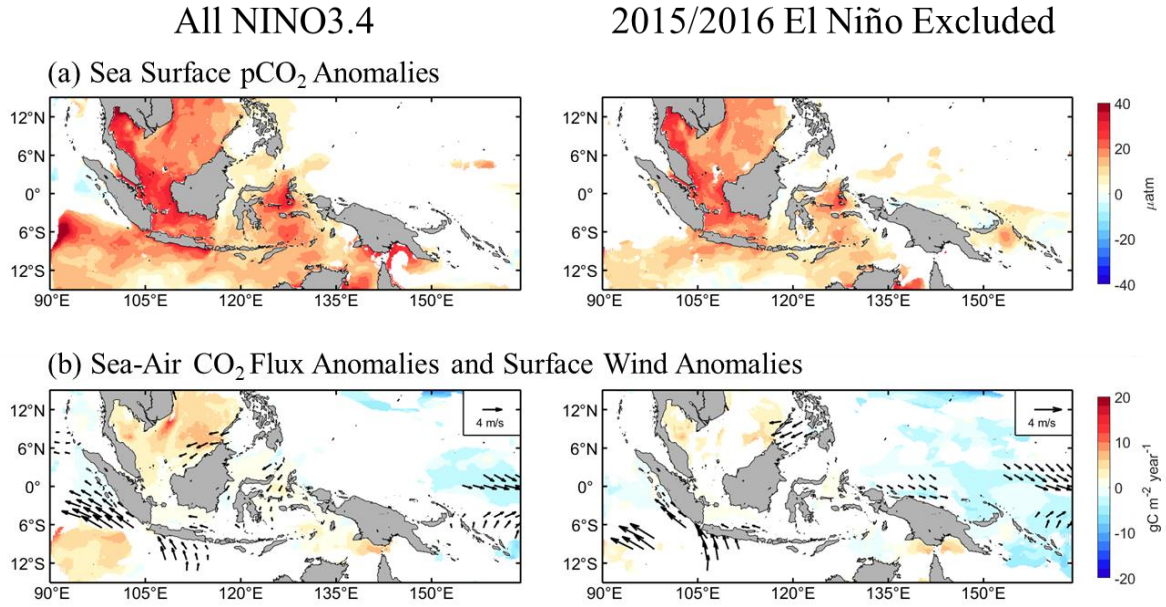

480   changes (not shown).

491   **4 Summary and conclusions**

492   Using a newly developed low-trophic ocean ecosystem model coupled with an OGCM, we

493   examined the upper-ocean carbon cycle variabilities over the last decade in the TMC, where long-

494   term observations in the area remained limited. By utilizing a suite of realistic atmospheric and

495   oceanic analysis/reanalysis products, we aimed to generate ocean dynamics under a series of

496   climate variabilities between 2010 and 2019 as realistic as possible to reduce the uncertainty

497   caused by overlooked ocean-atmosphere interactions. We also proposed a treatment for the initial

498   and boundary conditions in the ecosystem model that allowed us to approximate the vertical

499   structure of the important ecosystem parameters in the model.

500   In general, the model could capture the basic seasonality of the carbon cycle exhibited by available

501   observations along with its spatial variations, albeit some differences, especially in pCO_2, which

502   might be related to the selection of atmospheric CO_2 forcing used in this simulation and some not-

503   yet-involved biogeochemical processes (e.g., silicate dynamics and iron dynamics). Nevertheless,

504   produced atmospheric CO_2 sink/source characteristic from this modeling study were in agreement

505   with previous studies (Bakker et al., 2016; Chai et al., 2009; Hamzah et al., 2020; Kartadikaria et

506   al., 2015; Sutton et al., 2017; Xiu and Chai, 2014). This enabled us to further analyze the produced

507   upper-ocean carbon cycle variabilities in response to the forcing used in the simulation experiment.

508   While acted as full-year atmospheric CO_2 source with area-averaged flux equivalent to 0.08 PgC

509   per year, our simulation results indicated pronounced seasonality along the west of Sumatra-south

510   of Java. Strong seasonal winds that triggered upwelling around the area (Horii et al., 2018; Ningsih

511   et al., 2013: Siswanto et al., 2020; Susanto et al., 2001) created favorable conditions for strong

512   CO_2 degassing through a combination of accelerated gas exchange and an abundant supply of

513   subsurface inorganic carbon. This mechanism was not apparent in other areas across the TMC,

514   making it an unique feature of the upper-ocean carbon cycle perspective. Note that the aggregate

515   results of upwelling to carbon cycling might vary across regions (Chakraborty et al., 2018; Valsala

516   et al., 2014) and thus, the results presented by this model for the west of Sumatra-south of Java

517   should not be taken as a generalization for all upwelling-active regions.

518   Composite analysis of both pCO_2 anomalies and CO_2 flux anomalies clearly showed pronounced

519   features that could be related to Indo-Pacific climate variability (ENSO and IOD) over the last

520   decade. Strong anomalous pCO_2 enhancement along with stronger-than-usual CO_2 degassing

521   occurred from 2015 and lasted until (at least) the 2016 summer, making it the largest and longest

522   upper ocean carbon cycle modulation in the TMC according to the simulation results. The

523   sequence of IOD and ENSO events between 2015-2016 (2015 pIOD and 2015/2016 El Niño) was

524   strongly related to this unprecedented modulation over the last decade. The modulations were then

525   swung toward the negative territory (i.e., decreased pCO_2 and reduced CO_2 degassing) as the 2016

526   nIOD gained momentum. We further suggested the distinctive modulation characteristic

527   associated with ENSO and IOD, which caused the magnitude of the CO_2 flux variability during

528   ENSO to be lower than that during IOD.

529   An attempt to elucidate the extent of extreme climate events (2015/2016 El Niño and 2019 pIOD)

530   influence on the upper-ocean carbon cycle across the TMC through regression analysis yielded

531   notable results. It can be inferred that recent extreme climate events were likely responsible for a

532   larger extent of upper-ocean carbon modulation around the TMC over the last decade. Considering

533   the simulation results and analysis conducted here, further pronounced modulation of the upper-

534   ocean carbon cycle across the TMC can be expected, as recent studies have indicated an

535   intensification of extreme climate anomalies under the effect of greenhouse gas forcing (Cai et al.,

536   2018; Grothe et al., 2019; Zhang et al., 2018).

537   Finally, one of the biggest challenges hindering this study was that we could not incorporate river

538   discharge in the simulation experiment. The lack of reliable datasets, especially for carbonate

539   chemistry-related parameters, such as DIC, TA, and nutrients, as highlighted by Valsala et al.

540   (2014), was the main reason for this limitation. Such data are critical for evaluating the robustness

541   of any regional-scale watershed modeling effort before further use in coupled OGCM-ecosystem

542   models. Incorporating river discharge inappropriately for studying upper-ocean carbon cycle

543   variability will only produce questionable results. DIC from river discharge, for example, varies

544   widely between river mouths, with values ranging from 284 µmol. kg^{-1} (Rosentreter and Eyre,

545   2019) to as high as 3,500 µmol. kg^{-1} (Kawahata et al., 2000). This highly variable value did not

546   include the possible strong seasonal and interannual variability of the river-discharged material, as

547   presumed by Xiu and Chai (2014). Regardless of the limitations of this study, the results presented

548   here could invite interdisciplinary research collaborations to establish a continuous oceanic carbon

549   cycle monitoring system across the TMC and enrich our understanding of its dynamics under

550   changing environments.

551

552

560

561   **Data Availability Statement**

562   The original code of our model and necessary code to prepare the input for simulation experiment

563   can be accessed at https://github.com/NakamuraTakashi. Further guidance on how to utilize the

564   codes can be requested through personal communication with Faisal Amri

565   (amri.f.aa@m.titech.ac.jp/faisal.amri.os12@gmail.com) or Takashi Nakamura

566   (nakamura.t.av@m.titech.ac.jp). The Surface Ocean CO_2 Atlas (SOCAT) datasets can be accessed

567   through https://www.socat.info. Global sea surface temperature from HadISST1.1 used for

568   calculating the NINO3.4 and DMI can be retrieved from

569   https://www.metoffice.gov.uk/hadobs/hadisst/. Information about pCO_2 observation and sea-air

570   CO_2 flux estimation data in Indonesia sea used in this study can be requested through personal

571   communication with A.R. Kartadikaria (aditya.kartadikaria@kaust.edu.sa) or Atsushi Watanabe

572   (a-watanabe@spf.or.jp).
