Abstract

This study exploits the high-density zonal sampling at the turnaround latitude of the High Resolution Dynamics Limb Sounder (HIRDLS) in the Southern Hemisphere to investigate the missing drag in chemistry-climate models near 60 S. Gravity wave (GW) properties including amplitude, zonal wavenumber, vertical wavelength, and momentum flux are estimated with a wavelet analysis method based on the S-transform. Monthly means of GW properties compare well with estimates from previous studies. We further investigate the contribution to GW momentum flux above orographic and nonorographic regions and find that while fluxes are much larger locally over orographic regions, the contribution to the zonal mean is roughly 3 times smaller than the contribution over nonorographic regions. We also investigate the relationship with the zonal wind and find that GW momentum flux is highly correlated with the near surface winds over orographic regions. In addition to momentum flux, we also provide estimates of the zonal drag and use these estimates to evaluate the current GW parameterizations and resolved wave forcing in models participating in phase 1 of the Chemistry-Climate Model Initiative (CCMI-1). The HIRDLS zonal drag estimates suggest that the CCMI-1 models have insufficient zonal drag, especially in June, July, and August, and that the majority of the missing drag is over nonorographic regions. Our discussion includes implications for the Brewer-Dobson Circulation and ozone hole.

Exploiting close zonal-sampling of HIRDLS profiles near turnaround latitude to investigate missing drag in chemistry-climate models near 60°S

15 Abstract

This study exploits the high-density zonal sampling at the turnaround latitude of the 16 High Resolution Dynamics Limb Sounder (HIRDLS) in the Southern Hemisphere to in-17 vestigate the missing drag in chemistry-climate models near 60°S. Gravity wave (GW) 18 properties including amplitude, zonal wavenumber, vertical wavelength, and momen-19 tum flux are estimated with a wavelet analysis method based on the S-transform. 20 Monthly means of GW properties compare well with estimates from previous stud-21 ies. We further investigate the contribution to GW momentum flux above orographic 22 and nonorographic regions and find that while fluxes are much larger locally over oro-23 graphic regions, the contribution to the zonal mean is roughly 3 times smaller than 24 the contribution over nonorographic regions. We also investigate the relationship with 25 the zonal wind and find that GW momentum flux is highly correlated with the near 26 surface winds over orographic regions. In addition to momentum flux, we also pro-27 vide estimates of the zonal drag and use these estimates to evaluate the current GW 28 parameterizations and resolved wave forcing in models participating in phase 1 of the 29 Chemistry-Climate Model Initiative (CCMI-1). The HIRDLS zonal drag estimates 30 suggest that the CCMI-1 models have insufficient zonal drag, especially in June, July, 31 and August, and that the majority of the missing drag is over nonorographic regions. 32 Our discussion includes implications for the Brewer-Dobson Circulation and ozone 33 34 hole.

35 1 Introduction

Gravity waves (GWs) play a key role in the dynamics of the atmosphere, but it 36 remains a challenge to represent them in chemistry-climate models (CCMs). This con-37 tributes to biases in temperatures and winds in the Southern Hemisphere stratosphere. 38 Generally, winds are too strong and temperatures too cold compared to observations. 39 Additionally, the stratospheric final warming in the Southern Hemisphere is typically 40 one or two weeks late in CCMs compared to observations (Eyring et al., 2010; Butchart 41 et al., 2011). Although the reasons for these biases are not completely understood, it 42 is generally thought that missing Southern Hemisphere wave drag in models is a major 43 culprit. 44

Possible sources of the missing wave drag include inadequate continental oro-45 graphic GW drag (McLandress et al., 2012), orographic GW drag from small, unre-46 solved islands (Alexander et al., 2009; Alexander & Grimsdell, 2013), lateral prop-47 agation of GWs generated at other latitudes (e.g., Sato et al., 2009; Yamashita et 48 al., 2010; Sato et al., 2012; Jiang et al., 2013; Krisch et al., 2017; Thurairajah et al., 49 2017; Strube et al., 2021), and nonorographic GWs generated by fronts and convection 50 (Hendricks et al., 2014; Shibuya et al., 2015; Holt et al., 2017). Several observational 51 and modeling studies have documented large, intermittent momentum fluxes over the 52 Southern Ocean (e.g., Hertzog et al., 2008, 2012; Plougonven et al., 2013; Jewtoukoff 53 et al., 2015), supporting the case for large-amplitude nonorographic GWs generated 54 by strong convection. Studies have also shown improved model biases and improved 55 timing of the stratospheric final warming in the Southern Hemisphere when the grav-56 ity wave parameterization is based on an intermittent source function (de la Cámara 57 & Lott, 2015; de la Cámara et al., 2016). Understanding the sources of the missing 58 drag and correcting the deficiencies in modeled GW effects is a high priority since 59 the resulting model biases in wind and temperature hinder our ability to realistically 60 model the ozone hole and its recovery, which also has implications for our ability to 61 model surface climate change (e.g., Arblaster et al., 2014). 62

McLandress et al. (2012) showed that adding extra orographic GW drag at 60°S in a CCM resulted in a significant improvement in the cold-pole bias and timing of the vortex breakdown, which in turn affect the ozone hole depth. Garcia et al.

(2017) achieved similar improvements in the cold-pole bias in a CCM by increasing 66 the parameterized orographic GW drag in the Southern Hemisphere. These approaches 67 are justified as long as the observational guidance remains ambiguous for constraining 68 the missing Southern Hemisphere drag, but these methods are not ideal. For example, while strong localized orographic GW drag may have similar effects on the zonal mean 70 as more zonally uniform drag, there can be dramatically different interactions with 71 Rossby waves and horizontal and vertical mixing effects on tracers. Ideally we would 72 get the stratospheric wind and temperature responses to GW drag correct and for 73 the right reasons, and for this it is essential that the tunable parameters in CCMs be 74 constrained by observations. 75

In this paper, we exploit the close zonal sampling of the High Resolution Dy-76 namics Limb Sounder (HIRDLS) at the turnaround latitude to obtain estimates of 77 the missing drag in the Southern Hemisphere. At the turnaround latitude ($\sim 63.4^{\circ}$ S), 78 HIRDLS provides a wealth of information on waves spanning zonal wavenumbers 1 79 through 90. This information has not yet been utilized to investigate missing South-80 ern Hemisphere drag. While previous studies have used HIRDLS to look at the largest 81 scale waves between wavenumbers 1 through 8 in the tropics (Alexander et al., 2010) 82 or global properties of small-scale GWs (Alexander et al., 2008; Ern et al., 2011; 83 Wright et al., 2010), none have focused on the turnaround latitude in the Southern 84 Hemisphere. 85

Waves of all scales, from planetary waves to small-scale GWs, contribute to the drag on the zonal wind and the driving of the Brewer-Dobson circulation near 60°S. GWs with higher zonal wavenumbers are only observable with HIRDLS where zonal sampling occurs more frequently. For example, zonal measurements near the equator are ~400 km apart which means the shortest observable wavelength is ~800 km, whereas the zonal sampling near the turnaround latitude is between ~70-140 km. This makes sampling at the high latitudes ideal for investigating the missing drag near 60°S.

This paper is organized as follows: in Section 2 we describe the data and Stranform method we use to estimate GW properties. In Section 3 we describe the observed wave properties, including momentum flux and wave statistics. Finally, in Section 4 we present estimates of potential drag and compare HIRDLS GW potential drag to parameterized and resolved drag in CCMs and discuss the implications for the Brewer-Dobson Circulation and ozone hole.

¹⁰⁰ 2 Data and Methodology

101

2.1 HIRDLS Temperature Profiles

The HIRDLS instrument on board NASA's Aura satellite is a limb-scanning 102 infrared radiometer. Aura is in a sun-synchronous, polar orbit with an orbital period 103 of 99 minutes making approximately 14.9 revolutions per day (Gille et al., 2008). The 104 basis of our analysis uses HIRDLS high vertical resolution temperature profiles with ~ 1 105 km vertical resolution and \sim 70-140 km horizontal resolution. This study uses version 106 7 of the Level 2 HIRDLS data for the period from January 2005 to March 2008, with a 107 focus on May through November (days 121 to 334) in the Southern Hemisphere winter 108 and spring seasons. Note that each year a few days have incomplete measurements, so 109 days listed in Table 1 were removed. Occasionally, profiles were flagged as bad data, 110 showing single-level spikes in the temperature profile as large as 10 times the normal 111 temperature perturbation. Further investigation found that temperature quality and 112 cloud top pressure did not flag these cases, so such profiles were removed from the 113 analysis. 114

	Table 1.	HIRDLS	Data Removed
--	----------	--------	--------------

Year	Days
2005	132, 193, 194, 195, 205, 306, 349, 350
2006	143, 186, 191, 236, 307
2007	163, 194, 310

Figure 1 shows the geographic location of each profile scan for 7 September 115 2006. HIRDLS provides approximately 5,530 profile measurements per day and scans 116 vertically at a fixed azimuth of -47° on the anti-sun side of the orbit track. High density 117 zonal sampling occurs near a satellite's turnaround latitude, where the measurement 118 track switches between descending and ascending nodes. For HIRDLS, this turnaround 119 latitude in the Southern Hemisphere is at $\sim 63.4^{\circ}$ S. In this study, we focus on the 120 profiles between 61 and $\sim 63.4^{\circ}$ S that are highlighted pink in Figure 1. For these 121 latitudes, the zonal distance between profiles is ~ 20 times larger than the meridional 122 distance between profiles on average. Therefore, the sampling at these latitudes can be 123 assumed to be zonal and we will assume that our analysis provides the zonal component 124 of the horizontal wavenumber and an estimate of the zonal component of the GW 125 momentum flux. Focusing on measurements at these latitudes reduces the number of 126 profiles to roughly 375 per day. 127

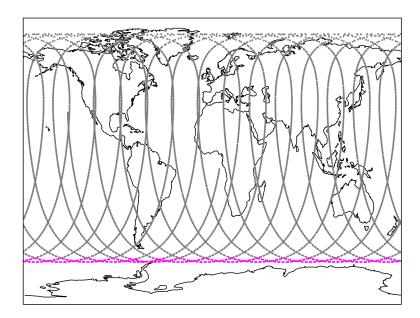

Figure 1. HIRDLS temperature profiles for 7 September 2006. The profiles used in our analysis are highlighted in pink.

128 **2.2 MERRA-2**

Winds influence vertically propagating GWs at every stage of the GW lifecycle,
 from generation to refraction, filtering, and dissipation. We use the MERRA-2 3 hourly, instantaneous, pressure-level assimilated meteorological fields (doi:10.5067/
 QBZ6MG944HW0). This V5.12.4 data has a spatial resolution of 0.5° x 0.625° and 42
 vertical levels. Zonal winds between 60 and 66°S are used to investigate the relationship
 between winds and momentum flux and drag from HIRDLS data.

135 **2.3 CCMI-1**

To highlight how our results could be applied to improve chemistry-climate simulations, we use output from the Chemistry-Climate Model Initiative (CCMI-1) (Eyring et al., 2013; Hegglin et al., 2015). We include CCMI-1 models that provide zonal acceleration due to paramaterized orographic and nonorographic GWs and EP flux divergence in the refC1 zonal mean files. This allows us to compare the total wavedriven zonal forcing in the CCMI-1 models to the zonal GW forcing inferred from the HIRDLS analysis in Section 4.1.

¹⁴³ 2.4 S-Transform Wavelet Analysis

We compute wave properties from the HIRDLS data by using the S-transform (Stockwell et al., 1996) with the method described by Alexander et al. (2008). This analysis provides amplitude, horizontal and vertical wavelength, and momentum flux for GWs observed in HIRDLS temperature profiles. The S-transform is well-suited for analyzing GWs in satellite data and has been used in many other studies with a variety of geophysical datasets (e.g., Stockwell et al., 2007; Alexander & Barnett, 2007; Wright et al., 2010; Wright & Gille, 2013; Hindley et al., 2015, 2016, 2019).

Here we briefly outline the method in Alexander et al. (2008). For each day 151 of HIRDLS measurements, we compute the zonal mean temperature as a function of 152 latitude (in 2.4° bins) and altitude. Then we compute planetary-scale perturbations 153 from the remaining temperature variations using the S-transform. Wave numbers 0-5 154 are used to define the "large-scale temperature", and we subtract the large-scale tem-155 perature from the HIRDLS temperatures to obtain "perturbation" profiles. Next the 156 S-transform is computed for each HIRDLS perturbation profile south of 61°S, pro-157 viding a complex-valued function of altitude, z and vertical wavelength, λ_z : $T(z, \lambda_z)$. 158 Then the cospectrum 159

$$C_{(i,i+1)} = \tilde{T}_i \tilde{T}_{i+1}^* = \hat{T}_i \hat{T}_{i+1} e^{i\Delta\phi_{i,i+1}}$$
(1)

and the covariance spectrum, $|C_{(i,i+1)}|$, are computed for each adjacent profile pair, *i* and *i* + 1, where the asterisk represents the complex conjugate. For the S-transform analysis, we zero pad the HIRDLS profiles below 10 km and above 70 km to reduce wraparound effects. The covarying temperature amplitude is

$$\hat{T}_{(i,i+1)} = \sqrt{|C_{i,i+1}|}.$$
(2)

¹⁶⁴ and the phase difference between profiles is

$$\Delta \phi_{i,i+1} = \tan^{-1} \frac{\Im(C_{i,i+1})}{\Re(C_{i,i+1})}$$
(3)

From the horizontal (zonal) phase difference $\Delta \phi_{i,i+1}$, we estimate the zonal wavenumber via

$$k = \frac{\Delta \phi_{i,i+1}}{\Delta r_{i,i+1}} \tag{4}$$

where $\Delta r_{i,i+1}$ is the distance between the adjacent profiles.

Figure 2a highlights a swath of HIRDLS profiles near the turnaround latitude 168 near the Antarctic Peninsula on 7 September 2006. Figure 2b shows temperature 169 perturbation profiles for all of the solid black circles in (a). These temperature per-170 turbations show the wave like structure with height. The tilting of the wave from 171 east to west with altitude above the tip of the Antarctic Peninsula indicates that the 172 wave is propagating westward. Figure 2c shows the covarying temperature amplitude, 173 \hat{T} (Equation 2) as a function of vertical wavelength and altitude for the profile pair 174 highlighted in pink near 60°W. The S-transform reveals that the dominant vertical 175 wavelength is ~ 20 km and increases slightly with altitude. The peak amplitude of this 176 wave contribution is ~ 15 K near 50 km in altitude. At 50 km there is another peak 177 in the covariance spectrum near 10 km vertical wavelength. These features can also 178 be satisfactorily confirmed by eye in (b). The black lines in (c) indicate the cone of 179 influence for zero-padding effects from the S-transform: the values below and above 180 the black lines are possibly contaminated by these effects and should be used with cau-181 tion. We choose a vertical wavelength cutoff of 40 km to compromise between including 182 longer wavelength waves and excluding signals that would be largely contaminated by 183 zero-padding effects. 184

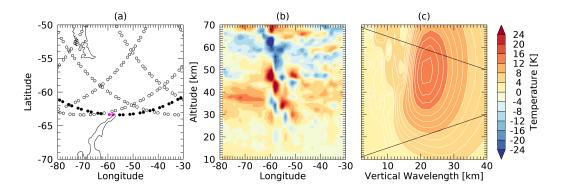

Figure 2. (a) HIRDLS profile locations near the Antarctic Peninsula for 7 September 2006. Solid black circles highlight one swath of HIRDLS profiles south of 61°S, and the solid pink circles highlight one profile pair. (b) Temperature perturbation profiles for the solid black measurement swath in (a). (c) Covarying temperature amplitude, \hat{T} (square root of the covariance spectrum as in Equation 2) as a function of vertical wavelength and altitude for the two profiles in pink in (a). The color bar applies to both (b) and (c), and the white contours in (c) are 1 K. Black lines indicate cone of influence for zero-padding effects from the S-transform.

To estimate the zonal momentum flux for each peak in the covariance spectrum, we use $(1 + 1)^2$

$$M_{i,i+1}(z,\lambda_z) = \frac{\rho}{2} \lambda_z \frac{k}{2\pi} \left(\frac{g}{N}\right)^2 \left(\frac{\hat{T}_{i,i+1}(z,\lambda_z)}{\bar{T}}\right)^2 \tag{5}$$

where $M_{i,i+1}$ is momentum flux, ρ is density, g is the gravitational acceleration of 187 Earth, N is buoyancy frequency, and \overline{T} is the background temperature. In previ-188 ous work only one or two peaks in the covariance spectrum were used to compute 189 the momentum flux, and vertical wavelengths were limited to those less than 25 km 190 (Alexander et al., 2008; Wright et al., 2010). Here we use all of the peaks in the covari-191 ance spectrum with vertical wavelengths less than 40 km since the strength of winds 192 in the Southern Hemisphere near the turnaround latitude can be particularly strong, 193 and therefore we expect HIRDLS to detect waves with longer vertical wavelengths. 194 We further stipulate that the peaks must be higher than the HIRDLS noise threshold 195 of 0.5 K. We identify all the peaks in $C_{i,i+1}$ at each altitude and then use a quadratic 196

fit to estimate the true temperature amplitude of each peak. For example in Figure 197 2c, the temperature amplitude peak is 15 K at $z \sim 50$ km and $\lambda_z \sim 20$ km, and with 198 our quadratic fit the "true peak" is 19 K. The total temperature amplitude and total 199 momentum flux for each profile pair at each altitude are computed as the sum over all 200 detected peaks. Each peak corresponds to a particular vertical wavelength and zonal 201 wavenumber. We compute an average vertical wavelength and zonal wavenumber for 202 each profile pair at each altitude by a weighted average, where the vertical wavelength 203 and zonal wavenumber are weighted with the corresponding temperature amplitude of 204 each peak detected. 205

In addition to the zonal momentum flux, we estimate the zonal mean drag on the mean flow with

$$F = -\frac{1}{\bar{\rho}} \frac{\delta M_{i,i+1}}{\delta z} \tag{6}$$

and call this the "potential drag" because it is non-directional, and in reality there
is an undetermined amount of cancellation between eastward and westward (positive
and negative) flux and drag. The uncertainties of this method are discussed in more
detail in Ern et al. (2011) and Alexander and Ortland (2010).

The minimum observable horizontal wavelength is twice the separation distance 212 between profiles and shorter wavelengths may be aliased to longer values (e.g., Ern et 213 al., 2004; Eckermann & Preusse, 1999). Since zonal wavenumber is in the numerator 214 of Equation 5, our momentum fluxes most likely have a low-bias. As stated previously 215 we assume that the separation between adjacent profiles near the turnaround latitude 216 is zonal in orientation, so the wavelengths we observe and the momentum fluxes we 217 compute are assumed to be the zonal components thereof. The zonal component is 218 most important to the momentum budget at these latitudes. 219

²²⁰ 3 Gravity wave properties

In this section we present GW properties derived from the S-Transform method 221 discussed in the previous section. These GW properties include temperature ampli-222 tude, momentum flux, horizontal wavenumber, and vertical wavelength. Our GW 223 analysis was performed on all adjacent profile pairs between 61° and 63.4°S from May 224 to November for each year of HIRDLS data. Figure 3 shows HIRDLS temperature 225 perturbation amplitudes for the winter and spring seasons for each year. The data is 226 binned 5° in longitude and 2.4° in latitude (61°-63.4°S) and averaged between 35 and 227 45 km altitude. The top panels are averaged over the winter months of June, July, 228 and August. The bottom panels are averaged over the spring months of September, 229 October, and November. 230

The winter season shows peaks over the peninsula, although there is considerable wave activity over large non-orographic areas. During the spring months temperature amplitude peaks are smaller but have a similar spatial pattern. The most apparent consistency among each year and seasonal average is the geographic location of the hot spot over the Peninsula. This GW hot spot is an important feature in the Southern Hemisphere, which we will explore in more detail in the following sections.

Figure 4 shows HIRDLS average GW properties for the month of September 237 2006, in 5° longitude bins and averaged from 61° to 63.4° S. Temperature perturba-238 tion amplitude, |T| (top left), momentum flux, M (top right), zonal wavenumber, k 239 (bottom left), and vertical wavelength, λ_z (bottom right) are shown as a function of 240 longitude and altitude. These averages only include nonzero momentum fluxes. That 241 is, where the momentum flux is zero, we do not include the corresponding temperature 242 perturbation amplitude, momentum flux, zonal wavenumber, and vertical wavelength 243 in the means. Note that we have the most confidence in the results in the middle of the 244 altitude range displayed in Figure 4, and the results in the lower and upper portions of 245

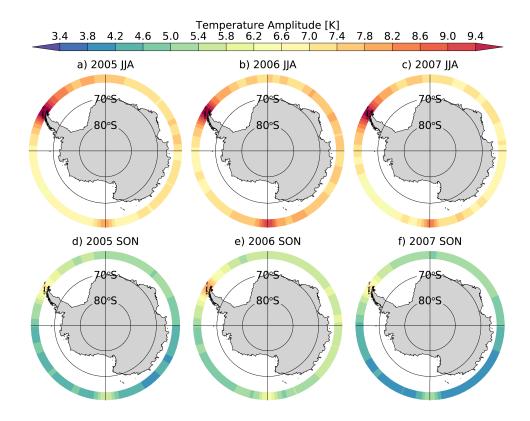

Figure 3. Polar view of Antarctica with HIRDLS temperature perturbation amplitudes averaged between 35 and 45 km altitudes. Top three panels are averaged over June, July, and August for each year. Bottom three panels are averaged over September, October, and November for each year.

the domain are to be used with caution because they may suffer from contamination
from the zero-padding effects of the S-transform. The panel on the right shows the
MERRA-2 mean wind profile averaged for the month of September.

In general, the largest temperature perturbation amplitudes are between 40 and 249 70°W, above the Antarctic Peninsula and increase with increasing altitude. The peak 250 in temperature perturbation amplitude corresponds to large momentum fluxes that 251 decrease with increasing altitude, with a sharp decrease in momentum flux where zonal 252 wind peaks near 40 km. The absolute momentum flux values are reasonable for this 253 region compared to other studies using satellite observations to estimate momentum 254 flux (e.g., Ern et al., 2004; Alexander et al., 2008; Geller et al., 2013; Hindley et al., 255 2020). These studies also show localized spots of enhanced temperature amplitude 256 and momentum flux over the Andes, just north of the Antarctic Peninsula. 257

The area of large temperature perturbation amplitudes and momentum fluxes 258 also corresponds to smaller horizontal scales (larger k) and slightly longer vertical 259 wavelengths. Vertical wavelengths range between approximately 10 to 17 km and 260 decrease with altitude, especially where winds are increasing. Refraction of GWs 261 can occur when either the buoyancy frequency or intrinsic phase speed changes with 262 altitude as elucidated by the dispersion relation for medium frequency GWs, |m| =263 $N/|\hat{c}_h|$, where m is the vertical wavenumber, N is the buoyancy frequency, and $\hat{c}_h =$ 264 c-u is the horizontal intrinsic phase speed. The intrinsic phase speed is the phase 265 speed that would be observed in a frame of reference moving with the background 266

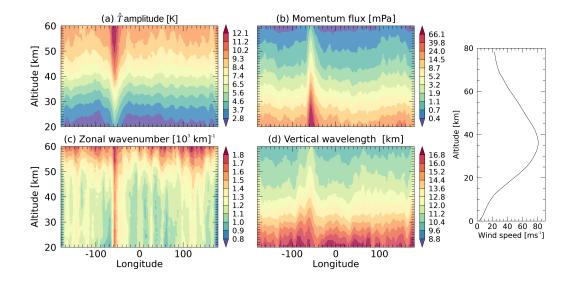

Figure 4. Monthly mean (a) temperature perturbation (\hat{T}) amplitude, (b) GW absolute momentum flux, (c) zonal wavenumber, and (d) vertical wavelength as a function of longitude and height for September 2006. The panel on the right is the MERRA-2 zonal wind profile averaged for the month of September 2006 and 61° to 63.4°S.

wind. The decrease in λ_z with altitude is certainly partly due to the increase in N in the stratosphere with altitude.

The relationship to the zonal wind is less straightforward, but Figure 4 shows 269 that the winds increase with height up ~ 40 km then decrease. The dispersion relation 270 therefore dictates that the intrinsic phase speed of westward propagating waves would 271 increase below ~ 40 km and decrease above, corresponding to decreasing m (increasing 272 λ_z) below ~40 km and increasing m (decreasing λ_z) above ~40 km. Likewise the 273 intrinsic phase speed of eastward propagating waves would decrease below ~ 40 km 274 and increase above, corresponding to increasing m (decreasing λ_z) below ~40 km and 275 decreasing m (increasing λ_z) above ~40 km. Additionally, as will be shown in Section 276 3.2, GWs with larger momentum fluxes are associated longer vertical wavelengths at 277 20 km (see Figure 7), and those GWs with larger momentum fluxes break lower in 278 altitude. To summarize, the decrease of λ_z below ~40 km in Figure 4 is probably 279 due to a combination of eastward propagating GWs refracting to shorter λ_z as they 280 approach critical levels, increasing N, and breaking of GWs with larger momentum 281 fluxes and longer λ_z . 282

3.1 Zonal mean momentum flux and relationship to zonal mean zonal wind

283

284

Figure 5 shows HIRDLS zonal mean momentum fluxes as a function of time 285 and altitude from May through November for each year of HIRDLS data. The black 286 contours show winds from MERRA-2 with 10 ms^{-1} intervals and the solid dark line 287 is the zero-wind line. The overall shape of the momentum flux roughly corresponds 288 to the winds (i.e., momentum flux decreases as zonal mean zonal wind increases), 289 particularly when the zero-wind line descends in late September to mid October when 290 the momentum flux drops off sharply. However, individual peaks in the momentum 291 flux do not appear to correspond to individual peaks in the stratospheric winds in 292 either the nonorographic or orographic region. We point out that although it looks 293 as though the momentum flux over the orographic region is more intermittent than 294

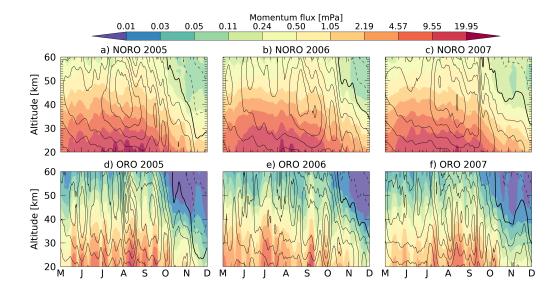

Figure 5. Zonal mean GW momentum flux for nonorographic (a-c) and orographic (d-f) regions from May to November for 2005-2007 averaged from 61° S and 63.4° S. The zonal mean zonal wind from MERRA-2 is shown in the black contours with contour intervals of 10 ms⁻¹. Eastward and westward winds are shown with solid and dashed lines, respectively and the zero wind line is indicated by the thick contour line. The momentum flux is smoothed with a 7-day boxcar average.

over the nonorographic region, this is because the nonorographic region is so much
larger than the orographic region (330° versus 30° longitude) that there are many
more profiles in the nonorographic region and this results in a smoother appearance.
A 30° subsample over the nonorographic region shows just as much intermittency (not
shown).

Next we investigate the relationship between zonal wind at different altitudes 300 and GW absolute momentum flux in the middle of our altitude range, where we have 301 the most confidence in our results. Figure 6 shows HIRDLS absolute momentum 302 fluxes averaged between 35 and 45 km and between 40° and $70^{\circ}W$ (black, left axis) 303 and MERRA-2 near-surface winds averaged between 1 and 3 km and between 40° 304 and 70° W and 63° S and 66° S (gray, right axis) for the three years of HIRDLS data. 305 Again, we are calling the region between 40 and 70° W orographic because this is the 306 only region with orographic features between 61°S and 63.4°S. We chose 63°S and 307 66° S for the MERRA-2 near-surface winds because this is directly over the Antarctic 308 Peninsula. Both the momentum flux and the wind are smoothed with a 3-day boxcar 309 average. The linear Pearson correlation coefficient, r, of the two time series between 310 May and the end of September is also shown in the corresponding panel. The GW 311 absolute momentum flux is highly correlated with the near-surface winds, especially 312 in 2005 and 2006, between May and September. The sudden decrease of momentum 313 flux to near zero in October in all three years is due to the descent of the zero wind 314 line near 40 km. The year with the strongest correlation, 2006, also has the strongest 315 near-surface westerlies. The winds in the chosen region rarely drop below 0 ms^{-1} 316 between May and September. The near-surface winds in 2005 also rarely drop below 317 0 ms^{-1} between May and September, but the magnitude of the winds isn't as large as 318 in 2006. However, in 2007, the year with the lowest correlation coefficient, the winds 319

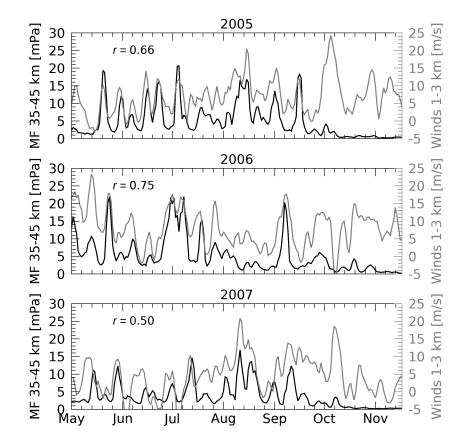

Figure 6. HIRDLS momentum fluxes averaged between 35 and 45 km and between 40° and 70° W (black, left axis) and MERRA-2 near-surface winds averaged between 1 and 3 km (gray, right axis) for the three years of HIRDLS data. The linear Pearson correlation coefficient, r, of the two time series in each plot is also shown in the corresponding panel.

frequently drop below 0 ms^{-1} and the maximum peaks rarely exceed 10 ms^{-1} before August.

We also performed this analysis for winds at different altitudes, and the relation-322 ship between winds at higher levels and GW absolute momentum flux isn't as strong. 323 For example, the correlation coefficients of the winds between 10 and 25 km and 60° S 324 and $64^{\circ}S$ and the fluxes is 0.47, 0.44, and 0.24 for 2005, 2006, and 2007, respectively 325 and the correlation coefficients of the winds between 27 and 35 km and the fluxes 326 is 0.36, 0.09, 0.13 for 2005, 2006, and 2007, respectively. We additionally performed 327 this analysis for all nonorographic longitude bins and found no significant correlations. 328 Altogether, this analysis suggests that the surface winds are the most important factor 329 driving the variability of orographic GW momentum flux in the middle stratosphere 330 and that the strongest westerly surface winds lead to the largest momentum fluxes. 331

332

3.2 Statistical properties of GW events

In the previous section we presented results for averages of many wave events: seasonal means, monthly means, and zonal means or zonally averaged properties of wave events. In this section we present the statistical analysis of individual wave events. Figure 7a shows the probability of occurrence of HIRDLS orographic and nonorographic GW absolute zonal momentum fluxes. The distributions are popu-

lated with events from each peak in the covariance spectrum at 20 km from every 338 profile pair between 61° and 63.4° S and from May to Nov 2006. We have not ap-339 plied any spatial or temporal averaging to the fluxes. The shape of the distributions 340 is approximately lognormal: the dashed lines in (a) show the theoretical lognormal 341 distributions with the same geometric mean and standard deviation as the HIRDLS 342 orographic (black) and nonorographic (gray) momentum fluxes. Many previous stud-343 ies using both observations and models have shown that GW momentum fluxes have 344 an approximately lognormal distribution with a broad tail of rare but large momen-345 tum flux events (e.g., Hertzog et al., 2012; Alexander & Grimsdell, 2013; Wright et 346 al., 2013; de la Cámara et al., 2014; Jewtoukoff et al., 2015; Holt et al., 2017). The 347 contribution of the large events to the total flux can be assessed by computing the 348 percentage of the total flux coming from fluxes larger than a given quantile (Hertzog 349 et al., 2012). The 90th and 99th percentiles are shown in (a) along with the percentage 350 of the total flux coming from fluxes larger than the 90th and 99th percentiles. For both 351 orographic and nonorographic GW events, a considerable portion (67% for orographic 352 and 53% nonorographic) of the total flux is due to the largest 10 percent of events. 353 For orographic events, almost a third of the total momentum flux is due to only 1%354 of all events. This underlines that these large GW momentum fluxes, while rare, are 355 extremely important for the zonal mean momentum budget. 356

The black line in Figure 7b shows the probability of occurrence of vertical wave-357 length for all events shown in (a), orographic and nonorographic combined. Addition-358 ally, the blue line is the contribution of the smallest 10% of events and the red line 359 is the contribution of the largest 10% of events. The overall distribution shows an 360 almost uniform distribution between 10 and 40 km. Recall that we excluded verti-361 cal wavelengths smaller than the Nyquist wavelength for HIRDLS (2 km) and larger 362 than 40 km. The smallest 10% of fluxes also reflect this lack of preference for verti-363 cal wavelength. However, the largest 10% of fluxes are skewed toward longer vertical 364 wavelengths. To evaluate the effects of noise on the results, we performed our analysis 365 on the same HIRDLS profiles replaced with random temperature perturbations with 366 standard deviation of 0.5 K. The gray line shows the distribution for the random noise 367 profiles. The dotted lines, with colors corresponding to the colors of the distributions 368 with solid lines, show the results when no amplitude cutoff is applied to our analysis 369 (i.e., no noise is removed). The results show that without the amplitude cutoff ap-370 plied to the analysis of the HIRDLS data, the distributions for the total events and 371 the smallest 10% of events start to take on characteristics of the noise distribution: 372 a preference for small vertical wavelengths. The distribution for the largest 10% of 373 events is basically the same whether an amplitude cutoff is included or not. This 374 analysis along with the fact that the noise distribution is a very different shape than 375 the distributions with the amplitude cutoff gives us confidence that our results are due 376 to robust wave events detected by HIRDLS and that our amplitude cutoff is indeed 377 necessary to remove the effects of noise. 378

The black line in Figure 7c shows the probability of occurrence of zonal wavenum-379 ber for all events in (a). Again the blue line is the contribution of the smallest 10% of 380 events, the red line is the contribution of the largest 10% of events, the gray line shows 381 the result for noise, and the dotted lines show the results when no amplitude cutoff 382 is applied to our analysis. The total distribution for zonal wavenumber (black solid 383 line) shows a preference for smaller zonal wavenumbers (larger zonal wavelengths). 384 The zonal wavenumbers corresponding to the smallest 10% of fluxes (blue solid line) 385 are strongly skewed toward smaller wavenumbers. The zonal wavenumbers corre-386 sponding to the largest 10% of fluxes (red solid line) are also skewed towards smaller 387 wavenumbers for wavenumbers below about $4 (1000 \text{ km})^{-1}$, but are much more broadly 388 distributed in general and are almost uniformly distributed for larger zonal wavenum-389 bers. The largest zonal wavenumber is $\sim 7.2 (1000 \text{ km})^{-1}$, which corresponds to ~ 139 390 km zonal wavelength. This is 2 times the shortest zonal distance between HIRDLS 391

profiles, or the Nyquist cutoff. HIRDLS may be sensitive to waves with zonal wave-392 lengths as short as about 10 km, but these waves are undersampled (Alexander et al., 393 2008). Waves with wavelengths below the Nyquist cutoff will be aliased into longer 394 wavelengths (smaller wavenumbers). There is another bump in the zonal wavenumber 395 distribution at $\sim 3.6 \ (1000 \ \text{km})^{-1} \ (278 \ \text{km} \text{ zonal wavelength})$. This is because the 396 HIRDLS profiles are in pairs: the zonal distance of the pairs is ~ 69 km and is ~ 139 397 km from one pair to the next for this measurement period (see Figure 1). The bump 398 at $\sim 3.6 \ (1000 \ \text{km})^{-1}$ is due to aliasing of zonal wavelengths longer than $\sim 139 \ \text{km}$. 399

For a set of zonal waves smaller than the Nyquist cutoff, the distribution of zonal 400 wavenumbers is expected be uniform. This is because the phase difference, $\Delta \phi_{i,i+1}$, 401 is random and uniformly distributed (Ern et al., 2004). Similarly, if adjacent profiles 402 have perturbations from different waves (or random fluctuations from noise), phase 403 differences will also be random and uniformly distributed. This is apparent in the 404 wavenumber distribution for noise (gray line, 7c). The distribution of zonal wavenum-405 ber with no amplitude cutoff applied (black dotted line) is quite uniform in distribution. 406 Some of this uniformity is removed when the amplitude cutoff is applied (solid black 407 line), especially at the smaller zonal wavenumbers. However, some uniformity is still 408 apparent as zonal wavenumber grows. This uniformity is most likely due to the alias-409 ing of waves below the Nyquist cutoff instead of noise. This is more apparent in the 410 distribution for the highest 10% of momentum fluxes (red solid line), which is quite 411 uniform. Furthermore, the distribution for the highest 10% of momentum fluxes is vir-412 tually unchanged when the amplitude cutoff is applied, suggesting that the uniformity 413 in this distribution is indeed due to aliasing of waves below the Nyquist cutoff. On 414 the other hand, the zonal wavenumber distribution for the lowest 10% of momentum 415 fluxes shows a very strong preference for small wavenumbers with no hints of unifor-416 mity in the distribution. It is also drastically impacted by including the amplitude 417 cutoff (difference between blue dotted and solid lines). All of this suggests that the 418 momentum flux estimates for the smallest fluxes are more accurate than for the largest 419 fluxes, and that the largest fluxes are underestimated (since zonal wavenumber, k is 420 in the numerator of Equation (5)). 421

422 4 Gravity Wave Potential Zonal Drag

In this section we present estimates of the zonal mean zonal GW drag estimated 423 by HIRDLS. We estimate this quantity with the vertical derivative of absolute mo-424 mentum flux, as shown in Equation 6. We call this the "potential drag" because it 425 is non-directional, and there is an undetermined amount of cancellation between east-426 ward and westward (positive and negative) GW drag. The uncertainties of this method 427 are discussed in more detail in Ern et al. (2011) and Alexander and Ortland (2010). 428 Although the drag we calculate is not a vector quantity, we can use the direction of 429 the wind and the dispersion relation to interpret the direction of the force on the zonal 430 mean flow. For example, the momentum fluxes above mountains are typically assumed 431 to be from GWs propagating westward against the zonal mean flow. 432

Figure 8 shows HIRDLS GW potential drag as a function of longitude and height, 433 averaged from May through November and 61°S and 63.4°S. Again, we emphasize that 434 the results are most reliable between 30-50 km. The peak potential drag occurs over 435 the Antarctic Peninsula and corresponds to the momentum flux peak in Figure 4, but 436 there is considerable variability in the strength of the peak. Although the peak locally 437 over the orographic region is around 4-5 times larger than over the nonorographic 438 regions, the contribution to the zonal mean is greater from nonorographic regions than 439 orographic regions because the area over nonorographic regions is so much larger. This 440 is apparent in Figure 9 which shows the zonal mean GW potential drag as a function 441 of time and altitude averaged between 61°S and 63.4°S for nonorographic (a-c) and 442

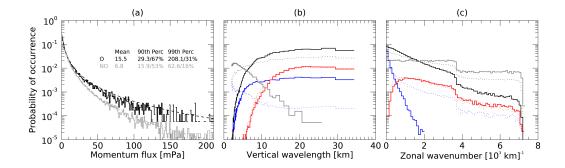

Figure 7. (a) Probability of occurrence of HIRDLS orographic and nonorographic GW absolute momentum fluxes. In (a) the mean momentum flux and 90th and 99th percentiles of the distributions are displayed (in mPa) along with the percentage of the total flux corresponding to fluxes larger than the 90th and 99th percentiles. (b) The black line shows the probability of occurrence of vertical wavelength for all events shown in (a). The blue line is the contribution of the smallest 10% of events and the red line is the contribution of the largest 10% of events. The gray line shows the result for noise (see text). (c) The black line shows the probability of occurrence of zonal wavenumber for all events in (a). Again the blue line is the contribution of the smallest 10 percent of events and the red line is the contribution of the largest 10 percent of events. The gray line shows the result for noise (see text). The dotted lines in (b) and (c) show the results when no amplitude cutoff is applied to our algorithm (i.e., no noise is removed). All quantities in these plots are at 20 km for May–Nov 2006.

orographic (d-f) regions. Again, note that we define the orographic region to be between 40° and 70° W.

The shape of the potential drag in Figure 9 roughly follows the shape of the zonal 445 mean zonal winds (which is more apparent in a-c), i.e., drag increases as zonal mean 446 zonal winds increase. However the short-term variability in the potential drag does not 447 appear to correspond to the short-term variability in the winds in the stratosphere. 448 Recall that Figure 6 showed that the short-term variability of the momentum flux 449 at least over the orographic region is highly correlated with the surface winds. As 450 in Figure 5 we point out that although it looks as though the potential drag over 451 the orographic region is more intermittent than over the nonorographic region, this is 452 because the nonorographic region is so much larger than the orographic region (330°) 453 versus 30°) that there are many more profiles in the nonorographic region and this 454 results in a smoother appearance. A 30° subsample over the nonorographic region 455 shows just as much intermittency (not shown). 456

457

4.1 HIRDLS GW potential drag and CCMI-1 zonal wave forcing

Figure 10 shows the zonal acceleration due to parameterized GW drag for 9 of 458 the models participating in the Chemistry-Climate Model Initiative (CCMI-1) (Eyring 459 et al., 2013; Hegglin et al., 2015). We included the CCMI-1 models that had zonal 460 acceleration due to paramaterized orographic and nonorographic GWs available in the 461 refC1 zonal mean files. While there are large differences in the magnitude of the zonal 462 GW drag, there is one conspicuous feature that is consistent in all the models: a gap 463 in the zonal forcing near 60°S. This is a result of the way that GW parameterizations are designed. In general, parameterized orographic GWs exert their influence on 465 the upper troposphere and lower stratosphere, whereas parameterized nonorographic 466 gravity waves are important only in the mesosphere (McLandress et al., 2013). This 467

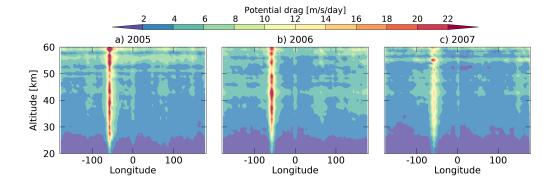

Figure 8. GW potential drag as a function of longitude and height, averaged from May through November for each year and 61° S and 63.4° S.

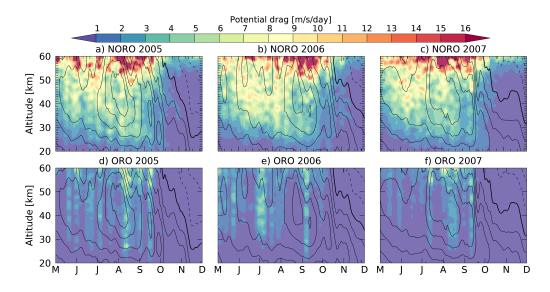

Figure 9. Zonal mean GW potential drag for nonorographic (a-c) and orographic (d-f) regions from May to November for 2005-2007 averaged from 61° S and 63.4° S. The zonal mean zonal wind from MERRA-2 is shown in the black contours with contour intervals of 10 ms⁻¹. Eastward and westward winds are shown with solid and dashed lines, respectively and the zero wind line is indicated by the thick contour line. The potential drag is smoothed with a 7-day boxcar average.

separation of the influence of orographic and nonorographic gravity waves is contrived via the choice of launch amplitudes of gravity waves in the parameterization; larger amplitude waves break lower in altitude. Furthermore, GW parameterizations are column-based, so that parameterized GWs only exert their forces in the column above the grid-cell in which they were launched. Since there is a gap in orographic sources near 60°S, there is a gap in the orographic GW forcing in the stratosphere (where the orographic GW parameterizations are designed to exert their influence).

Recent evidence, however, highlights several shortcomings in the current parameterization methods (see summary by Plougonven et al. (2020)). For example, current
parameterizations do not account for large-amplitude nonorographic gravity waves
that break in the lower stratosphere (e.g., Hertzog et al., 2008; Plougonven et al.,

2013; Wright et al., 2013; Jewtoukoff et al., 2015; Stephan et al., 2016) or lateral propagation of gravity waves generated at other latitudes (e.g., Sato et al., 2009; Yamashita et al., 2010; Sato et al., 2012; Hindley et al., 2015; Ehard et al., 2017; Krisch et al., 2017; Thurairajah et al., 2017; Strube et al., 2021).

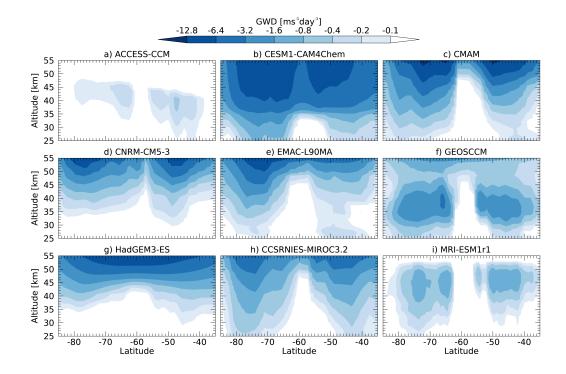

Figure 10. Zonal wind tendency due to parameterized GW drag for 9 of the CCMI-1 models averaged over JJA for 2005-2007.

Figure 11 shows HIRDLS zonal mean potential zonal drag (solid black) com-483 pared to zonal EP-flux divergence (blue), and parameterized zonal mean zonal GW 484 drag (red) from the CCMI-1 models averaged between 35 and 45 km. We emphasize 485 that this type of analysis with HIRDLS data is only possible at the narrow latitude 486 band between $61^{\circ}S$ and $63.4^{\circ}S$ and in this limited height range due to the HIRDLS 487 sampling pattern. For HIRDLS (black line) the contributions to the zonal mean po-488 tential zonal drag from waves over nonorographic regions and orographic (between 489 40° and 70° W) regions are shown with the dashed-dot and dashed line respectively. 490 Although the potential drag is larger locally over orographic regions (see Figure 8), 491 the nonorographic contribution to the zonal mean is larger because the nonorographic 492 region is much larger. HIRDLS potential drag peaks in June or July depending on 493 the year, whereas the CCMI-1 multi-model mean (MMM) resolved EP flux divergence 494 and parameterized GW drag peak in October. Furthermore, the magnitude of the EP 495 flux divergence and parameterized drag in the CCMI-1 MMM is less than the HIRDLS 496 zonal mean potential drag, although the HIRDLS potential drag has large unquantified 497 uncertainties. The HIRDLS results suggest that the CCMI-1 models are missing zonal 498 drag from May through September near 60° S and could explain some of the biases in 499 temperatures and winds and the offset in the timing of the breakdown of the polar 500 vortex in the models. Furthermore, the HIRDLS results suggest that the missing drag 501 near 60°S in Figure 10 is largely over nonorographic regions and support the case made 502 by Hertzog et al. (2008), Plougonven et al. (2013), and Jewtoukoff et al. (2015) that 503 the missing drag near 60° S is from nonorographic sources which, when summed over 504

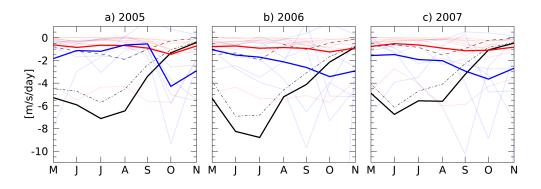

Figure 11. HIRDLS zonal mean potential zonal drag (solid black), CCMI-1 zonal EP flux divergence (blue), and CCMI-1 parameterized zonal mean zonal GW drag (orographic+nonorographic; red) averaged from 35–45 km and between 61°S and 63.4°S for (a) 2005, (b) 2006, and (c) 2007. The contribution to the HIRDLS zonal mean potential zonal drag from nonorographic regions is shown with the dashed-dot line and the contribution from orographic regions with the dashed line. The CCMI-1 multi-model means are shown in thick red and blue and the individual models are shown in the lighter red and blue.

the vast nonorographic areas, eclipse the very localized orographic sources. Because of the study design, these results do not address lateral propagation.

507 508

4.2 Discussion of implications for the Brewer-Dobson Circulation and ozone hole

Continuous measurements of ozone concentration and ozone hole size have been 509 recorded since 1979. Within the first decade after the discovery of the ozone hole, 510 Carslaw et al. (1998) found that mountain waves increased stratospheric ozone deple-511 tion in the Arctic and suggested that GWs occurring at the vortex edge should be 512 examined for their potential contribution to ozone depletion. The largest ozone hole 513 area in the 41 year record reached a maximum area of ~ 29.6 million square kilometers 514 and the polar cap ozone concentration reached a minimum of ~ 160 Dobson units in 515 September 2006. This was an extreme peak in ozone hole size that corresponds with 516 large momentum fluxes observed in HIRDLS GWs in September 2006. 517

Figure 12 shows the zonal mean zonal momentum flux time series for all three 518 consecutive years of HIRDLS data for the total (black), orographic (purple), and 519 nonorographic (blue) GWs. The orographic momentum fluxes are smaller in the zonal 520 mean, while the larger area for the the nonorographic (waves between $40^{\circ}E$ and $70^{\circ}W$) 521 gives a larger contribution to the zonal mean. The largest momentum flux occurs in 522 2006 and corresponds to a large peak in orographic momentum flux. Momentum fluxes 523 in 2006 are higher in general than the other years and the maximum momentum flux 524 for all years of data also occurs in September 2006. Higher gravity wave momentum 525 fluxes near 40 km could indicate deeper GW penetration and less dissipation and drag 526 above the ozone peak. Less drag would also contribute to generally colder temperatures 527 and potentially stronger ozone depletion. Figure 3 showed that average temperature 528 amplitudes were also higher for both orographic and nonorographic GW regions in 529 Sep-Nov 2006 than in the other years. Large gravity wave temperature amplitudes 530 are associated with formation of polar stratospheric clouds (e.g., Dörnbrack et al., 531 2002; Hoffmann et al., 2017) where heterogeneous chemistry leads to enhanced ozone 532 depletion. 533

We propose that the edge of the polar vortex and the magnitude of zonal mean momentum flux and temperature amplitudes in our HIRDLS results could be correlated through the symmetry of the ozone hole. The ozone hole/vortex was more symmetric in 2006 and the edge of the vortex coincided with the band near 60°S at most longitudes. The vortex edge is where maximum winds tend to focus wave propagation (Sato et al., 2012) leading to larger momentum fluxes and higher temperature variances in our analysis.

The observations suggest that GWs may be contributing much more to the total zonal forcing than the models suggest. It is also noteworthy that HIRDLS is more likely to observe longer vertical wavelengths in 2006 due to the stronger zonal mean zonal winds at our analysis latitudes. Longer vertical wavelengths suggests that there is greater potential for GWs to propagate higher. In addition, stronger zonal mean zonal winds will be associated with the symmetry of the ozone hole.

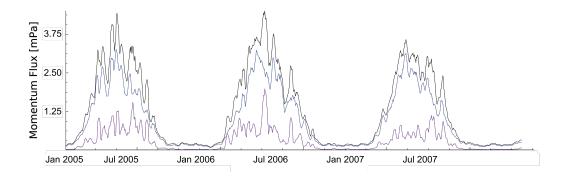

Figure 12. HIRDLS zonal mean zonal momentum flux averaged between 35 and 45 km. The total zonal mean flux is shown in black. Orographic (between 40° W to 70° W) and nonorographic GW contributions to the zonal mean momentum flux are shown in purple and blue, respectively.

547 5 Summary and Conclusion

In this study, we applied an S-transform analysis to HIRDLS profiles near the 548 turnaround latitude ($\sim 63.4^{\circ}$ S) to investigate the missing drag in CCMs in the South-549 ern Hemisphere winter. At the turnaround latitude HIRDLS provides dense zonal 550 sampling, making it an excellent tool for this analysis. While previous studies have 551 used HIRDLS to investigate the largest scale waves between wavenumbers 1 through 552 8 in the tropics (Alexander et al., 2010) and properties of GWs globally (Alexander et 553 al., 2008; Ern et al., 2011; Wright et al., 2010), this is the first study to focus on the 554 turnaround latitude in the Southern Hemisphere. 555

In general, HIRDLS observes the largest GW temperature amplitudes and zonal 556 momentum fluxes near the Antarctic Peninsula. The S-transform analysis also shows 557 that orographic GWs have shorter horizontal wavelengths and slightly longer vertical 558 wavelengths than nonorographic GWs. While fluxes are much larger locally over this 559 orographic region, the contribution to the zonal mean flux is roughly 3 times smaller 560 than the contribution over nonorographic regions simply because the nonorographic 561 region is so large. The zonal mean zonal momentum flux has a distinct seasonal 562 pattern, peaking in JJA, and is related to the overall shape of the zonal mean zonal 563 wind. However, short-term variability in the zonal mean zonal momentum flux does not 564 correspond to short-term variability in stratospheric zonal mean zonal wind. Instead, 565 we found that the zonal mean zonal momentum flux is highly correlated with the near 566 surface winds over orographic regions. 567

As shown in many previous studies, the distribution of GW momentum flux is ap-568 proximately lognormal. We showed that this is also true near the HIRDLS turnaround 569 latitude and that a considerable portion (67%) over the orographic region and 53% over 570 nonorographic region) of the total momentum flux near the turnaround latitude is due 571 to the largest 10% of events. We also found evidence that the tails of the momentum 572 flux distributions are actually much longer: the zonal wavenumber distributions sug-573 gest that a considerable amount of aliasing is occurring for small-scale waves. This 574 leads to an underestimate of the momentum flux. 575

576 We also provided estimates of the zonal drag and used these estimates to evaluate the parameterized GW drag and resolved wave forcing in models participating in phase 577 1 of CCMI-1. The HIRDLS zonal drag estimates suggest that the CCMI-1 models have 578 insufficient zonal drag, especially in JJA, and that the majority of the missing drag is 579 over nonorographic regions. Again we found that although the potential drag is larger 580 locally over orographic regions, the nonorographic contribution to the zonal mean is 581 larger because the nonorographic region is much larger. The HIRDLS results suggest 582 that the CCMI-1 models are missing zonal drag from May through September near 583 60° S and could explain some of the biases in temperatures and winds and the offset 584 in the timing of the breakdown of the polar vortex in the models. Furthermore, the 585 HIRDLS results suggest that the missing drag near 60° S in Figure 10 is largely over 586 nonorographic regions and support the case that the missing drag near 60° S is from 587 nonorographic sources. 588

There are several important limitations of this study to keep in mind. Because 589 of the study design these results do not address lateral propagation, which has been 590 shown to be significant in many studies. There are also large uncertainties associated 591 with the estimates of both momentum flux and potential drag. It is very difficult to 592 quantify these uncertainties. A major uncertainty in the estimate of potential drag is 593 the unknown cancellation between eastward and westward propagating waves. Con-594 sideration of HIRDLS vertical wavelengths and the MERRA-2 zonal mean zonal wind 595 profile makes a compelling argument for both eastward and westward nonorographic 596 wave dissipation below and above the jet maximum. In theory if all of the waves 597 were sufficiently sampled horizontally, it would be possible to determine the propaga-598 tion direction of the waves through the horizontal phase difference computed with the 599 S-transform. However, because many of the waves are undersampled, the horizontal 600 phase difference for those waves is random and the propagation direction cannot be 601 determined. However, even with these large uncertainties, the HIRDLS results still 602 provide compelling evidence that CCMs should include more nonorographic GW drag 603 near 60° S. 604
