## Abstract

Laboratory studies have shown that rhizodeposits could lead to either soil structural formation or dispersion depending on plant species, soil conditions, and microbial activity. However, these studies have usually been conducted in dry soils and rarely considered the combined effect of rhizodeposit and organic residues on soil structure. This study hypothesizes that root exudates promote soil dispersion initially, but over time decomposition of root exudates produce binding agents that promote stable soil structure in the rhizosphere. To test this hypothesis, a sandy loam soil sieved to  $< 500 \mu\text{m}$  particle size was first amended with root exudate compounds ( $14.4 \text{ mg C g}^{-1}$ ),  $\delta^{13}\text{C}$ -barley residue ( $0.44 \text{ mg C g}^{-1}$  soil), or both. Six replicate samples per treatment were packed in cores to a bulk density of  $1.27 \text{ g cm}^{-3}$  and then equilibrated on a tension table at  $-2 \text{ kPa}$  matric potential. Rheological measurements of flow characteristics (dynamic viscosity) and strength (storage modulus, loss modulus,  $\tan \delta$ , and yield stress) of the control and amended soils were obtained immediately after amendment and after twelve days of incubation at  $20 \text{ oC}$ . Only root exudate compounds initially decreased the capacity of soil to retain water at  $-2 \text{ kPa}$  by 21% and by 49% after incubation. Likewise, the yield stress of root exudate amended soil was significantly ( $P < 0.05$ ) lower than that of the unamended soil, reflecting dispersion of soil. However, microbial decomposition/activities significantly ( $P < 0.05$ ) increased yield stress over the corresponding pre-incubation values for these treatments by 200% (root exudate) and 230% (root exudate +  $\delta^{13}\text{C}$ -barley residue). These results confirmed the hypothesized dual effect of root exudates on rhizosphere structure. The initial soil dispersion may facilitate root growth by augmenting soil penetrability and releasing nutrients that were occluded in soil aggregates, whereas stable soil structure is achieved upon decomposition of root exudates.

24 **Abstract**

25 Laboratory studies have shown that rhizodeposits could lead to either soil structural  
26 formation or dispersion depending on plant species, soil conditions, and microbial activity.  
27 However, these studies have usually been conducted in dry soils and rarely considered the  
28 combined effect of rhizodeposit and organic residues on soil structure. This study  
29 hypothesizes that root exudates promote soil dispersion initially, but over time  
30 decomposition of root exudates produce binding agents that promote stable soil structure in  
31 the rhizosphere. To test this hypothesis, a sandy loam soil sieved to  $< 500 \mu\text{m}$  particle size  
32 was first amended with root exudate compounds ( $14.4 \text{ mg C g}^{-1}$ ),  $\delta^{13}\text{C}$ -barley residue ( $0.44$   
33  $\text{mg C g}^{-1}$  soil), or both. Six replicate samples per treatment were packed in cores to a bulk  
34 density of  $1.27 \text{ g cm}^{-3}$  and then equilibrated on a tension table at  $-2 \text{ kPa}$  matric potential.  
35 Rheological measurements of flow characteristics (dynamic viscosity) and strength (storage  
36 modulus, loss modulus,  $\tan \delta$ , and yield stress) of the control and amended soils were  
37 obtained immediately after amendment and after twelve days of incubation at  $20 \text{ }^\circ\text{C}$ . Only  
38 root exudate compounds initially decreased the capacity of soil to retain water at  $-2 \text{ kPa}$  by  
39 21% and by 49% after incubation. Likewise, the yield stress of root exudate amended soil  
40 was significantly ( $P < 0.05$ ) lower than that of the unamended soil, reflecting dispersion of  
41 soil. However, microbial decomposition/activities significantly ( $P < 0.05$ ) increased yield  
42 stress over the corresponding pre-incubation values for these treatments by 200% (root  
43 exudate) and 230% (root exudate +  $\delta^{13}\text{C}$ -barley residue). These results confirmed the  
44 hypothesized dual effect of root exudates on rhizosphere structure. The initial ,  
45 whereas stable soil structure is achieved upon decomposition of root exudates.

## 49 **Introduction**

50 Plant roots drive changes in soil structure and stability through localized compaction  
51 from growth stresses (Aravena *et al.*, 2010; Helliwell *et al.*, 2017; Oleghe *et al.*, 2017;  
52 Dupuy *et al.*, 2018) and the release of rhizodeposits that change the mechanical behaviour  
53 of the soil in immediate contact with the roots (Iijima *et al.*, 2003; Galloway *et al.*, 2017).  
54 Among the rhizodeposits involved in rhizosphere structure and stability, the production of  
55 exudates is of great importance (Morel *et al.*, 1991; Czarnes *et al.*, 2000; Di Marsico *et al.*,  
56 2017). Root exudates serve as a source of energy and drive microbial activities (Sessitsch *et*  
57 *al.*, 2001; Bailey *et al.* 2013; Blaud *et al.*, 2014) that impact the rate of soil organic matter  
58 (SOM) decomposition (Kuzyakov, 2002; Keiluweit *et al.*, 2015; Rousk *et al.*, 2015).  
59 Furthermore, SOM decomposition changes the properties and abundance of microbial-  
60 derived mucilage, which has knock-on impacts on soil structural aggregation and stability  
61 (Oades, 1993; Rashid *et al.*, 2016).

62 Many factors drive the formation and stability of rhizosphere structure (Denef *et al.*,  
63 2002; Six *et al.*, 2004), among the most important ones are exudates, micro-organisms, and  
64 organic matter, which affect inter-particle bonding and flocculation at the microscale  
65 (Hallett *et al.*, 2003; Albalasmeh and Ghezzehei 2014; Rashid *et al.*, 2016; Buchmann *et al.*,  
66 2020). Most studies exploring the impact of exudates and associated microbial activities on  
67 rhizosphere mechanical properties have typically focused on aggregation and aggregate  
68 stability (Ndour *et al.*, 2017; Demenois *et al.*, 2018). Increasingly, studies have started  
69 exploring how exudate addition affects the underlying mechanisms involved in mechanical  
70 stability. For example, Carrizo *et al.* (2018) demonstrated that root exudates increased soil  
71 strength and structural stability. Naveed *et al.* (2018) found that seed and root exudates  
72 increase hardness and elasticity markedly but postulated that changes in water content  
73 caused by these exudates could be driving soil mechanical behaviour. Zhang *et al.* (2008)

74 quantified interparticle bonding properties in the rhizosphere by demonstrating that  
75 polygalaturonic acid increased the fracture toughness and bond energy of clay samples.  
76 While Wang *et al.* (2017) showed that secretion of exudate tends to stabilize soil aggregates  
77 by simultaneously increasing bonding strength while decreasing the wetting rate. These  
78 studies explored relatively dry soils, but much of structure formation in the rhizosphere  
79 likely occurs when the soil is wet.

80         The rhizosphere tends to be temporally wetter than bulk soil (Young 1995; Carminati  
81 2012, Carminati & Vetterlein, 2013) and exudation may enhance the mobility of soil  
82 particles, thus promoting the onset of aggregation (Naveed *et al.*, 2017). Markgraf *et al.*  
83 (2006) suggested that rheometry could provide physically-based measurements of the  
84 mechanical properties of wet soils. The impact of mechanical stress on soil rheological  
85 properties and stability varies with time, water content (Ghezzehei and Or, 2001; Pértile *et*  
86 *al.*, 2016) and the types of organic compounds added to the soil (Tarchitzky and Chen,  
87 2002). Barré and Hallett (2009) quantified the underlying physical mechanisms affecting  
88 simulated rhizosphere soil from rheological studies and found evidence that exudate  
89 analogues (polygalacturonic acid, PGA, and scleroglucan) increased viscosity and shear  
90 resistance in clay soils. Naveed *et al.* (2017) characterised the mechanical stability of  
91 rhizosphere soils by demonstrating that rhizodeposits from different plant origin and their  
92 microbial decomposition have differing impacts on yield stress and subsequently  
93 rhizosphere mechanical stability. Most importantly, they observed that barley rhizodeposits  
94 initially caused mechanical dispersion, followed by gelling after microbial decomposition.  
95 Maize exudates, on the other hand, gelled the soil. More recent research using nuclear  
96 magnetic resonance relaxometry has quantified chemical interactions that drive gelling by  
97 mucilages in soils (Buchmann *et al.*, 2020). Some of the gelling in soils are driven by  
98 improved interparticle bonding (Brax *et al.*, 2020), but mucilages may also have non-

99 Newtonian behaviour affecting rheological response to fast (e.g., rapid aggregate  
100 breakdown) or slow (e.g., root growth) mechanical stresses in soil (Haas *et al.*, 2018).

101 Further impacts on soil structural stability could result from the interaction between  
102 rhizodeposits and decomposing residues in soil. A rheological study by Markgraf *et al.*  
103 (2012) found that the application of farmyard manure increased water content and soil  
104 organic carbon, which resulted in increased viscoelasticity, stability and shear behaviour.  
105 On the other hand, the interacting effect of root exudates and added organic residues, which  
106 is the typical situation in freshly tilled soils, has yet to be explored. We address this gap in  
107 understanding by applying rheology-related measurements to wet soils amended with root  
108 exudate compounds and/or labelled  $\delta^{13}\text{C}$ -barley shoot residue. The rheological properties of  
109 the amended soils (yield stress, dynamic viscosity, loss and storage modulus, and  $\tan \delta$ )  
110 were measured with amplitude sweep tests in a parallel plate rheometer (Barré and Hallett,  
111 2009; Mezger, 2014). A model root exudate cocktail previously used in other laboratory  
112 studies (Paterson *et al.*, 2007; de Graaff *et al.*, 2010; Oleghe *et al.*, 2019) was used because  
113 of the difficulty in extracting and preserving real plant root exudates under sterile conditions.  
114 Decomposition of the added compounds was measured from microbial respiration, with the  
115 isotopic label used to separate the added barley residue from native soil organic matter. This  
116 approach enabled us to assess exudate, microbial activities and biological impacts together,  
117 so that interacting effects could be explored.

## 118 **Materials and methods**

### 119 *Soil sampling and description*

120 Sandy loam topsoil (0-20 cm) was sampled from the Bullion field at the James  
121 Hutton Institute, Dundee, UK (56.27N 3.40W). The soil is a Dystric Cambisol (FAO  
122 classification) with sand, silt and clay fractions of 60%, 24% and 16%. The respective  
123 carbon, C, and nitrogen, N, contents of the soil were  $2.25 \pm 0.14 \text{ mg g}^{-1}$ , and  $0.16 \pm 0.03 \text{ mg}$

124 g<sup>-1</sup> respectively, which resulted in a C: N ratio of 16:1. The pH in CaCl<sub>2</sub> was 5.48. The bulk  
125 sample was air-dried at 30 °C to about 1 % water, sieved through 500 µm and then stored at  
126 4 °C.

#### 127 *Root exudate preparation*

128 An artificial root exudate cocktail was produced after Paterson *et al.* (2007) by  
129 combining common sugars, organic acids, and amino acids found in root exudates (Rovira  
130 and McDougall, 1967; Jones 1998; Hütsch *et al.*, 2002). Labelled δ<sup>13</sup>C-barley (*Hordeum*  
131 *vulgare*, spp. Belgravia) shoot fine powder with a C content of 44.2% and a C: N ratio of  
132 10.8 was used. The bulk plant material was 1.98 atom% excess δ<sup>13</sup>C using a 20/20 isotope  
133 ratio mass spectrometer (Sercon Ltd, Crewe, UK). Details of the production of the labelled  
134 barley can be found in Kuntz *et al.* (2016).

#### 135 *Gravimetric moisture content*

136 Six unamended soil samples were saturated before placing them onto a tension table  
137 (EcoTech MeBaystem GmbH, Germany) and dried to water content at equilibrium with -2  
138 kPa matric potential while keeping the temperature at 4 °C to suppress microbial  
139 decomposition. The soil gravimetric water content,  $w$ , was measured as the mass of water  
140 per unit mass of soil ( $w$ , (%) = [mass of moist soil (g) – mass of oven-dried soil (g)/mass  
141 of oven-dried soil (g)] × 100). This water content at -2 kPa matric potential (0.40 g g<sup>-1</sup>) was  
142 considered to be the upper limit at field capacity and used as a reference throughout the  
143 experiment.

#### 144 *Sample preparation*

145 Sieved air-dried soils <500 µm were treated with or without δ<sup>13</sup>C-barley residue  
146 (0.44 mg C g<sup>-1</sup> soil) and brought to 0.20 g g<sup>-1</sup> water content by mixing the soil with either  
147 model root exudate (14.4 mg C g<sup>-1</sup> soil) solution or distilled water. This results in four

148 treatments i.e. unamended or control soil, soil treated with root exudate compounds only,  
149 soil treated with  $\delta^{13}\text{C}$ -barley residue only, and soil treated with root exudate compounds and  
150  $\delta^{13}\text{C}$ -barley residue together. In total 48 soil samples with 6 replicates for each treatment  
151 were prepared by packing 4.0 g of soil in plastic rings that were 4 mm in height and 40 mm  
152 in diameter, which resulted in a bulk density of  $1.27 \text{ g cm}^{-3}$ . Out of 48 soil samples, 24 were  
153 tested immediately after equilibrating at -2 kPa on the tension table at 4 °C representing  
154 fresh or before decomposition treatment. The rest of the 24 soil rings were placed in  
155 respiration pots, covered and randomly placed in a plant culture incubator (SANYO Electric  
156 Co. Ltd, Japan) at a controlled temperature of 20 °C for 12 days. The water content was  
157 adjusted and maintained at field capacity with deionised water by replacing the mass of  
158 water lost to evapotranspiration using a 5 ml syringe. The hourly rates of microbial  
159 respiration for days 0, 1, 3, 7 and 12 were determined by feeding the emissions captured  
160 from the respiration pots into a Picarro G2201-i isotopic- $\text{CO}_2$  gas analyser (Picarro Inc.,  
161 Santa Clara, CA, USA), to determine the total and isotopic carbon signature ( $\delta^{13}\text{C-COO}$ ).

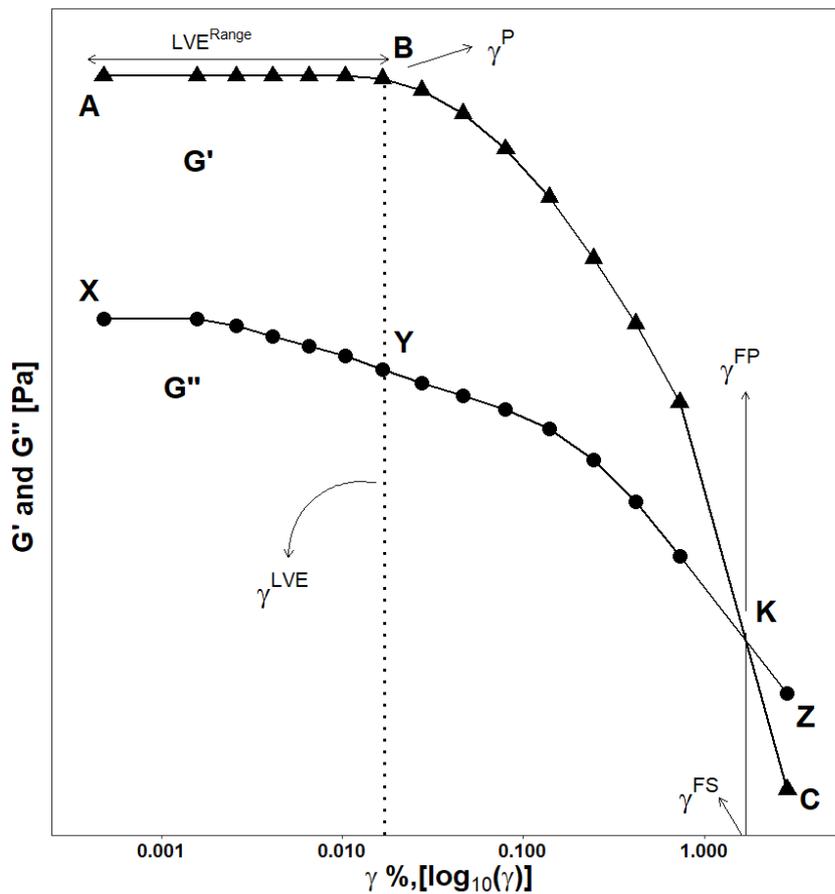

#### 162 *Rheological measurements*

163 The rheological properties of the soils when freshly packed and after 12 days of  
164 incubation were measured on samples that were first saturated and then dried to -2 kPa  
165 matric potential using the described tension table and temperature conditions. Amplitude  
166 sweep tests at constant frequency and temperature were performed with a Discovery Hybrid  
167 Rheometer (DHR, TA instruments, Delaware, USA), equipped with parallel plates of 40  
168 mm in diameter. The lower plate was fixed and the upper plate rotated. The faces of the  
169 plates were serrated to improve grip. To ensure minimal disturbance, the samples were  
170 placed on the lower plate of the rheometer and gently pushed out of the rings with a spatula,  
171 resulting in samples that fit closely to the diameter of the plates.

172           The experimental program included linear amplitude sweep tests with a single  
173 loading profile. The parallel plate was separated by a gap of 4 mm and the temperature of  
174 the lower plate was maintained constant at 25 °C (controlled by a Peltier unit). The resting  
175 period before the test was 60 s and the variation of the amplitude of deformation ranged  
176 from 0.001 to 1000 %. The angular frequency was 10 rad/s and the number of measuring  
177 points was 30. The test duration was about 15 min. The normal force on the sample did not  
178 exceed 40 kPa at the beginning of the test and tended to 0 kPa at the end of the test (Naveed  
179 *et al.*, 2018).

#### 180 *Rheological characterization of soil*

181           Soil rheological behaviour was assessed from the curves of storage modulus ( $G'$ ),  
182 and loss modulus ( $G''$ ) as a function of oscillation strain (Figure 1). The storage modulus,  
183  $G'$  measures the elastic component of a soil where the induced energy from applied stress is  
184 temporarily stored and is fully recoverable upon withdrawal of the stress. The loss modulus,  
185  $G''$ , is the viscous component or dissipated energy, which means that the energy used to  
186 initiate the flow is irreversible. The dynamic viscosity ( $\eta = \text{stress/strain rate}$ ) is the measure  
187 of its resistance to flow when an external force is applied (Markgraf *et al.*, 2006).

188

189 **Figure 1:** Schematic diagram of soil amplitude sweep test showing the stress-strain curve  
 190 ( $G'$  and  $G''$ ):  $G'$  is storage modulus (A, B, C),  $G''$  is loss modulus (X, Y, Z),  $\gamma$  (%), is  
 191 oscillation strain. The yield point  $\gamma^P$  (B) is the point on a stress-strain curve that indicates the  
 192 limit of elastic behavior (A, B) and the beginning of plastic behavior (B, C). The normal  
 193 stress ( $\gamma^{LVE}$ ) and flow stress ( $\gamma^{FS}$ ) are the corresponding stress for the limits of elastic (B) and  
 194 plastic behavior (K); the flow point  $\gamma^{FP}$  indicates the points where the soil begins to flow like  
 195 liquid while the Linear ViscoElastic Range  $LVE^{Range}$  (A, B) describes the soil elasticity.

196

197 The Linear ViscoElastic Range ( $LVE^{Range}$ ) is the range of deformation stress where  
 198  $G'$  and  $G''$ , are constant (Schramm, 2006). The  $LVE^{Range}$  is determined between points A -  
 199 B and X - Y, with point B at the limit of deformation (Markgraf *et al.*, 2006; Holthusen *et*  
 200 *al.*, 2010). Within the  $LVE^{Range}$ , no significant change in the soil's internal structure occurs,  
 201 the soil structure will deform elastically and will return to its original shape when the applied  
 202 stress is removed. The point of intersection (K) between the curves  $G'$  and  $G''$  defines the  
 203 flow point where the elastic and viscous components are equal. The value  $\tan\delta$  ( $G''/G'$ )

204 indicates the relative degree of energy dissipation or damping of the material. The elastic  
205 stress was plotted as a function of oscillation strain (Naveed *et al.*, 2018). The peak elastic  
206 stress was denoted as yield stress and the corresponding strain was denoted as yield strain  
207 as suggested by Walls *et al.* (2003). The yield stress is the onset of soil structural collapse,  
208 which generally lies between the linear viscoelastic range (LVE<sup>Range</sup>) and flow point.

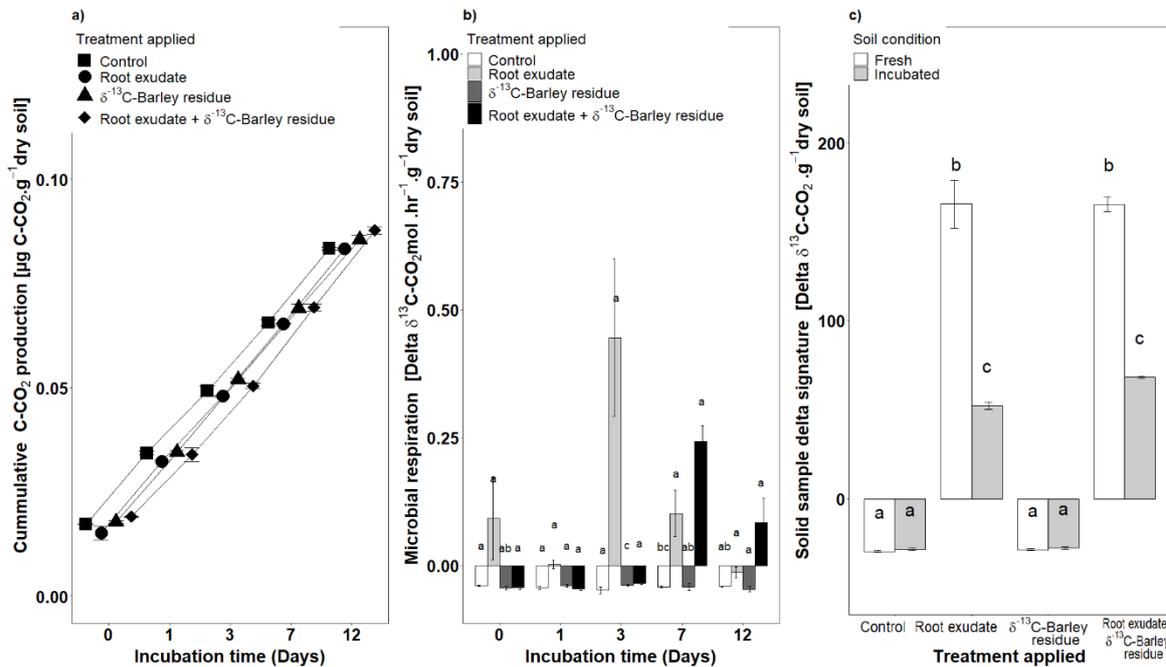

### 209 *Statistical analysis*

210 The experiment was set up as a three-way factorial design with two levels of root  
211 exudates (0 and 14.4 mg C g<sup>-1</sup> soil), and two levels of the  $\delta^{13}\text{C}$ -barley residue amendment  
212 (0 and 0.44 mg C g<sup>-1</sup> soil) and two levels of soil mineralization (0 and 12 days). Each  
213 treatment had six replicates. Statistical analyses were done using the R statistical computing  
214 language (R Core Team, 2020). The response variable satisfied normality tests and the data  
215 were analysed as an N-factor analysis of variance (N-way-ANOVA) or repeated ANOVA  
216 for respiration data, at a significant level of  $P < 0.05$ . When the F statistic from the ANOVA  
217 showed that the mean effect of the treatments was significant, a pairwise comparison of  
218 means with Tukey HSD tests was used to indicate when arithmetic means of various  
219 properties differed significantly between the treatment factors at  $P < 0.05$  level.

## 220 **Results**

### 221 *Soil mineralisation*

222 Daily mean CO<sub>2</sub> emitted over 12 days showed no significant variations among the  
223 treatments (Figure 2a). The isotopic <sup>13</sup>C-CO<sub>2</sub> emitted was larger on day 3 for the  $\delta^{13}\text{C}$ -barley  
224 residue treatment and day 7 for the root exudate +  $\delta^{13}\text{C}$ -barley residue interaction and both  
225 treatments followed a steady decline until the incubation ended (Figure 2b). After  
226 incubation, the amount of remaining  $\delta^{13}\text{C}$ -barley residue in the soil was not significantly  
227 different between  $\delta^{13}\text{C}$ -barley residue treatment and root exudate +  $\delta^{13}\text{C}$ -barley residue  
228 treatment (Figure 2c).

229

230 **Figure 2:** Microbial activities on root exudate and  $\delta^{13}\text{C}$ -barley residue sandy loam soil (a)  
 231 rate of decomposition were determined for  $\text{CO}_2$  ( $\mu\text{g C-CO}_2\text{g}^{-1}\text{dry soil}^{-1}\text{hour}^{-1}$ ), (b) cumulative  
 232 mineralization, (c) respired isotopic  $^{13}\text{C}$ - $\text{CO}_2$  signal and (d) depleted isotopic  $^{13}\text{C}$ - $\text{CO}_2$  signal  
 233 for solid sample.

234 *Soil water retention*

235 The water content of soil treated with root exudate compounds was significantly  
 236 lower whereas the water contents of soils treated with  $\delta^{13}\text{C}$ -barley residue and root exudate  
 237 +  $\delta^{13}\text{C}$ -barley residue treatments were significantly higher compared to the unamended soil  
 238 (Table 1). The water content of fresh soil samples at -2 kPa water potential was initially  
 239 increased by  $\delta^{13}\text{C}$ -barley residue and root exudate +  $\delta^{13}\text{C}$ -barley residue treatments ( $P <$   
 240 0.05), but incubation of the soil samples resulted in a decrease in water content for all the  
 241 treatments except the for the control treatment ( $P < 0.05$ ) (Table 1).

242 **Table 1.** Mean values of interaction effects for root and  $\delta^{13}\text{C}$ -barley residue on gravimetric  
 243 water content ( $w$ ) and delta isotopic signature ( $\delta$ ) for sandy loam soil ( $< 500 \mu\text{m}$ ).

Soil	Treatments	$\delta^{13}\text{C}$ signature on soil solid		$\theta\text{g or }w(\text{g})$	
		LSMean	Group	LSMean	Group
Fresh	Control	-29.613	a	0.416	b
	$\delta^{13}\text{C}$ -barley residue	165.545	c	0.500	d
	Root	-28.566	a	0.343	a
	Root exudate + $\delta^{13}\text{C}$ - barley residue	165.397	c	0.465	c
Decompose	Control	-28.225	a	0.495	cd
	$\delta^{13}\text{C}$ -barley residue	52.310	b	0.473	cd
	Root	-27.599	a	0.333	a
	Root exudate + $\delta^{13}\text{C}$ - barley residue	68.350	b	0.402	b

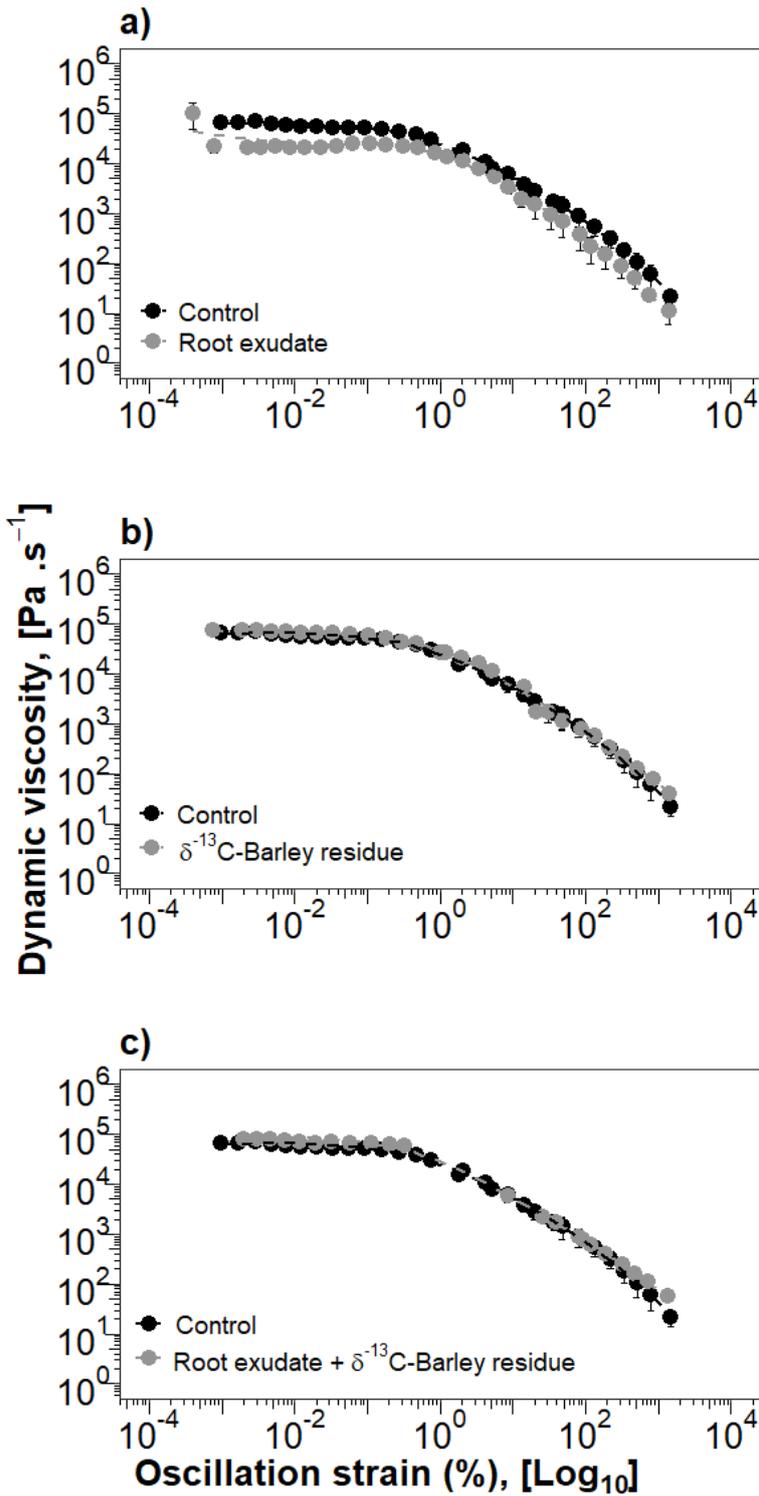

244 **LSMean** = Least Squares Mean,  $\theta\text{g or }w$  = gravimetric water content

245

246 *Soil rheological behaviour*

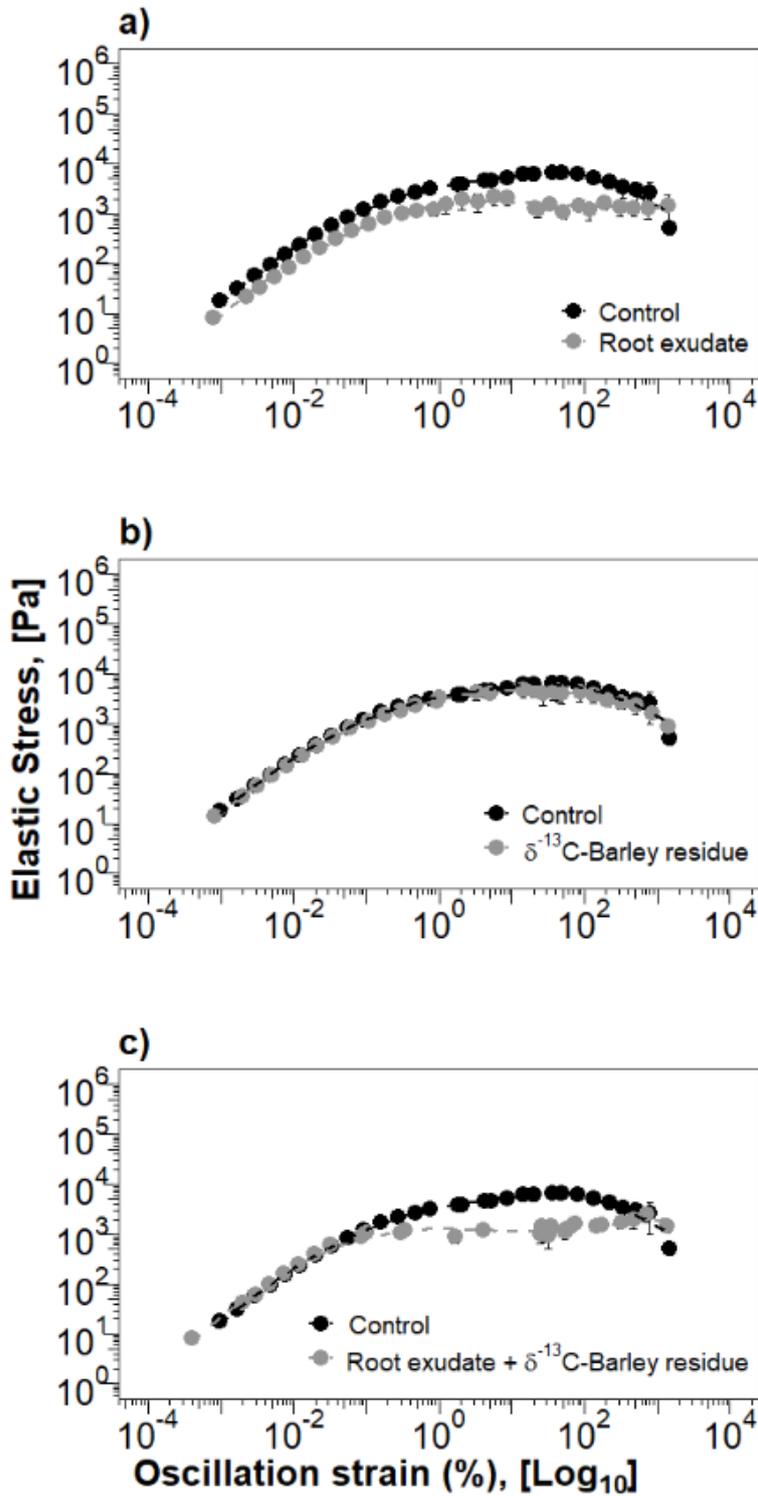

247 With the application of fresh treatment, the dynamic viscosity (the resistance to  
 248 movement of one layer of soil over another) for soils treated with root exudate at -2 kPa  
 249 matric potential was significantly ( $P < 0.05$ ) decreased compared to that of the control soil  
 250 (Figure 3a). At 0.1% oscillation strain, the soil structural resistance (dynamic viscosity)  
 251 following the application of fresh root exudate compounds was 205% less than that of  
 252 control soil (Figure 3a). While soils treated with  $\delta^{13}\text{C}$ -barley residue alone (Figure 3b) and  
 253 root exudate +  $\delta^{13}\text{C}$ -barley residue (Figure 3c) were not significantly different from that of  
 254 untreated soil (Figures 3b and, 3c). The yield stress (stress at structural collapse) for soils  
 255 with root exudate treatment and the combination of root exudate +  $\delta^{13}\text{C}$ -barley residue  
 256 treatment was significantly ( $P < 0.05$ ) lower compared to the unamended soil (Figure 4a and  
 257 4c). The yield stress for soils with root exudate treatment and the combined treatment of

258 root exudate +  $\delta^{13}\text{C}$ -barley residue was 276% and 273% lower compared to that of untreated  
259 soil, respectively (Figure 4). Similarly, storage modulus ( $G'$ ), loss modulus ( $G''$ ), and  $\tan\delta$   
260 ( $G''/G'$ ) for soil treated with root exudate compounds were significantly lower compared to  
261 the control/unamended soil and  $\delta^{13}\text{C}$ -barley residue with or without root exudate compounds  
262 treatments (Table 2).

263

264 **Figure 3:** Dynamic viscosity,  $\eta$  (Pa.s), as a function of oscillation strain for different  
 265 treatments before decomposition (fresh). Dynamic viscosity for root exudate treatment is  
 266 significantly lower compared to the control.

272 LSMean = Least Squares Mean,  $\gamma$  or  $\sigma_y$  = Yield stress,  $\eta$  = Dynamic viscosity,  $G''$  = Loss modulus, and,  $G'$  = Storage modulus

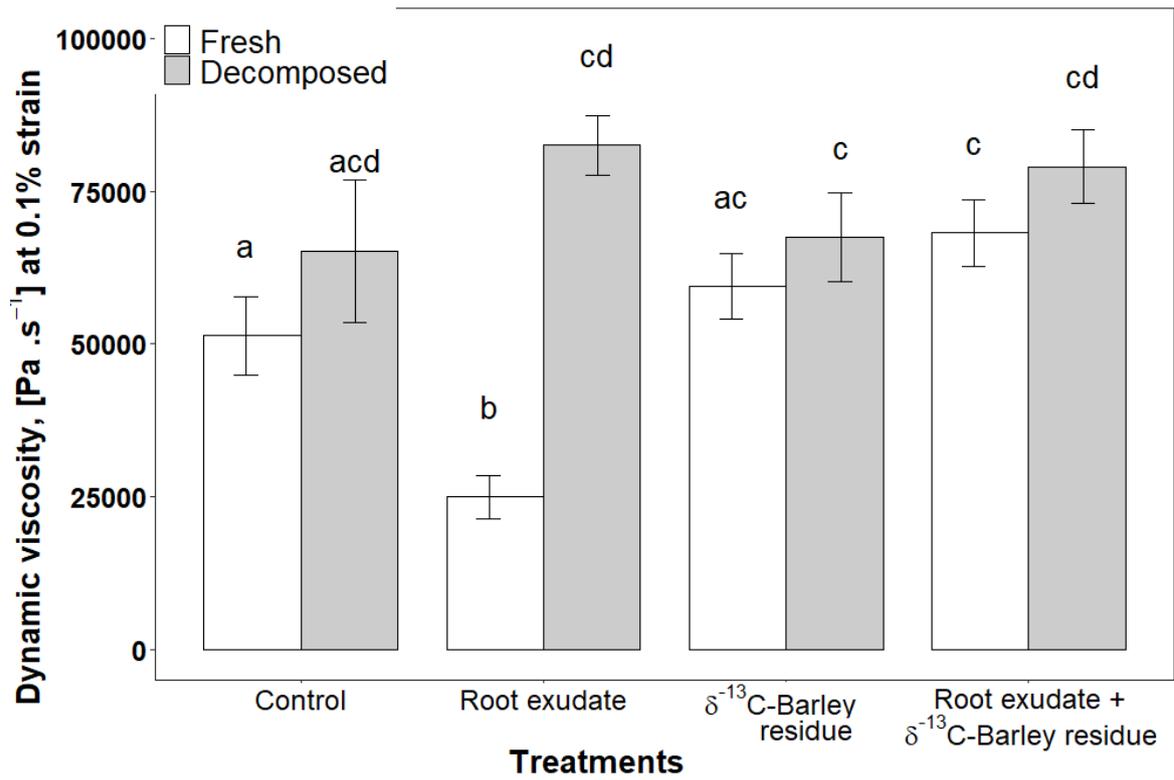

273           Root exudate compounds initially weaken the soil by reducing its resistance to  
274 deformation (Figures 3a and 4), but after 12 days of incubation and microbial  
275 decomposition, the soil structural resistance deformation stress was quickly increased for  
276 soils treated with root exudate compounds (Figures 5b). After decomposition, the dynamic  
277 viscosity ( $\eta$ ) at 0.1% oscillation strain for soil treated with root exudate compounds  
278 increased ( $P < 0.05$ ) by 331% compared to that of pre-decomposition (Figures 6). In a  
279 similar manner, soils treated with root exudate compounds showed an increase ( $P < 0.05$ ) in  
280 yield stress after decomposition. The yield stress for soils treated with root exudate  
281 compounds alone and root exudate +  $\delta^{13}\text{C}$ -barley residue treatments was increased by 201%  
282 and 230% after decomposition as compared to that of pre-decomposition, respectively  
283 (Figures 7b and 7d). Both dynamic viscosity and yield stress for the control/unamended soil  
284 and  $\delta^{13}\text{C}$ -barley residue treated soil were not significantly different after  
285 decomposition/incubation (Figures 6 and 8). A comparison of dynamic viscosity and yield  
286 stress for all samples after decomposition/incubation, did not show significant differences  
287 between the treatments (Figures 8).

304

### 305 Discussion

#### 306 *Soil mineralisation*

307 Daily mean CO<sub>2</sub> emitted over 12 days showed no significant variations among the  
 308 treatments. A possible reason is that sieving the soil to a particle size of less than 500 μm  
 309 liberated so much of the native carbon that our amendments were insignificant. Another  
 310 possible reason could be the state of the soil microbial community before the treatments  
 311 since the soil was air-dried to about 1% moisture content. The isotopic <sup>13</sup>C-CO<sub>2</sub> emitted was  
 312 significantly higher for the δ<sup>13</sup>C-barley residue treatments with and without root exudate  
 313 compounds reflecting the impact of readily available carbon on the mineralization.

#### 314 *Soil water retention*

315 The soil with root exudate treatment retained significantly less water compared to  
 316 unamended soil and soil amended with δ<sup>13</sup>C-barley residue. Relatively larger amounts of  
 317 organic acids and fewer free and polysaccharide-derived sugars present in the root exudate

318 compounds could have been the reason for the decreased water retention in the soil (Naveed  
319 *et al.*, 2017). This suggests that root exudate compounds act as surfactants reducing the  
320 surface tension of the soil water and consequently the amount of water retained at any matric  
321 potential. These results are in agreement with Naveed *et al.*, (2019) for the case of barley  
322 root exudate. These authors reported that soil with barley root exudate amendment retained  
323 significantly less water whereas the soil with maize root exudate and chia seed exudate  
324 amendments retained significantly more water than the unamended soil. Our results are also  
325 in agreement with Whalley *et al.* (2005) who reported that the rhizospheres of both maize  
326 and barley tended to be drier at a given matric potential than the bulk soil. In contrast,  
327 various other studies have observed that microbial polysaccharides and root mucilages  
328 increase water content by acting as a hydrogel (Ahmed *et al.* 2014; Moradi *et al.* 2012). This  
329 reflects that soil water retention in the rhizosphere depends on the physico-chemical  
330 characteristics of root exudates and their origin. There is a need to understand how this  
331 rhizosphere water dynamics influenced by root exudates would impact root water uptake.  
332 Kroener *et al.* (2014) showed that mucilage increased the rhizosphere water content,  
333 however, simulations were conducted with chia seed mucilage with high viscosity. In this  
334 study, soils amended with  $\delta^{13}\text{C}$ -barley residue and root exudate +  $\delta^{13}\text{C}$ -barley residue  
335 retained significantly higher water compared to the unamended soil (Table 2). This is in  
336 agreement with several studies carried out on the impact of organic amendments on soil  
337 water retention (Ankenbauer and Loheide, 2017; Blanco-Canqui *et al.*, 2015; Naveed *et al.*,  
338 2014; Olness and Archer, 2005). After 12 days of incubation, retention of soil water slightly  
339 decreased compared to pre-incubation values for all the soil amendments. This is logical  
340 and might be caused by the loss of soil organic matter due to mineralization.

341

342

343 *Soil rheological behaviour*

344           The dynamic viscosity and yield stress measured at -2 kPa matric potential for soil  
345 treated with root exudate compounds were significantly lower compared to that of  
346 unamended soil. This is despite significantly lower water content for the root exudate-  
347 treated soil. This suggests that the addition of root exudate compounds dispersed soil by  
348 changing interparticle bonding. The possible reason could be anions of organic acids,  
349 present in large amounts in root exudate compounds, might be adsorbed onto the mineral  
350 soil particles, which might in turn increase the net negative charge of clays and result in  
351 greater clay dispersibility (Shanmuganathan & Oades, 1983). This is in agreement with  
352 Naveed *et al.*, (2017) who reported that barley root exudate significantly dispersed the soil  
353 at the onset. The dispersion of soil due to the amendment of root exudate compounds could  
354 potentially promote root growth and increase the release of nutrients and carbon from the  
355 soil through the exposure of new particle surfaces. However, the dispersion of soil due to  
356 root exudate compounds is not universal and depends on the physical and chemical  
357 characteristics of the root exudate compounds (Naveed *et al.*, 2017, Traoré *et al.*, 2000;  
358 Morel *et al.*, 1991). For example, Naveed *et al.*, (2017) reported that maize root exudates  
359 and chia seed mucilage gelled the soil at the onset. Similarly, Barré and Hallett (2009) show  
360 that root exudate compound polygalacturonic acid (PGA) increased the viscosity of clays  
361 considerably. The dynamic viscosity and yield stress for soil treated with  $\delta^{13}\text{C}$ -barley  
362 residue were not significantly different from that of unamended soil. A possible reason is  
363 that the reactivity of the  $\delta^{13}\text{C}$ -barley residue due to its surface area increased the soil  
364 structural resistance and its susceptibility to deformation stress.

365           Incubation had a greater impact on soil rheological behaviour for the soil amended  
366 with root exudate compounds. The initial decrease in dynamic viscosity and yield stress at  
367 the onset of the root exudate amendment was recovered after 12 days of incubation. Both

368 dynamic viscosity and yield stress were not significantly different among the treatments  
369 after the incubation period. The observed increase in dynamic viscosity and yield stress for  
370 root exudate amendment following the incubation period suggests that microbial  
371 decomposition stabilizes the soil, and the observed role of root exudate compounds to  
372 disperse soil was rather short-lived. The resistance to displacement increased for the soils  
373 following incubation, which may be associated with microbial activity. Furthermore, the  
374 weak mechanical characteristics of fresh soils were reversed for all treatments after  
375 microbial decomposition, and agree with findings by Naveed *et al.* (2018) who showed that  
376 incorporation of barley root exudate in soil resulted in an immediate weakening and  
377 dispersion of aggregates, followed by an increase in aggregation due to microbial  
378 decomposition. Brax *et al.* (2020) showed that the mineralisation of organic carbon  
379 compounds in soils affects interparticle bonding by substituting ions in exchange sites.  
380 Liang *et al.* (2006) and Omari *et al.* (2017) found that the increases in cation substitution at  
381 charge surfaces are driven by microbial activities which markedly increase the absorption  
382 of organic matter to particle surfaces, resulting in meaningful increases in the absorption of  
383 negatively charged cations followed by a drop in zeta-potential, a key indicator of the  
384 stability of colloidal dispersions (Hanaor *et al.*, 2012). In addition, Alazigha *et al.* (2018)  
385 found that changes in cationic exchange properties at clay particle surfaces from microbial  
386 decomposition of organic carbon prompted flocculation, which could be the reason for the  
387 stability of soil amended with root exudate compounds after incubation. It may have been  
388 that the complex compounds produced from microbial decomposition of organic  
389 compounds had a greater impact on soil stabilization and may account for the large increases  
390 obtained in dynamic viscosity for soils amended with root exudate after decomposition. This  
391 suggests that microbial decomposition increased soil resistance and exhibited a greater  
392 range in yield stress than the range found on fresh soils (Figure 8).  $\tan\delta$  ( $G''/G'$ ) represents

393 the quality or stiffness of soil structure following the application of stress.  $\tan\delta$  increased  
394 on incubation/decomposition irrespective of the treatment (Table 2). This means that  
395 following decomposition soil aggregate and structural resistance to deformation stress is  
396 enhanced.

### 397 **Conclusions**

398 The impact of root exudate compounds and  $\delta^{13}\text{C}$ -barley residue on the micro-  
399 mechanical properties of soils at -2 kPa matric potential enhances our understanding of the  
400 processes driving soil structure formation and stabilization in the rhizosphere by serving as  
401 a model system to understand the impact of plant root exudate, decomposition dynamics  
402 and the rhizosphere formation pathway under wet conditions. Our results highlight the  
403 significant effect of root exudate on soil structural stability, through reduced rate of micro-  
404 mechanical behavior before microbial decomposition of these substrates. Specifically, the  
405 yield stress and dynamic viscosity for soil treated with root exudate compound at the onset,  
406 reflect the weakening and dispersion effect of root exudates on soil aggregates which is  
407 important for root growth and access to protected nutrients within the aggregates, although  
408 this effect is reversed following decomposition of the exudate. The values for soil micro-  
409 mechanical properties observed following the application of root exudate +  $\delta^{13}\text{C}$ -barley  
410 residue treatment alone at both stages of decomposition are important as it shows that root  
411 exudate compounds and the associated soil microbial activities are essential to predict how  
412 soils amended with organic residue may respond structurally to mechanical stress.
