November 24, 2022

#### Abstract

NTCM is a simple and relatively faster global climatological model that is developed, using ionospheric VTEC measurements from unevenly globally distributed GNSS receivers, to mitigate ionospheric effects on GNSS applications. As it is climatological, its ionospheric weather characteristic specification capability is limited. Also, its nowcasting and forecasting performance of the East-African equatorial ionosphere has not yet been tested. Therefore, this paper demonstrates techniques to change NTCM to ionospheric weather model to nowcast and forecast VTEC for East-Africa. NTCM has been changed to ionospheric weather model through adapting it to quiet days VTEC from nineteen GNSS receivers in East-Africa in 2013 and 2014. Adaptation has been done by calculating its driver, effective ionization level, when NTCM modeled VTEC fits the best with observed VTEC. Then, performances of the model in nowcasting and forecasting VTEC, before and after adaption, have been investigated compared to observed VTEC. It is found that NTCM, after adaptation, represents observed features of diurnal variations of VTEC and equatorial ionization anomaly (EIA) much better than before adaptation. After adaptation, the mean and standard deviation of daily mismodelings are found comparable with the mean and standard deviation of yearly mismodelings. It is demonstrated also that NTCM after adaptation to a reference station performs better than before adaptation at the stations nearby the reference station; however, its performance decreases at the locations far away from the reference station. In addition, after adaptation, one hour ahead prediction of NTCM is found to be the best compared to its longer hours prediction.

6 Abstract

7 NTCM is a simple and relatively faster global climatological model that is developed, using 8 ionospheric VTEC measurements from unevenly globally distributed GNSS receivers, to 9 mitigate ionospheric effects on GNSS applications. As it is climatological, its ionospheric 10 weather characteristic specification capability is limited. Also, its nowcasting and forecasting 11 performance in the East-African equatorial ionosphere has not yet been tested. Therefore, this 12 paper demonstrates techniques to change NTCM to ionospheric weather model to nowcast 13 and forecast VTEC for East-Africa. NTCM has been changed to ionospheric weather model 14 through adapting it to quiet days VTEC from nineteen GNSS receivers in East-Africa in 2013 15 and 2014. Adaptation has been done by calculating its driver, effective ionization level, when 16 NTCM modeled VTEC fits the best with observed VTEC. Then, performances of the model 17 in nowcasting and forecasting VTEC, before and after adaption, have been investigated 18 compared to observed VTEC. It is found that NTCM, after adaptation, represents observed 19 features of diurnal variations of VTEC and equatorial ionization anomaly (EIA) much better 20 than before adaptation. After adaptation, the mean and standard deviation of daily 21 mismodelings are found comparable with the mean and standard deviation of yearly 22 mismodelings. It is demonstrated also that NTCM after adaptation to a reference station 23 performs better than before adaptation at the stations nearby the reference station; however, 24 its performance decreases at the locations far away from the reference station. In addition, 25 after adaptation, one hour ahead prediction of NTCM is found to be the best compared to its 26 longer hours prediction.

27 Key words: data ingestion, NTCM-model, model performance.

28 Key points: 1) The diurnal performance of NTCM is found to be improved by data ingestion.

2) Spatial performance of NTCM has become better after adaptation.3) Model VTEC map30 run by Az reflects the observations such as EIA.

#### 33 Introduction

34 Ionosphere is the region of Earth's atmosphere which contains significant amount of free electrons and ions (Schunk and Nagey, 2009). The primarily source of the ions and free 35 electrons is photoionization of solar radiation. Ionosphere is approximately located in altitude 36 37 range between 50 kms and higher than 2000 kms above sea level. The level of significance of 38 number of ions and electrons found in the atmosphere is determined by the effect that the 39 atmosphere acts on the radio signals when it attempts to pass through (Davies, 1990, Zolesi. 40 et al., 2014). Ionosphere is mainly characterized by its electron density (Ne) or total electron 41 content (TEC) of a column of unit base area extended between the Global Positioning System 42 (GPS) satellite and receiver along the signal path. Ionosphere is taken as both resource and 43 setback for some of the modern technologies. In case of satellite based navigation, it degrades 44 performance by introducing extra delay (slowing down and bending propagation) and/or 45 scintillation of radio signals used by GPS. Error in GPS navigation caused by ionosphere is 46 the most significant (Tiwari et al., 2013, Davies, 1990). However, in radio communication, 47 radio signals are reflected by the bottom side of the ionosphere thus ionosphere helps radio 48 transmission over the horizon (Rawer, 1993).

49 After extensive studies for more than five decades, it is well known that the "climate" change 50 and "weather" disturbance of ionosphere are caused by processes extended from ionosphere-51 thermosphere system to mesosphere, solar, interplanetary and magnetosphere dynamics 52 (Schunk et al., 2004). The ionosphere characteristics depend on location, season, time of the 53 day, and solar activity level (Jakowski et al., 2011; Scherliess et al., 2008).

The ionosphere variability affects radio signal propagation adversely. However, it is possible to mitigate this effect if we specify and predict spatiotemporal dynamics of the ionosphere. This can be possible through developing a model that characterizes ionosphere. Empirical models such as International Reference Ionosphere (IRI) (Bilitza et al., 2018), NeQuick-2 (Nava et al., 2008), and Neustrelitz TEC model (NTCM) (Jakowski et al., 2011) have been developed to specify the climatological ionosphere behavior.

In specifying peak electron density, IRI and NeQuick models perform well, however they take longer time and lack accuracy in estimating TEC. Measuring their shape parameters is difficult, and inaccuracy of modeling the topside ionosphere and plasmasphere morphology results in crucial errors in estimating TEC (Jakowski et al., 2011). To calculate TEC, IRI and NeQuick models integrate Ne numerically along the line joining two points in space. However, NTCM model is another empirical model which estimates VTEC directly. It takes shorter time to compute TEC since it doesn't need to integrate Ne. NTCM works for all solar activity levels taking F10.7 as the main driving parameter and it uses only 12 model coefficients (Jakowski et al., 2011). These empirical models represent the monthly median value of the ionosphere Ne or TEC. They lack capability of reproducing the current ionosphere conditions (Bilitza et al., 2008; Nava et al., 2011; Jakowski et al., 2011).

71 In order to a model can capture short-time variations, we use either data assimilation or data 72 ingestion technique (Ercha et al., 2018; Nava et al., 2011; Brunini et al., 2011). In case of data 73 assimilation, we use measurements and optimization algorithms like Kalman filter to 74 determine the initial and boundary conditions of ionosphere physical models. Global 75 Assimilation Ionosphere models (GAIM), for example, used different sources of ionosphere 76 data like ground and space based GPS measurements, Ionosonde-derived electron density 77 profiles, UV airglow, in situ electron and neutral densities, plasma drift, neutral wind 78 measurements to create "weather" prediction model (Wang et al., 2004). Another example 79 of data assimilative model is Electron Density Assimilative Model (EDAM) (Angling and 80 Jackson-Booth, 2011). EDAM used different ionosphere data sources such as TEC-data taken 81 from both ground and space based GNSS receivers and electron density profiles obtained 82 from ionosondes, incoherent scattering radars, and in situ measurements in order to 83 effectively specify nearly real-time characteristics of the ionosphere with minimal errors in 84 both TEC and *fo*F2. However, due to its simplicity and less computation time, data ingestion 85 into empirical models attracts more of space weather communities (Ercha et al., 2018). Data 86 ingestion uses the application of simple minimization algorithms like least square to force a 87 parameterized empirical model to capture nearly the current behavior of the ionosphere. One 88 of the parameters of the model represents level of ionization which is known as effective 89 ionization level (Az). The purpose of data ingestion is to determine Az that minimizes the 90 deviation of the model from the observation.

Number of studies showed that data ingestion into NeQuick model has improved its performance. Nava et al. (2006) has applied data ingestion to NeQuick model using single and multiple GPS receivers and showed that in both cases near real-time ionosphere characteristics are retrieved. Moreover, the capability of TEC reconstruction in case of multiple stations is more remarkable than single station due to higher data density. Brunini et al. (2011) have applied data ingestion into NeQuick2 model and found that the model error could be reduced to 25-30% for slant TEC (STEC) and Ne. Olwendo et al. (2016) applied the

98 ingestion for NeQuick2 model using GPS data over the Kenyan regions and was able to show 99 that the difference between the measured and model TEC is minimized to the value of 0.5 100 TECU. Nigussie et al. (2012) also used data ingestion into NeQuick2 model using GPS data 101 over Easter Africa ionosphere and showed that the performance of the model after data 102 ingestion at a reference station is substantially improved for stations located up to 620 kms from the reference station. Ercha et al. (2018) used data ingestion for NeQuick2 model in 103 104 combination with Empirical Orthogonal Function (EOF) analysis and reached to a result 10-105 15% improvement of accuracy over the standard ionosphere correction algorithm in the 106 Galileo navigation system.

107 IRI and NeQuick models use smoothed monthly mean sun spot number  $(Rz_{12})$  or F10.7 108 which are related by (M. G. Deminov and G.F Deminova, 2018, Rec. ITU-R P.371-8)

109 
$$F_{12} = 63.7 + 0.78Rz_{12} + 8.9x10^{-4}Rz_{12}^2 , \qquad (1)$$

110 where  $F_{12}$  is monthly mean of F10.7.

111 Equation 1 implies that to get positive sun spot number, there is a constraint on values of 112 F10.7 flux that it has to be greater than 63.7 Solar Flux Unite (SFU) as recommended by 113 ITUR (1997). The mathematical function used in NTCM and IRI (NeQuick) are different and 114 hence it will have difference on application of data ingestion in these families of empirical 115 models. When we apply data ingestion into IRI and NeQuick models, the Az value might be 116 less than 63.7 SFU, as shown for example in Nigussie et al.(2016) against ITUR (ITU-R 117 P.371-8) recommendation, and that will be used in the models internally to compute negative 118 sunspot number which is unrealistic. This might be resolved when we apply data ingestion to 119 NTCM model, since the mathematical formulation for NTCM is different from IRI and 120 NeQuick2.

In this study, we focus on the investigation of NTCM model performance in the East African equatorial ionosphere by assisting it with GPS vertical TEC (VTEC) data applying ingestion technique. First GPS-VTEC data is ingested to the model to determine the optimal Az then the performance of the model in reconstructing VTEC using Az is tested. To test the spatial performance of adapted model, the Az computed at one particular (reference) station is used for different stations. Some statistical analysis is also made for the comparison of the mismodeling level in reproducing VTEC before and after ingestion.

128

#### 129 2. Data and the Analysis Method

#### 130 2.1 **Model**

NTCM model has been developed by Jakowski et al. (2011) at DLR Neustrelitz Germany. It 131 132 is an empirical model with few model coefficients (only 12). The model consists of five 133 major independent functions. The functions depend on location (latitude and longitude), time 134 (diurnal and seasonal) and solar activity. The solar activity is represented by the daily solar 135 flux index F10.7. The output of NTCM is VTEC of ionosphere of region of interest. The details and full mathematical expressions of the model are found in Jakowski et al. (2011). 136 137 NTCM model is simplified but it doesn't capture the real-time variation of VTEC. To use the model for weather variation, we have to adapt it to ionosphere sector of interest at a given 138 time (local time, day, month or season). 139

#### 140 2.2 **Data ingestion**

As NTCM is regarded a monotonic function of F10.7, it is assumed that NTCM is a local ionization driven model. The local ionization level that plays the role of effective solar flux index in estimating VTEC of the model at a given Ionosphere pierce point (IPP) and in an epoch of time is Az. As many literatures reviewed (Nigussie et al., 2012, Ercha et al., 2018, Nava et al., 2006), Az is determined by minimizing the root mean square error (RMSE) defined in equation 2.

147 RMSE(Az) = 
$$\sqrt{\frac{\sum_{i}^{N}(VTECm_{i}(Az) - VTECo_{i})^{2}}{N}}$$
, (2)

where,  $VTECm_i(Az)$  is the model VTEC computed as function of Az ,  $VTECo_i$  is measured VTEC, and N is the number of satellites visible in an epoch of time.

To determine Az, NTCM is driven by a range of F10.7 values then the one which minimizes equation (2) for each hour of measurements is chosen. The chosen values will be Az in the hours of the day. Then the model VTEC after data ingestion is calculated using Az whereas before ingestion VTEC is computed using daily average F10.7. To test the spatial performance of the model after adaptation, we run the model using Az computed at one (reference) station to other stations.

## 156 **2.3 Vertical TEC mapping Techniques**

157 NTCM has been also used to develop map of VTEC before and after data ingestion for East 158 African region. Nineteen GPS stations (see Table 1 for their coordinates) have been used to 159 develop VTEC maps after data ingestion. First Az values have been estimated at each IPP for 160 every hour using equation (2), then Az values in IPP plan is represented by the quadratic 161 function that varies in latitude and longitude. The polynomial used is formulated from linear 162 variation in longitude ( $\lambda$ ) and quadratic variation in latitude ( $\theta$ ), and it is expressed by

$$Az (\vartheta, \lambda) = a_0 + a_1 \vartheta + a_2 \lambda + a_3 \lambda \vartheta + a_4 \vartheta^2$$
(3)

where, the a's are coefficients of the polynomial and they are estimated from the Az values 164 165 applying the least-square fitting technique. Once the coefficients are estimated, equation (3) has been used to estimate the map of Az that has been used to drive NTCM to estimate the 166 167 map of VTEC after data ingestion. Similarly, equation (2) has been also fitted directly to 168 VTEC observation and then the equation has been used to estimate VTEC at any latitude and longitude to produce VTEC map. The corresponding map of VTEC before adaption has been 169 170 estimated by running NTCM in the same region using daily F10.7 values as model driver. 171 The performance of the model in estimating VTEC map before and after adaptation has been 172 compared with the VTEC maps estimated directly from the quadratic equation (3) and observed VTEC. 173

#### 174 **2.4 Data**

These days GPS data over African sector are easily accessible due to ground based receivers deployed in the continent. For example in Ethiopia there are numbers of GPS receiver stations (www.unavco.org). These opportunities have laid a good platform for studying the region's ionosphere dynamics. Using these data many global models are under investigation for their validity of performance (Nigussie et al., 2012; Nigusie et al., 2016; Tariku et al., 2015; Olwendo et al., 2016).

For this particular study, we chose nineteen sample sites in East Africa. The geographic and geomagnetic locations of the sites are shown in Table 1. We considered data of magnetic quiet time in the years 2014 and 2013 so the study is limited for quiet conditions. Days of year (DOYs) with Ap greater than 20 are excluded. The reason taken to choose the sites is 185 availability of relatively full data for the four seasons of the year (Jun solstice, September

186 equinox, December solstice and March equinox).

		Geographic		Geomagnetic		Dip –latitude

187 Table 1: geographic and geomagnetic location of the GPS stations

188

The GPS RINEX data taken from UNAVCO website have been calibrated according to the techniques discussed in Ciraolo et al. (2007). The VTEC has been computed from calibrated STEC using the mapping function described in *Mannucci et* al. (1998). VTEC data of elevation angle less than 20° were not included in order to reduce multipath effects. 193 The performances of the model (before and after ingestion) are determined by taking the 194 difference of observed and modeled VTECs. Mis-modeling of the model is defined to be the 195 difference between the measured and modeled value of ionosphere parameter at a location 196 and in an epoch where data was taken. The level of mis-modeling determines the 197 performance of the model. If the mis-modeling is high the performance of the model is low. 198 If the mis-modeling is low the performance of the model becomes high. So to evaluate the 199 effectiveness of the method we make a comparison of the model performance before and 200 after data ingestion into the model.

## 201 **3. Results and discussion**

## **3.1 Day -to -day variation of performance of NTCM**

Panels (a-d) of Figure 1 show the diurnal variations of observed (\*red) and modeled VTEC 203 204 before (black) and after (blue) adaptation at Ambo station for the DOYs 79, 171, 263 and, 205 355 in the year 2014. As we can see from the graphs, the model (before and after adaptation) 206 generally captures the pattern of diurnal variation of observed VTEC throughout hours of the 207 days. However, the model before adaptation reproduces observation VTEC for only small 208 portion of the hours of the days. For larger portion of hours of the days, it generally 209 overestimates VTEC as compared to the observation. For example, panel 'a' (DOY 79), 210 Panel 'b' (DOY 171) and panel 'c' (DOY 263) show that the model before adaptation 211 captures observed VTEC from about 5 to 10 UTCs and for the rest hours of the days it 212 overestimates. As shown in panel 'd' (DOY 355), the model before adaptation reproduces the observed VTEC approximately from about 5 to 8 UTCs. However, after adaptation the 213 214 capability of the model to capture diurnal variations of VTEC is greatly improved. It retrieves 215 the observation VTEC for almost all hours of the days considered.

216 The frequency distribution of mismodeling after and before adaptation for Ambo station is 217 depicted in the middle and right panels of Figure 1, respectively. Each row panel depicts for different DOYs. The means ( $\mu$ ) and standard deviations ( $\delta$ ) are also included in the 218 219 corresponding panels. The means of mismodeling before data ingestion in general are larger 220 than their corresponding means of mismodeling after data ingestion. As seen from Figure 1, 221 the mean before adaptation ranges from -5 to -26 TECU. However, the means after ingestion 222 are from -0.030 to 0.04 TECU. The negative sign of means indicates that the model averagely 223 overestimated the observation. The standard deviations of mismodeling after ingestion have

also decreased as compare to their values before ingestion. The standard deviations after
ingestion for the DOY 79,171,263 and 355 are 3.92, 1.56, 3.51 and 3.91 TECU, respectively.
The corresponding mismodeling standard deviations before adaptation are 14.54, 5.29, 11.23
and 17.85 TECU.

Figure 2 shows the same results as in Figure 1 but for Bahir Dar Station. Panels (a-d) in 228 229 Figure 2 present the graphs of the modeled VTEC before (black) & after (blue) adaptation, 230 and the observed (\*red) VTEC versus hours of the selected days. Before adaptation, the 231 capability of the model in retrieving VTEC seems poor. It only captures the trend of diurnal 232 variation. However after adaptation, its capability is improved. In Figure 2, it is seen that the 233 model (after adaptation) VTEC is more approximated to the observation VTEC. The middle 234 and the right panels of Figure 2 present the frequency distributions of mismodeling before 235 and after ingestion, respectively. The means and standard deviations of the mismodeling are 236 included in the corresponding histograms of the distributions. Generally the means of 237 mismodeling after adaptation are lower than that of before adaptation.

The mean after adaptation ranges from -0.02 to 0.02 TECU but it ranges from -5.66 to -21.42 TECU before adaptation. The standard deviations of mismodeling after adaptation are significantly decreased as compared to their corresponding values before ingestion. The range of standard deviations after adaptation is 1.57 to 5.78 TECU. But the standard deviation before adaptation varies from 5.11 to15.83 TECU. The reduction of means and standard deviations of mismodeling after adaptation indicates that the technique of ingestion has assisted the model to retrieve the observation better.

245 The same data ingestion technique has been applied for GPS data taken from Addis Ababa 246 (Ethiopia), Malindi (Kenya), Mbarara (Uganda) and Asab (Eretria) stations. Figure 3-6 show 247 results for these stations, respectively. Panels (a-b) in these figures indicate that the modeled 248 VTEC after adaptation are in better agreement to experimental than the modeled VTEC 249 before adaptation. The frequency distribution of mismodeling after ingestion is almost 250 symmetric about 0 TECU. But in case of model before adaptation, the frequency distributions 251 of the mismodeling are not as such much Gaussian. The means and standard deviations 252 presented in Figure 3-6 panels (middle after adaptation and right before adaptation) quantify 253 the performance of the model. The means and standard deviations of mismodeling have been 254 significantly reduced by data ingestion as compared to their values of standard model. The 255 model before adaptation, in all the mentioned stations averagely overestimated the 256 experimental VTEC.

257 In order to complement the results shown in Figures 1-6, we applied data ingestion for quiet 258 354 days in 2014 at Ambo station. Figure 7 presents frequency distribution of mismodelings before and after adaptation. As seen from the plots, the mean value before adaptation is -259 260 6.71 TECU but it is approximated to 0.01 TECU after adaptation. On average the model 261 before adaptation overestimated the experimental values. The standard deviation is decreased 262 from 14.56 to 3.34 TECU due to ingestion. In addition, the frequency distribution becomes more symmetric to 0 TECU after adaptation than before adaptation. In general, yearly mean 263 264 and standard deviation of the mismodeling shown in Figure 7 are similar to the daily mean 265 and standard deviations shown in the Figures 1-6. Therefore, the results shown above indicate 266 that data ingestion assists NTCM model to capture the daily variability of VTEC.

## **3.2 Spatial Performance of NTCM after and before**

#### 268 adaptation

269 To validate spatial performance of NTCM model after ingestion, we first ingested VTEC at 270 Addis Ababa (reference) station to compute Az's. Then we tested its performance at stations 271 Ambo, Bahir Dar, Assab and Nazret. The diurnal variations of both modeled and observed 272 VTEC and mismodelings after and before ingestions for these stations respectively are shown 273 in Figures 8, 9, 10, 11 for the DOY 79,171,263, and 355 in the year 2014. Figures 8-11, (a-b) 274 panels present the diurnal variation observed (red) and modeled VTEC,- after (blue) and 275 before (black) ingestion. The trends of retrieving the observed VTEC before and after 276 adaptation are similar to results discussed in section 3.1. The modeled VTEC after adaptation 277 is in better agreement with the observed VTEC than before adaptation. In the above 278 mentioned figures, the mismodeling frequency distributions (the middle panels are after, and 279 right are before adaptation) are included with their corresponding means and standard 280 deviations. As seen, the means and standard deviations after adaptation have significantly 281 decreased as compared to the corresponding values before adaptation. For example, the mean 282 of mismodeling after adaptation for DOY 79 at Ambo is -5.79 TECU, whereas before 283 adaptation, it is -20.29 TECU, and the standard deviation after adaptation is 5.07 TECU and 284 before adaptation is 14.54 TECU. Similar improvement in the performance of NTCM has 285 been observed at the other stations using Az from reference station as NTCM driver (see

Figures 9, 10, and 11). These indicate that NTCM adapted to a reference station performs better at other nearby stations compared to its performance before adaptation. However, the spatial performance decreases as the distance between a station and a reference (Addis Ababa) increases. The air distances between Addis Ababa, and Bahir Dar, Nazret, Ambo and Assab are around 324, 79, 98, and 620 km, respectively. For example, the performance of the model at Nazerte (nearest) station (see Figure 11) is by far better than at Assab (farthest) station (see Figure 10).

## **3.3 Prediction capability of NTCM after adaptation**

294 For operational application, a model performance ahead of time is very essential. As a test 295 study, 1hr, 2hrs, 3hrs and 4hrs prediction capability of NTCM have been investigated. For 296 example, Az obtained at previous hour has been used to drive NTCM to predict VTEC at the 297 present hour; and the comparison between predicted and observed VTEC at the present hour 298 indicates one hour ahead prediction capability of the model. Figure 12 shows the diurnal 299 variation of measured, modeled (before & after ingestion) and predicted VTEC at Ambo 300 station for DOY 355 in 2014. As seen in the figure, the prediction capability of the model 301 decreases, as the length duration of computing Az increases. The gap between the predicted 302 VTEC and measured VTEC for 1hr ahead prediction is small as compared to for 4hrs ahead prediction. So the performance of the model gets weaker when the prediction time is 303 304 elongated.

## 305 3.4 Vertical TEC map after and before adapting NTCM

Data taken from 19 stations on DOY 110 in the year 2013 have been used to develop VTEC 306 307 maps. NTCM modeled VTEC maps before and after adaptation have been developed by 308 driving the model using F10.7 and Az maps, respectively. Also, VTEC maps have been 309 developed by representing observed VTEC using quadratic polynomial function. Samples maps were developed on DOY 110 in 2013 at 2, 4, 6,8,10,12,14,16 and 18 UTCs. Figures 13 310 and 14 show the scatter (left column) and contour map  $(2^{nd}, 3^{rd} \text{ and } 4^{th} \text{ column from the left})$ 311 plots of observed and modeled VTEC, respectively. Each row panels, from top to bottom, in 312 313 these figures respectively indicates the observed and the map VTEC for 2, 4, 6,8,10,12,14,16 and 18 UTCs. The 2<sup>nd</sup>, 3<sup>rd</sup>, and 4<sup>th</sup> columns, from the left, in these figures show the VTEC 314 315 maps obtained from quadratic polynomial, NTCM driven by Az maps and daily F10.7, respectively. As seen in both figures, spatial variations of observed VTEC (left panels) are 316

317 similar with the spatial variations of VTEC maps obtained from polynomial and NTCM 318 driven by Az maps compared to VTEC maps of NTCM driven by F10.7. More importantly, 319 the equatorial ionization anomaly (EIA) shown by observations are captured by the VTEC 320 maps obtained by polynomial fit and NTCM after adaptation; whereas the NTCM map of 321 VTEC before adaptation (right column) portrayed smooth latitude variations of VTEC that 322 don't agree with observations. These plots also show that polynomial fit and NTCM driven 323 by Az map captures the diurnal variation of VTEC maps much better than the NTCM model 324 driven its standard input (F10.7). Therefore, the model VTEC after adaptation is in good 325 agreement with the experimental VTEC as compared to model VTEC before adaptation. This 326 means that the local ionization level, Az drives NTCM model by far better than the solar flux, 327 F10.7.

#### 328 Conclusion

329 Data ingestion into NTCM model has been carried out to validate the performance of the 330 model in estimating VTEC of the East-African Ionosphere sector. This has been done by 331 determining the optimum value of the input effective ionization level Az and by running the 332 model using Az. We found that data ingestion into NTCM enables it to estimate diurnal 333 observed TEC in a better way than it estimates before ingestion. The model driven by Az's of 334 a reference station, in regions around it, estimates the observed VTEC better than the model 335 driven by F10.7. After adaptation the mismodeling means and standard deviations have 336 significantly decreased in comparison to the mismodeling means and standard deviations 337 before adaptation. This reduction of means and standard deviations quantifies the 338 improvement of the performance of the model after ingestion. The model driven by Az 339 computed at 1hr ahead can estimate the measured VTEC better than it is driven by Az 340 computed at 4 hrs ahead. Moreover, NTCM VTEC maps reproduced from updated Az maps 341 by polynomial fitting reflect the VTEC maps developed by polynomial fitting of the observed 342 VTEC including the EIA which are not seen by the NTCM VTEC maps using the standard 343 input F10.7. These findings suggest that the proposed ingestion technique can bring a 344 performance improvement to NTCM model and it is effective to progress from climatology 345 model to a model that describes the near-real-time weather conditions of the ionosphere.

Acknowledgments: The authors would like to thank the UNAVCO Consortium for GPS data
freely available at <u>https://www.unavco.org/</u> and NASA for F10.7 data available at
<u>https://omniweb.gsfc.nasa.gov/form/dx1.html</u>. The work has been partially supported by Air

Force Office of Scientific Research and Air Force Office of Material Command USAF
under Award FA9550-16-1-0070. The authors are also grateful to Norbert Jakowiski and
Mainul Hoque for the code of the NTCM model we used.
