Abstract

Extraction of sulfides from the partially molten mantle is vital to elucidate the cycling of metal and sulfur elements between different geochemical circles but has not been investigated systematically. Using laboratory experiments and theoretical calculations, this study documents systematical variations in lithologies and compositions of silicate minerals and melts, which are approximately consistent with the results of the thermodynamically-constrained model. During a melt-peridotite reaction, the dissolution of olivine and precipitation of new orthopyroxene generate an orthopyroxene-rich layer between the melt source and peridotite. With increasing reaction degree, more melt is infiltrated into and reacts with upper peridotite, which potentially enhances the concomitant upward transport of dense sulfide droplets. Theoretical analyses suggest an energetically focused melt flow with a high velocity (~ 170.9 µm/h) around sulfide droplets through the pore throat. In this energic melt flow, we, for the first time, observed the mechanical coalescence of sulfide droplets, and the associated drag force was likely driving upward entrainment of fine µm-scale sulfide. For coarse sulfide droplets whose sizes are larger than the pore throat in the peridotite, their entrainment through narrow constrictions in crystal framework seems to be physically possible only when high-degree melt-peridotite reaction drives high porosity of peridotite and channelized melt flows with extremely high velocity. Hence, the melt-rock reaction could drive and enhance upward entrainment of μμ- το μμ-σςαλε sulfide in the partially molten mantle, potentially contributing to the fertilization of the sub-continental lithospheric mantle and the endowment of metal-bearing sulfide for the formation of magmatic sulfide deposits.

40   **Text S1.** The methodology for the measurement of grain sizes of olivine and clinopyroxene

41   In this study, grain sizes of olivine and clinopyroxene in the partially molten peridotite were

42   measured by mapping analyses of electron backscattered diffraction (EBSD) using a Quanta 450

43   FE-SEM equipped with an HKL Nordlys EBSD detector at the State Key Laboratory of

44   Geological Processes and Mineral Resources (GPMR) of China University of Geosciences.

45   Measurements were performed under the conditions of an accelerating voltage of ~ 20 kV, ~ 0.8

46   μm step size, a beam current of ~ 6 nA, a tilt angle of ~ 70°, and about ~ 20-25 mm working

47   distance. The smallest detectable grain size was about ~ 4 μm. EBSD patterns of different crystal

48   minerals are determined by the orientations of the grains being examined. By scanning the beam

49   in a grid pattern, a map of the grain orientations can be produced. When a discontinuous change

50   in the orientation occurs, this indicates that a grain boundary has been crossed. The

51   misorientations of greater than 15° were recorded as being distinct grains. Then, orientation maps

52   of different crystal minerals can be built using the commercially available software channel5[©] to

53   obtain grain sizes of different minerals.

54   **Text S2.** The methodology for the measurement of water content in silicate melt using Fourier

55   transform infrared spectroscopy (FTIR)

56   We used the FTIR to determine the water content of silicate melt in experiments PC520 and

57   PC528 at the State Key Laboratory of Geological Processes and Mineral Resources (GPMR) of

58   China University of Geosciences. Before the FTIR measurements, the samples were double

59   polished to a thickness of 100 μm and kept in a vacuum stove at 400 K for at least 12h to

60   preclude the grain boundary water in samples. The water content can be calculated by using the

61   Beer-Lambert law:

62 $C_H = \dfrac{A \times 18.0152}{d \times \rho \times \varepsilon}$,   (1)

63   where C_H is the total H_2O content (wt.%), A is the measured absorbance of the peak at 3550 cm^{-1},

64   after linear baseline correction (≤1), d is the sample thickness (cm); ρ is the density (g L^{-1}) of

65   silicate melt, ε is the molar absorptivity (62.8 ± 0.8 L mol^{-1} cm^{-1}) (Mercier et al., 2010).

12 **Key Points:**

13 • Systematical variations are produced by the melt-rock reaction in lithologies and

14 compositions of silicate melt and minerals

15 • Melt-rock reaction is conducive to the upward transport of sulfide droplets in a crystal

16 framework based on experimental observation

17 • Focused melt flow with high velocity can drive upward extrusion and entrainment of μm-

18 to mm-scale sulfides through narrow melt tubes

19

20 **Abstract**

21 Extraction of sulfides from the partially molten mantle is vital to elucidate the cycling of metal

22 and sulfur elements between different geochemical circles but has not been investigated

23 systematically. Using laboratory experiments and theoretical calculations, this study documents

24 systematical variations in lithologies and compositions of silicate minerals and melts, which are

25 approximately consistent with the results of the thermodynamically-constrained model. During a

26 melt-peridotite reaction, the dissolution of olivine and precipitation of new orthopyroxene

27 generate an orthopyroxene-rich layer between the melt source and peridotite. With increasing

28 reaction degree, more melt is infiltrated into and reacts with upper peridotite, which potentially

29 enhances the concomitant upward transport of dense sulfide droplets. Theoretical analyses

30 suggest an energetically focused melt flow with a high velocity (~ 170.9 μm/h) around sulfide

31 droplets through the pore throat. In this energic melt flow, we, for the first time, observed the

32 mechanical coalescence of sulfide droplets, and the associated drag force was likely driving

33 upward entrainment of fine μm-scale sulfide. For coarse sulfide droplets whose sizes are larger

34 than the pore throat in the peridotite, their entrainment through narrow constrictions in crystal

35 framework seems to be physically possible only when high-degree melt-peridotite reaction

36 drives high porosity of peridotite and channelized melt flows with extremely high velocity.

37 Hence, the melt-rock reaction could drive and enhance upward entrainment of μm- to mm-scale

38 sulfide in the partially molten mantle, potentially contributing to the fertilization of the sub-

39 continental lithospheric mantle and the endowment of metal-bearing sulfide for the formation of

40 magmatic sulfide deposits.

41 **Plain Language Summary**

42 Sulfides are a pivotal potential reservoir for sulfur and economically important metals. Their

43 transport in the Earth's mantle plays a vital role in understanding many crucial geological and

44 environmental processes, especially the formation of mineral deposits, and the environmental

45 damage and health hazards related to volcanic eruptions. This work proposes a new driving force

46 for the upward transport of dense sulfide drops in the upper mantle that experiences partial

47 melting. The reaction between melt and rock potentially leads to focused melt flow in new-

48 forming channels with three orders of magnitude higher velocity than that of melt flowing among

49 the crystal framework of peridotite. This energetic melt flow drives the upward transport of tiny

50 μm-scale sulfide droplets in peridotite and may also facilitate the amalgamation of droplets

51 contacting each other. Coarse sulfide droplets could be possibly entrained upward through

52 narrow pore throats, especially when a high-degree melt-peridotite reaction drives fast-flowing

53 melt in the mantle with high porosity.

1 Introduction

55 Sulfide is a ubiquitous phase in the mantle (Alard et al., 2011) and an important

56 repository for sulfur and geochemically and economically important chalcophile metals, which

57 plays a pivotal role in the partitioning behaviors of PGE, Cu, and Ni (Mungall & Brenan, 2014;

58 Patten et al., 2013). Understanding the factors that control the fate of sulfide phases in the

59 partially molten mantle is of fundamental importance in exploring the recycling of sulfur and

60 chalcophile elements among different geochemical reservoirs (Ding & Dasgupta, 2017; Farquhar

61 et al., 2002; Yao et al., 2018; Chen et al., 2022) and identifying the re-fertilization of the

62 depleted lithospheric mantle, which potentially provides the metal endowment for the formation

63 of Cu-rich porphyry and/or Ni-rich magmatic ore system (Holwell et al., 2022; Lee & Tang,

64 2020; Mungall et al., 2015; Zhao et al., 2022). However, it remains highly contentious for the

65 driving forces of the transport of metal-bearing sulfide liquid, which severely blocks our

66 understanding of the details of fertilization processes that occurred in the sources of sulfide-

67 related magmatic and hydrothermal deposits.

68 Conventionally, the removal of sulfide from a partially molten peridotite requires

69 progressive dissolution of sulfide into the departing silicate melt (Holzheid & Grove, 2002;

70 Mungall & Brenan, 2014; Yao et al., 2018). Nevertheless, the mechanical entrainment of sulfide

71 could also potentially be an efficient process driving the redistribution and local enrichment of

72 sulfur and chalcophile elements in the mantle (Iacono-Marziano et al., 2022; Heinrich &

73 Connolly, 2022; Z. Wang et al., 2020; Yao & Mungall, 2020). Although a small amount (<

74 percolation thresholds) of sulfide under hydrostatic conditions may not be entrained through the

75 slow porous flow of silicate melt due to high surface tension (Bagdassarov et al., 2009; Holzheid

76 et al., 2000; Yoshino et al., 2003, 2004), it has been argued that the extraction of sulfide driven

77 by stress in a partially molten peridotite could be further facilitated by the directional porous

78 flow of silicate melt, strongly affecting the fractionation and abundances of chalcophile metals in

79 the mantle melting products, *i.e.*, basalts (Ballhaus et al., 2006; Bockrath et al., 2004; Z. Wang et

80   al., 2020). Except for the deviatoric stress, a preliminary experimental study (Wang & Jin, 2020)

81   proposed that during the melt-rock reaction, entrainment of sulfide liquid may be enhanced by

82   the reaction infiltration instability (RII) in the partially molten peridotite when a reacting melt

83   percolates through a dissolvable, porous, melt-mineral mixture. The mechanical transport and

84   enrichment of sulfide during this melt-rock reaction have been extensively demonstrated in

85   mantle   peridotites,   which   has   clarified   some   geochemical   paradoxes   of   the

86   chalcophile/siderophile elements (Ciazela et al., 2018; Lorand & Luguet, 2016). The RII theory

87   proposed by Chadam et al. (1986) also applies to magmatic systems by introducing compaction

88   of crystal mush and driving a solubility gradient along the flow direction instead of the

89   propagating reaction front (Aharonov, 1995), resulting in positive feedback among the increasing

90   permeability driven by melt-rock reaction and the associated reinforcement of melt flux in

91   reacting regions. This melt-rock reaction is well known as a pervasive process even forming

92   melt-rich channels with an extremely speedy magma flow due to the positive feedback in

93   partially molten regions of the mantle, which has been broadly demonstrated by geological

94   investigations (*e.g.*, Kelemen et al., 1995; Sundberg et al., 2010), high-temperature, high-

95   pressure (HTHP) laboratory works (*e.g.*, Daines & Kohlstedt, 1994; Pec et al., 2015) and

96   theoretical analyses (Aharonov, 1995; Chadam et al., 1986; Spiegelman et al., 2001). During a

97   reaction of melt with a depleted mantle, melt re-fertilization processes potentially occur, thereby

98   impregnating the mantle with sulfides, which have been widely found in mantle xenoliths,

99   orogenic and abyssal peridotites (*e.g.*, Ciazela et al., 2018; Luguet et al., 2003; Niu, 2004; Wang

100   et al., 2009).

101   Although it has been tentatively demonstrated that the rapid enough ascending magma

102   flow in these melt-rich channels could hold upward entrainment of large olivine phenocrysts or

103   even dense sulfide droplets during a melt-rock reaction (Pec et al., 2017; Wang & Jin, 2020),

104   extraction of sulfide driven by the RII has received little attention, and the precise physical and

105   chemical constraints about these processes appear to be worth studying thoroughly. Here we

106   conducted systematically two-layer reaction experimental studies in which a partially molten

107   peridotite was placed on a sulfide-bearing silicate melt source to explore the entrainment of

108   sulfide liquids driven by the RII and trace the physical and chemical variations of liquid and

109   solid phases during these processes, which sheds lights on the fertilization of lithospheric mantle,

110   as well as the formations of magmatic and/or hydrothermal sulfide deposits.

111 **2 Experimental Methods**

112   2.1 Starting materials

113   As a melt source, the starting materials were a mixture of the powdered calc-alkaline

114 tholeiitic basalt (70 wt.%) from the East Pacific Rise (102.7044 °W, 2.64961 °S), olivine crystals

115 (20 wt.%) from fresh spinel lherzolite xenoliths at Damaping (Hannuoba region, North China),

116 and sulfide aggregates (10 wt.%) from Jinchuan Ni-Cu sulfide deposit, NW China. Additionally,

117 0 or 2 wt.% oceanic sediments (mainly carbonate) were mixed into the melt source. The sulfide

118 aggregate (59 wt.% pyrrhotite, 36 wt.% pentlandite, and 5 wt.% chalcopyrite) adopted here is

119 similar to that in massif peridotites (Lorand et al., 2010), and was grounded in alcohol for about

120 6h to < 10 μm measured by using the scanning electron microscope (SEM).

121   To prepare a partially molten rock, the olivine and clinopyroxene crystals from

122 Damaping spinel lherzolite xenoliths were mixed in a 50:50 ratio by weight. Then, ~ 0 or ~ 5

123 wt.% calc-alkaline tholeiitic basalt was added to change the initial porosity of the crystal

124 framework. All silicate mineral grains were ground to about 10-20 μm grain size in an agate

125 mortar. The partially molten rock was placed on the melt source to explore the possible upward

126 transport of dense sulfides from the melt source to the peridotite. The length ratio of these two

127 parts was slightly larger than ~ 1:1 to avoid chemical equilibration among them over the

128 experimental time scales. Compositions of these starting materials were described by Z. Wang et

129 al. (2020) (Table S3), and Table 1 lists the experimental conditions.

130   2.2 Experimental methods and analytical techniques

131   The two-layer reaction experiments were conducted via a 150 Ton non-end-loaded type

132 piston-cylinder press at China University of Geosciences. Starting materials mentioned above are

133 loaded into a cylindrical platinum (Pt) capsule (3.75 mm diameter; 5-6 mm high) with a graphite

134 inner sleeve (Figure 1-inset in the lower left). Due to the graphite inner sleeve, the oxygen

135 fugacity of this experimental system was maintained at about CCO-0.8 (the graphite-CO_2

136 buffer), which corresponds to a log fO_2 < FMQ-2 log unit at ~ 1,360 °C and 1.5 GPa (*e.g.*,

137 Médard et al., 2008). Information on experimental assembly can be found in our previous work

138 (Z. Wang et al. 2020). In order to remove absorbed water, a 12-hour heating (120 °C) in a

139 vacuum oven is conducted for all capsules before being sealed, and we did not observe any

140 apparent sulfur loss during this drying. The experiment conditions in Table 1 should be held for
141 12-72 h, and then these materials were quenched to room temperature.

142   Polished sections were prepared from the recovered experimental specimens cut parallel
143 to the specimen axis. The observation of microstructure in these sections was conducted via a
144 Quanta 450 field-emission scanning electron microscope (FE-SEM) at China University of
145 Geosciences, with a 6.0 μm spot size, 20 kV accelerating voltage, and 12 mm working distance.
146 The backscattered electron (BSE) images were adopted to measure the morphological
147 characteristics of experimental products, such as the dissolution distance, the thickness of
148 reactive boundary layers, and the size of sulfide droplets. Quantitative compositional analyses for
149 olivine and clinopyroxene were obtained via a JEOL JXA-8230 electron probe microanalyzer
150 with four wavelength-dispersive spectrometers (WDS) at China University of Geosciences, with
151 an accelerating voltage of 15 kV, a probe current of 20 nA and a beam diameter of 1 μm.
152 Sulfides were analyzed with a higher accelerating voltage (20 kV), and the compositions of
153 quenched silicate melts were measured with a smaller probe current (10 nA). A defocused beam
154 of 20-30 μm diameter was adopted here for all the standardizations, quenched melts, and
155 sulfides. Dwell times were 10s on element peaks and half that on background locations adjacent
156 to peaks. Raw X-ray intensities were corrected using a ZAF (atomic number, absorption,
157 fluorescence) correction procedure. A series of natural and synthetic SPI standards were utilized
158 and changed based on the analyzing minerals. The following standards were used: sanidine (for
159 K), pyrope garnet (for Al), almandine garnet (for Fe), diopside (for Ca, Si, Mg), jadeite (for Na),
160 rhodonite (for Mn), olivine (for Si, Mg), rutile (for Ti), apatite (for P), chromium oxide (for Cr).
161 The analytical standards for sulfides were pentlandite (for Fe, Ni, S) and native copper (for Cu)
162 (Pan et al., 2023).

163 **3 Results**

164   In order to investigate the physical migration of sulfide during reaction infiltration of
165 silicate melt in the partially molten mantle, we have conducted eight reaction experiments at 0.5-
166 1.5 GPa, 800-1,300 °C, and 12-72 h (Table 1). Generally, several distinct lithological regions
167 were developed and, from bottom to top, respectively separated by a diffuse-dominated,
168 mineralogical interface in these two-layer reaction experiments (Figure 1; Figures S2-S8). The

169   freeware ImageJ (http://imagej.nih.gov/ij/) from the National Institute of Health was adopted to

170   analyze all two-dimensional BSE images obtained here.

171   3.1 Phase assemblages and textures

172   Under the low-temperature, high-pressure conditions (800 °C and 1.5 GPa), both

173   minerals and sulfides were generally polygonal and not molten, and sulfide droplets in the lower

174   part of the sample were uniformly distributed in pores among silicate grains. At 1.5 GPa, when

175   the experimental temperatures exceed ~1,250 °C, the basaltic material was completely molten,

176   and the diameter of sulfide droplets ranges from several μm to > 100 μm (Figure 1).

177   Gravitational segregation of sulfide was insignificantly observed in all sections, but obviously,

178   some huge sulfide droplets were attached to the wall of the graphite capsule, especially at high

179   temperature and long experiment durations (Figure 1). These coarse droplets were excluded from

180   the collected data to calculate the average sulfide size. Tiny exsolution lamellae with higher

181   backscattered electron (BSE) intensity were occasionally observed in some quenched large

182   sulfide droplets. Sometimes silicate melts were pooled at the edge of the sample (Figure 1).

183   In all high-pressure experiments (1.5 GPa), an orthopyroxene (Opx)-rich reaction layer

184   (ORL) was formed at the boundary of the lower melt source and upper partially molten peridotite

185   due to the reaction between them, and chiefly composed of Opx grains, silicate melt, and sulfide

186   droplets (Figure 1). With increasing the annealing time and/or run temperature, the morphology

187   of ORLs became more irregular (Figure 1b; Figures 2a, b, and d), and small olivine inclusions

188   were observed in a few large Opx grains (Figure 2a). The ORL at 1,300°C was even ruptured

189   mainly due to the growth of several Opx grains to enormous size (> 100 μm) and possible

190   gravitational settling (Figure 2d). We also observed the bulge of ORL toward the melt source

191   (Figure 1b), which can be attributed to the slight gravitational settling of Opx and volumetric

192   shrinkage of the melt source after the upward reactive percolation of silicate melt. Thus, the

193   original interface between the melt source and peridotite before the experimental reaction cannot

194   be marked by the offset of the graphite inner sleeve. At 1,250 °C, the thickness of ORL increases

195   from ~ 118 ± 11 μm (1σ) at 12 h to ~ 416 ± 119 μm at 72 h, which is likely a linear function of

196   the square root of the run duration (slope = 0.78 ± 0.05) (Figure 3a-blue line). With increasing

197   the temperature to 1,300 °C, the thickness increases considerably to 500 ± 128 μm at 12 h

198   (Figure 3a), implying the contribution of a higher temperature to the growth of ORL.

199   Additionally, based on the linear fit, the addition of 5 wt.% basalts into the partially molten

200   peridotite (run PC548) or 2 wt.% oceanic sedimentary into the melt source (run PC560) seems to

201   have no significant effect on the thickness of ORL (Figure 3a).

202   On the other hand, peridotites in the upper part of our samples were in disequilibrium

203   with silicate melt at these run conditions, thereby should be dissolved essentially into the melt.

204   The degree of dissolution is indirectly quantified via the dissolution distance (Figure 3b), which

205   is the distance between the current boundary (Figure 1-blue dotted lines) and the original

206   interface (Figure 1-red dotted lines) that is approximately represented by a sharp decrease in the

207   size of sulfide droplets in the melt source. All these dissolution distances are measured at least 5

208   times around the central part of experimental charges. Similarly, dissolution distance linearly

209   increases with the square root of time (Figure 3b-blue line) at 1,250 °C, and the increase of

210   temperature to 1,300 °C significantly enlarges the dissolution distance (Figure 3b). The addition

211   of oceanic sedimentary (PC560) or basalt (PC548) has no substantial effect on the dissolution

212   distance (Figure 3b).

213   Moreover, based on analyses of SEM images, with increasing run duration or

214   temperature, more silicate melt penetrated the Opx reaction layer into the partially molten

215   peridotite (~ 4.65 ± 0.78 area% at 12 h; ~ 7.13 ± 0.58 area% at 72 h) (Figure 4a), resulting in the

216   formations of melt junctions and channels among silicate minerals, and even some large melt

217   pools just above the ORL (Figure 2c; Figures S2-S8). At 1.5 GPa, with increasing annealing time

218   from 12 h to 72 h, the grain size of silicate minerals increases from 8.1 ± 3.4 μm to 11.0 ± 4.9

219   μm in the partially molten peridotite (Figure 4b; Supporting information; Table S1). Under

220   conditions of high temperature (1,300 °C) and long-run duration (72 h), an olivine-melt layer,

221   consisting of sulfide, olivine, and silicate melt, is present above the ORL (Figures 2a and 2d,

222   Figures S3 and S5), which may be attributed to the dissolution of clinopyroxene and

223   reprecipitation of olivine during the melt-peridotite reaction. Additionally, crystal faces between

224   olivine grains were open and full of silicate melt, forming abundant melt channels among the

225   crystal framework (Figure 2c, Figures S2-S8).

226   In the melt source, an amount of Opx grains were produced by the reaction between

227   olivine in starting materials and convecting silicate melt (Figure 1), and there is commonly no

228   significant boundary between these Opx grains and the ORL. The mean area-weighted diameter

229   of sulfide droplets was ~ 4.1 ± 0.1 μm in a low-temperature hot-press experiment (PC537, 800

230   °C), which potentially denotes the initial size of sulfide droplets in the starting material. At a

231   higher temperature (1,250 °C), sulfide size increases from ~ 14.7 ± 0.2 μm to ~ 49.4 ± 1.6 μm

232   with increasing the annealing time from 12 h to 72 h (Figure 5a; Table S2), in which the larger

233   standard deviations from the long annealing time (72 h) experiments may be partly attributed to

234   the presence of some enormous (> 50 μm) and tiny (< 1 μm) sulfide droplets. Under the same

235   annealing time (48 h), there is no conspicuous increase in sulfide size when 5 wt.% basalt was

236   added to the peridotite (PC548), but a slight increase in sulfide size was observed if the

237   experimental temperature increased to 1,300 °C (PC527) (Figure 5a). The addition of carbonate

238   into the melt source (PC560) resulted in a significant increase in sulfide size to ~ 54.0 ± 1.6 μm

239   at 24 h (Figure 5a). Additionally, we also observed that the number density of sulfide droplets

240   uniformly decreases with increasing annealing time in the lower melt source (Figure 5a-inset).

241   The area fraction of sulfide in the melt source of the low-temperature experiment (800 °C) was ~

242   3.26 ± 0.12 area%. At 1,250 °C, the area fraction was essentially constant (3.44 ± 0.14 area% at

243   12h; 3.50 ± 0.15 area% at 48h) when the annealing time was less than 48 h, but a visible increase

244   (5.46 ± 0.22 area%) can be observed for a longer annealing time, 72 h (Figure 5b). A similar

245   trend was also shown in the upper part of samples (Figures 5c and 5d), which may be due to

246   more silicate melts infiltrating into the upper part of samples with increasing annealing time to

247   72 h (Figure 4). As previously observed (Yoshino & Watson, 2005), the diffusion of Fe and Ni

248   components from silicate phases into sulfide liquids may be one of the reasons for the increase of

249   sulfide area fraction in the melt source. In contrast, with increasing temperature to 1,300 °C, a

250   lower area fraction (2.93 ± 0.07 area %) of sulfide was observed even in the experiment with a

251   short annealing time (12 h) (Figure 5b), potentially due to partial dissolution of sulfide driven by

252   the higher sulfur content at sulfide saturation (SCSS) at high temperature (*e.g.*, Liu et al., 2007;

253   Mavrogenes & O'Neill, 1999). Similarly, the additions of basalt and carbonate enhance the

254   permeation of more silicate melt into the upper part of samples, thereby increasing the area

255   fraction of sulfide in the melt source (Figure 5b).

256   Based on the SEM images of products from these high-temperature experiments (1,250

257   °C), it becomes evident that sulfide droplets in the melt source were entrained into the partially

258   molten peridotite by a porous flow of silicate melt during the melt-peridotite reaction (Figure 2).

259   With permeating more silicate melt upwards, more and larger sulfide droplets can be observed in

260   the partially molten peridotite, and meanwhile their sizes (area-weighted diameter ~ 3.1 ± 0.1 μm

261   at 12 h to ~ 11.1 ± 0.4 μm at 72 h) and area fractions (~ 0.15 ± 0.05 area% at 12 h to ~ 0.49 ±

262   0.03 area% at 72 h) increase with the increasing annealing time at 1,250 °C (Figures 5c and 5d;

263   Table S2). Apparently, the addition of carbonate and 5 wt.% basalt into melt source and partially

264   molten peridotite, respectively, drives a higher area fraction and larger size of sulfide droplet in

265   the upper part of samples (Figures 5c and 5d). Hence, these observations propose that the ORL

266   may not efficiently prevents the upward transport of silicate melt and sulfide droplets from the

267   lower melt source to the upper molten peridotite.

268   Notably, under the condition of lower pressure (0.5 GPa), some vapor bubbles have been

269   found in the partially molten peridotite due to the exsolution of volatile (mainly H_2O) in the

270   starting basaltic material, and they mostly absorb on sulfide droplets to form compound drops,

271   which has been proposed to potentially enhance the upward transport of sulfide (Figure S7;

272   Mungall et al., 2015; Yao & Mungall, 2020).

3.2 Phase compositions

3.2.1 Mineral compositions

275   Figure 6 and Figure 7 respectively showed the compositional variations of olivine and

276   clinopyroxene as a function of distance away from the final melt-peridotite interface (Table S4).

277   At 1.5 GPa and 1,250-1,300 °C, from the far-field region to the interface, olivine grains became

278   gradually lower in the Mg# (defined as molar Mg/(Mg+Fe)*100) and concentrations of SiO_2,

279   MgO, and NiO, and meanwhile shown the increases in the FeO and MnO contents (Figure 6).

280   Compared with the low-temperature, hot-press experiment (PC537) (Figure 6 purple dotted

281   lines), olivine grains from high-temperature experiments contain lower MgO and NiO, and

282   higher FeO and CaO concentrations. By contrast, olivine compositions in experiments PC548 (5

283   wt.% basalts) and PC559 (0.5 GPa) were roughly constant across the partially molten peridotite,

284   whereas olivine grains crystallized in the melt source at lower-pressure experiment (0.5 GPa,

285   PC559) had lower Mg#, MgO, SiO_2 and higher FeO than those in the peridotite region (Figure

286   6).

287   In contrast to olivine, more scatter compositions were observed in the clinopyroxene

288   (Cpx) grains from the partially molten peridotite (Figure 7). Only near the melt-rock interface,

289   the trends of decreasing Mg# and CaO and increasing FeO were present in Cpx grains from all

290   high-pressure experiments, whereas the Cpx compositions in the low-pressure and carbonate-

291   bearing experiment (PC559 and PC560) were essentially constant across the peridotite region

292   (Figure 7). On the other hand, the Opx grains in the reaction layer and melt source were the

293   products of silicate melt-olivine reaction. No distinct compositional difference was observed in

294   these Opx grains (Figure S9; Table S4).

295   3.2.2 Silicate melt and sulfide liquid compositions

296   The variations of the reacted melt compositions in these experiments mostly depend on

297   the extent of the melt-rock reaction and the formation of a new major phase. In the melt source,

298   with increasing run time and/or temperature, the compositions of silicate melt became higher in

299   CaO and MgO concentrations, and lower in SiO_2, Al_2O_3, and FeO (Figure 8; Table S5), implying

300   the effect of high-degree melt-peridotite reaction on the melt composition. No distinct variation

301   of the melt sulfur contents was observed under the conditions of 1,250 °C and 1.5 GPa. Based on

302   two new SCSS models (Chowdhury and Dasgupta, 2020; Smythe et al., 2017), the calculated

303   ranges of SCSS in silicate melt are almost the same or slightly lower than our results within the

304   error of measurement (Figure 8f-shadow gray region), potentially indicative of sulfur-saturated

305   silicate melt in these experiments. Moreover, the calculated SCSS in the melt source is nearly the

306   same as those in the interface within the error, which is consistent with our measurements

307   (Figure 8f). The decreases in pressure and temperature respectively to 0.5 GPa and 1,200 °C

308   caused the obvious increases in SiO_2 and Al_2O_3 concentrations and decreases in MgO and S

309   concentrations in silicate melt (Figures 8a, 8b, 8e, and 8f). No significant variations of melt

310   compositions were observed between the melt source and melt-peridotite interface within the

311   error of measurement (Figure 8), suggesting the convective flow is strong enough to drive the

312   chemical equilibrium of silicate melt. The composition of primary silicate melt infiltrating into

313   the peridotite cannot be analyzed due to the small scale. In addition, $\sim 1.57 \pm 0.15$ wt.% H_2O was

314   detected in the reacted melts from experiments PC520 and PC528 using the Fourier Transform

315   Infrared Microscopy (Supporting Information, Mercier et al., 2010), which is slightly higher than

316   that of basalt (~ 1.19 wt.%) added in the starting materials. On the basis of these melt

317   compositions, the viscosity (μ_m) of the starting basalt (~ 1.19 wt.% H_2O) before the melt-rock

318   reaction can be calculated as ~ 10.8 Pa·s at 1.5 GPa and 1,250 °C by using the model from

319   Giordano et al. (2008), whereas the μ_m of reacting melt after the reaction decreases to ~ 1.2-2.7

320   Pa·s at 1.5 GPa and 1,250-1,300 °C assuming the water content of ~ 1.5 wt.% (Figure 8g). When

321   the pressure and temperature respectively decrease to 0.5 GPa and 1,200 °C, the reacting melt

322   has a higher viscosity of ~10.5 Pa·s. Additionally, there is no evident difference in melt viscosity

323   between the melt source and the melt-peridotite interface. However, the addition of carbonate

324   (PC560) potentially leads to a peculiarly lower melt viscosity (~ 0.25 Pa·s) estimated by using a

325   simple model (Di Genova et al., 2014) under the assumption of the 2 wt.% carbonate dissolved

326   in silicate melt, which represents an order-of-magnitude evaluation of the melt viscosity due to

327   the uncertainty of extrapolation (Figure 8g).

328   Except for several large sulfide droplets containing the Ni-rich quenched phases, the

329   composition of sulfide was homogeneous in the lower melt source of all experiments. In the 12 h

330   experiment, the S content, Ni/S and Fe/S ratios of sulfide liquid were ~ 35.16 ± 0.72 wt.%, ~

331   0.39 ± 0.03, and ~ 1.43 ± 0.04, respectively, and these values remained constant within the error

332   of measurement when the annealing time increases to 72 h (S ~ 35.74 ± 0.74 wt.%, Ni/S ~ 0.37 ±

333   0.09, Fe/S ~ 1.42 ± 0.06). However, the Cu/S ratio of sulfide liquid slightly decreased from

334   0.017 ± 0.004 at the 12 h to 0.009 ± 0.002 at the 72 h at 1,250 °C, while an obvious increase in

335   the Cu/S ratio (~ 0.046 ± 0.010) was observed at 1,300 °C (Table S4).

4 Discussion

4.1 Grain-scale processes in melt-peridotite reaction

338   Firstly, if the upper peridotite reaches equilibrium at 1.5 GPa and 1,250-1,300 °C, the

339   corresponding melt fraction will be less than 0.04-0.08 wt.% based on the thermodynamic model

340   via the pMELTS (Ghiorso et al., 2002), implying that the self-partial melting of peridotite at the

341   experimental conditions is negligible here. The observed variations of melt area fraction, phase

342   proportions, and minerals' sizes and compositions in our experiments can be primarily attributed

343   to the melt-peridotite reaction. On the other hand, the upper peridotites are not in equilibrium

344   with the starting melts at the experimental conditions, and hence olivine and clinopyroxene in the

345   peridotite part should partially or completely dissolve in the reacting and upward percolating

346   melt (Liang, 1999; C. Wang et al., 2020). In multicomponent partially molten systems, the melt-

347   peridotite reaction is suggested to occur via multi-scale mass transfer processes that inevitably

348 involve both the grain-scale dissolution-precipitation-reprecipitation and diffusion, in

349 conjunction with large-scale advective transport (Cascio et al., 2008; Morgan & Liang, 2005).

350 In our high-temperature, high-pressure experiments (1.5 GPa and 1,250-1,300 ℃) here,

351 due to the disequilibrium between melt and peridotite, the consequent grain-scale processes can

352 mostly occur via the dissolution, precipitation, and reprecipitation of mineral grains, which is

353 evident from the formation of ORL. In the lower melt source, the basaltic melt in starting

354 materials is olivine-undersaturated, and thus the melt-rock reaction between basaltic melt and

355 olivine produces new Opx grains (Figure 1), which is consistent with the following reaction:

356 $$melt_0 + Ol_0 \longrightarrow melt_1 + Opx_1$$

357 (1)

358 where subscripts 0 and 1 designate melt and mineral grains from starting materials and the

359 reaction products, respectively. This reaction should occur via the dissolution of olivine, and

360 precipitation of new orthopyroxene, largely contributing to the formation of ORL in the interface

361 between the peridotite and melt source (Figure 1a). It is well known that dissolution and

362 precipitation occur simultaneously during the development of the ORL under high pressure (> 1

363 GPa) (Cascio et al., 2008; Morgan & Liang, 2003). With increasing the degree of melt-peridotite

364 reaction (a longer run duration and/or higher temperature), an olivine-melt layer above the ORL

365 is formed by the further dissolution of olivine and few clinopyroxene grains, with concomitant

366 reprecipitation of fresh olivine grains in the melt reaction flow (Figure 2) (Kelemen et al., 1995).

367 The grain size of silicate minerals plays a vital role in affecting the physical properties of

368 upper partially molten peridotite, such as permeability (Faul, 2001). Here, the growth of silicate

369 mineral sizes in the upper partially molten peridotite with increasing annealing time (Figure 4b)

370 is mostly driven by a reduction of grain boundary energy (Faul & Scott, 2006) and demonstrates

371 that textural coarsening by which small-size crystals are consumed to support the growth of

372 coarser grains (Higgins, 1998, 2011; Yao et al., 2017), may overweigh the decreasing-size effect

373 related to reprecipitation of new, fine-grained crystals. The transference of material from

374 dissolved olivine to other grains occurs via diffusion through grain boundaries, crystals

375 themselves, and interstitial melt (Yao et al., 2017), while the last one is much faster and becomes

376 the main pathway of these grain-scales processes. Finally, large-scale advective transport of

377   reacting melt is evident from the variations of melt area fraction in the partially molten peridotite

378   and the formations of melt junctions and channels (Figure 1; Figure 4a).

379   Based on the parabolic law of diffusive dissolution (Liang, 1999; Zhang et al., 1989), the

380   slope (*i.e.*, the diffusive dissolution constant) of the fitted linear regression line for our

381   experiments is used to estimate the growth rate of ORL (k_{ORL}), which is about $\sim 0.78 \pm 0.05$

382     $\mu m/s^{0.5}$ at 1.5 GPa and 1,250 °C. This growth rate is far lower than those of some previous

383   experiments conducted at higher temperatures and/or pressures (Figure 3a) (Morgan & Liang,

384   2005; C. Wang et al., 2020). The thickness of ORL in experiment PC527 at 1.5 GPa and a higher

385   temperature ($\sim 1,300$ °C) has a faster-increasing tendency ($k_{ORL} = 2.37 \pm 0.14$ $\mu m/s^{0.5}$), consistent

386   with the experiments under 2 GPa and 1,375 °C (C. Wang et al., 2020). This tendency of ORL

387   growth is likely unchanged in the experiments with the carbonate-bearing melt source (PC560)

388   and silicate melt-bearing peridotite (PC548) (Figure 3a), implying an insignificant effect of melt

389   composition and porosity on the growth of ORL. Our results indicate that the increase in

390   temperature will potentially enhance the growth rate of ORL thickness during the melt-rock

391   reaction, which can be mostly attributed to the higher diffusivities of elements in silicate melts at

392   a higher temperature (Mungall, 2002; Zhang et al., 2010).

393   Similarly, we observed the linear increase of dissolution distance with the square root of

394   time (Figure 3b), suggesting that a substantial amount of peridotite was dissolved in the

395   percolating melt. At 1.5 GPa and 1,250 °C, the dissolution rate of peridotite evaluated by the

396   slope of the linear regression line ($k_{diss} = 0.58 \pm 0.08$ $\mu m/s^{0.5}$) is lower than those in previous

397   experiments with higher temperatures and pressures (Figure 3b, C. Wang et al., 2013, 2020),

398   indicating that relatively high temperature also increases the dissolution rate. Moreover, the

399   higher dissolution rate of peridotite at experiment PC527 (1,300 °C) implies that an increase in

400   temperature significantly enhances melt-rock reaction (Mitchell & Grove, 2016). The high

401   content of water ($\sim 1.57 \pm 0.15$ wt.%) in silicate melt could enhance the formation of several

402   enormous Opx grains in the ORL (Figure 2) (Wang et al., 2016), partly because the addition of

403   water can strongly depress the peridotite solidus. This may be also the reason for the large

404   standard deviations of the dissolution rate in experiments PC527 and PC545 with a high

405   temperature (1,300 °C) and long annealing time (72 h). Overall, the growth rate of the ORL is

406   generally higher than the peridotite dissolution rate, which is potentially attributed to the volume-

407   increasing reaction during the replacement of olivine by orthopyroxene (Milke et al., 2009).

408   4.2 Compositional variations of melt and minerals

409   During a melt-peridotite reaction, besides the systematic changes in mineralogy and

410   texture of peridotite, we also observed the compositional variations of melt and minerals in the

411   reaction couple (Figures 6-8), which have been widely used to outline the grain-scale processes

412   governing this melt-peridotite reaction (Mallik & Dasgupta, 2012; C. Wang et al., 2020). On the

413   other hand, a thermodynamically-constrained mixing model has been recently used to examine

414   the variations of major element compositions of minerals during the melt-peridotite interaction

415   (Lambart et al., 2012; Pin et al., 2022; Shaw et al., 2018), and this forward model may offer a

416   key to testing and understanding the compositional evolution of our experimental products.

417   The melt-peridotite reaction here is modeled as a simplified, thermodynamic process in

418   which the peridotite is continually impregnated by a finite amount of basaltic melt from the

419   lower melt source, which is the same as the assumption in previous works (Lambart et al., 2012;

420   Pin et al., 2022; Shaw et al., 2018). After each increment of melt impregnation, the infiltrated

421   melt will eventually be equilibrated with surrounding peridotite, and the thermodynamic

422   properties of the whole system are adopted as a reference for the next increment. In each

423   increment, the proportions and compositions of melt and solid phases after chemical re-

424   equilibrium can be obtained by finding the minimum Gibbs energy of the whole system (Pin et

425   al., 2022; Yao et al., 2018). This process is modeled by constantly adding up to 200 g of the

426   lower basaltic melt by increments of 0.5 g, to 100 g of the upper peridotite, using the pMELTS

427   of alphaMELTS (Ghiorso et al., 2002; Ghiorso & Sack, 1995; Smith & Asimow, 2005) in

428   isenthalpic mode at 1.5 GPa, 1,250-1,300 °C and ΔQFM-2.0. Here, the incremental addition of

429   basaltic melt corresponds to the increase of melt: peridotite ratio from 0.005 to 2.

430   Our simulation shows that the mass fraction of olivine decreases from ~ 49 wt.% to ~ 22

431   wt.% with the increasing melt: peridotite ratio from 0.005 to 2 (Figure 8h). The silicate melt

432   becomes saturated with orthopyroxene when the melt: peridotite ratio reaches ~ 0.22. After this

433   point, the mass fraction of new orthopyroxene precipitated from silicate melt quickly increases to

434   ~ 32 wt.% at the melt: peridotite ratio of 2 (Figure 8h). The mass fraction of clinopyroxene in

435   peridotite has a quick increase from ~ 51 wt.% to ~ 57 wt.% before the precipitation of

436   orthopyroxene, but then slowly decreases to ~ 46 wt.% at melt: peridotite ratio = 2 (Figure 8h).

437   Hence, the increase in orthopyroxene proportion is mostly due to the dissolution of olivine,

438   accompanied by a limited contribution from the consumption of less than ~ 5 wt.%

439   clinopyroxene, which approximatively coincides with the hypothetical Reaction 1 mentioned

440   above.

441   Concurrently, the melt penetrates upwards and further reacts with the peridotite to result

442   in systematic variations of the compositions of olivine and Cpx grains towards the melt-rock

443   interface (Figure 6 and Figure 7). The modeled compositional evolutions of olivine show a

444   decreasing trend of MgO content from ~ 49.3 wt.% to ~ 44.1 wt.%, an increase of FeO content

445   from ~ 9.0 to ~ 14.5 wt.%, and the associated decrease of Mg# from ~ 90.7 to ~ 84.4, when the

446   melt: peridotite ratio increases from ~ 0.005 to ~ 1.5 (Figure 6h). In the same range of melt:

447   peridotite ratio, the clinopyroxene has an obvious increase in its MgO content (from ~ 17.5 to ~

448   20.0 wt.%) and approximately constant Al_2O_3 content (Figure 7h). The trends of these

449   compositional variations of minerals are nearly in agreement with those of our experiments,

450   except for the low-pressure experiment (PC559, Figure 6h and Figure 7h). Therefore, the

451   measured compositional variations of olivine and clinopyroxene as a function of distance away

452   from the final melt-peridotite interface may be connected to the melt: peridotite ratio during the

453   reaction. The measured compositions of olivine and Cpx grains just above the final melt-

454   peridotite interface are approximately consistent with those results simulated thermodynamically

455   (Figures 6h and 7h-gray shadow regions) in the melt-peridotite ratio of 1.0 to 1.5, which implies

456   that they have obtained locally chemical re-equilibrium with the reacting melt that is about ~ 1.0-

457   1.5 times the initial mass of peridotite in the same region. As the distance away from the final

458   melt-peridotite interface grows, the growing MgO and Mg# contents of olivine reflect the

459   decrease of melt: peridotite ratio, and consequently imply the gradual weakening of melt-

460   peridotite reaction. Therefore, when the upward-flowing melt encounters the partially molten

461   peridotite that initially has a low permeability, melt convection, backflow, and the associated

462   high-degree melt-peridotite reaction mostly occur at the bottom of peridotite, leading to an

463   increase of porosity of the reaction region and more motivation of upward melt flow. This

464   potentially produces positive feedback between the reaction and melt flow, contributing to

465   upward infiltration of more silicate melt into the partially molten peridotite.

466   Along with the increasing melt: peridotite ratio from ~ 1.0 to ~ 1.5, the modeled silicate

467   melt that is reacted with the peridotite shows a decrease of SiO_2 content from ~ 47.1 wt.% to ~

468   46.7 wt.%, which is partly less than the measured ranges in our experiments with long annealing

469   time (Figure 8a). The Al_2O_3 content of silicate melt varies from ~ 13.6 wt.% to ~ 13.1 wt.%,

470   while the MgO content of melt shows a narrow variation range of ~11.1 wt.% to ~11.4 wt.%,

471   which both roughly match our experiments (Figures 8b and 8e). The possible iron loss to Pt

472   capsule in these experiments due to the incomplete isolation of separate upper and lower graphite

473   capsules with different diameters for silicate melt from Pt capsule (J. Wang et al., 2020) is likely

474   to be the main reason for the lower FeO content (Figure 8c) measured in these experiments with

475   long annealing time (> 48 h). The model suggests that silicate melt contains ~ 7.6-7.9 wt.% CaO

476   at the melt-peridotite of 1.0-1.5, but this range is underestimated in contrast to our measurements

477   (Figure 8d), partly because of the slight differences in the Gibbs free energy among various

478   compositional models of pyroxenes (Yao et al., 2021) may drive large errors in the CaO content

479   of clinopyroxene in the AlphaMELTS. Although there still have some weaknesses in modeling

480   the compositional evolution of melt, the use of AlphaMELTS is encouraging here and helps to

481   examine how mineral modes and chemical compositions evolve as silicate melts are added into

482   the upper peridotite part.

483   4.3 Coarsening processes of sulfide droplets

484   In a partially molten system, the nucleation/growth rate and associated size distribution of

485   sulfide droplets are vital constraints on their dynamics (Yoshino & Watson, 2005). Along with

486   the increasing annealing time, the size of sulfide droplets shows a larger increase (from ~3.2 ±

487   0.1 µm to ~11.1 ± 0.4 µm) (Figure 5c) compared with that of the surrounding silicate minerals

488   (from ~8.1 ± 3.4 µm to ~11.0 ± 4.9 µm) (Figure 4b). The growth of silicate minerals has been

489   suggested to be mostly controlled by the melt-enhanced diffusion of material, but sulfur that is

490   the one of major elements in the sulfide has a much lower diffusivity than those of other

491   elements (Freda et al., 2005; Yao & Mungall, 2021). Given that the diffusion of S rather than Fe

492   limits the growth rate of sulfide droplets (Zhang, 2015), slow growth is expected for sulfide if its

493   growth completely occurred via element diffusion. However, the estimated growth rate of sulfide

494   droplets is larger than those of silicate minerals in our measurements, suggesting that there must

495   be other mechanisms, besides the diffusion-driven growth, contributing to the fast growth of

496   sulfide droplets.

497   On the other hand, the actual 3D size distribution of sulfide droplets in the melt source

498   shows a uniform, nearly log-normal size distribution with a skewed peak to a slightly smaller

499   size than the average one (Figure 9), which can be attributed to the possible contribution of the

500   Lifshitz-Slyozov-Wagner (LSW) coarsening and the occurrence of normal grain growth (Honour

501   et al., 2019; Yoshino & Watson, 2005). Based on the classical LSW theory (Lifshitz & Slyozov,

502   1961; Wagner, 1961), the kinetics of crystal growth can be approximately described as $r \sim t^{1/m}$,

503   where r is the grain size, with the exponent $m = 3$ for a diffusion-controlled process and $m = 2$

504   under the control of an interface reaction. At 1,250 °C and 1.5 GPa, growth rates of sulfide

505   droplets are slightly slower than that predicted ($m = 2$) by the interface-reaction-controlled

506   process via a transient regime ripening before static-state ripening (Figure 5a), implying the

507   likely combination of multiple coarsening processes here (Lautze et al., 2011; Sun, 2007). High

508   run temperature (1,300 °C) can contribute to a higher degree of interface-controlled reaction

509   (Yoshino & Watson, 2005), which potentially facilitates the coarsening processes of sulfide in

510   the melt source (Figure 5a). A dramatical decrease in the number density of sulfides (Figure 5a-

511   inset) and the presence of sulfide droplets in contact with each other (Figure 2b and Figure S1),

512   both imply that the contribution of mechanical coalescence of sulfides (agglomeration and

513   successive coalescence) to their coarsening processes may be more important at droplet contacts

514   (Yoshino & Watson, 2005). Moreover, the coalescence of sulfide droplets is enhanced at lower

515   viscous melts (Holzheid, 2010), potentially addressing a significant increase in growth rate

516   (Figure 5a) from the carbonate-bearing experiment (PC560) with a lower melt viscosity (Figure

517   8g) (Di Genova et al., 2014). Although the previous analog experiment (de Bremond d'Ars et al.,

518   2001) and static high-temperature, high-pressure experiments (Bockrath et al., 2004; Holzheid,

519   2010) did not observe the aggregation of sulfide droplets, their mechanical coalescence, for the

520   first time, has been demonstrated to be feasible in our experiments with strong melt convection

521   and melt-peridotite reaction. This mechanical coalescence may occur via the impaction of sulfide

522   droplets with each other, and further drainage and rupture of the infinitesimally liquid film

523   separating them in the reacting melt flow, as suggested by theoretical analyses (Yao et al., 2019).

524   **5 Implications**

525   5.1 Porous melt flow in the partially molten peridotite

526   These dissolution-reprecipitation processes not only change the composition and

527   proportion of solid phases, but also increase the porosity of peridotite in the upper part of

528   samples, thereby enhancing upward mobilities of silicate melt and sulfide droplets away from the

529   lower melt source (Figure 4 and Figure 5). Moreover, the porosity of ORL is enough high for the

530   entrainment of sulfide droplets into peridotite (Figure 1 and Figure 2). In addition, with

531   increasing annealing time to 72 h, more basaltic melt infiltrating into the peridotite region from

532   the melt source (Figure 4) could potentially enhance the reaction between basaltic melt and

533   peridotite. This melt-rock reaction may produce a high flow capacity of reacting melt through a

534   dissolvable peridotite (Chadam et al., 1986; Jackson et al., 2018), resulting in the formation of

535   the finger- or tree-like melt-rich channels in which a fast-ascending magma flow can even drive

536   the antigravitational migration of coarse olivine grains (Pec et al., 2017). Hence, the

537   development of positive feedback between the enhanced permeability and the associated increase

538   of melt flux in reacting regions produces a higher flow velocity of melt and the wider melt

539   channels among crystal framework (Aharonov, 1995; Pec et al., 2017), thereby potentially

540   facilitating the upward entrainment of sulfide droplets (Wang & Jin, 2020).

541   To quantitatively outline the upward physical migration of sulfide droplets along with the

542   reactive melt flows in the dissolvable peridotite, some theoretical parameters of physical

543   properties of the partially molten peridotite should be considered first (*e.g.*, von Bargen & Waff,

544   1986; Mckenzie, 1984). For an ideal porous crystal framework, the permeability (k) can be cast

545   by using a power-law relationship between grain size (d) and porosity (Φ) of the crystal matrix

546   (von Bargen & Waff, 1986):

547        $$k = \frac{\Phi^n d^2}{C}$$ (2)

548   where C and n are constant parameters depending on the topology of the melt phase and the

549   geometry of an individual melt channel. Based on the previous works (Miller et al., 2014; Z.

550   Wang et al., 2020), some suitable ranges of C (36-94) and n (2.4-2.8) are used for our

551   experiments that contain the multiphase-mineral assemblage.

552   On the basis of the numerical model from McKenzie (1989), the extraction velocity of

553   melt relative to the stationary crystal framework can be estimated by:

554        $$v = \frac{k \Delta \rho_m g}{\Phi \mu_m}$$

555   (3)

556 where $\Delta\rho_m$ - the density contrast between silicate melt and solid mineral, g - the gravitational

557 acceleration, and μ_m - the melt viscosity, which decreases with increasing temperature and

558 volatile content (mainly CO_2 and H_2O) (Dingwell, 1996; Di Genova et al., 2014). Based on

559 equation (2) and (3), the porous flow velocity of melt through grain-scale percolation is ~ 0.74

560 μm/h in the partially molten peridotite of experiment PC545 (C ~ 36, n ~ 2.6, Miller et al., 2014;

561 Φ ~ 7.13 %; μ_m ~ 2.2 Pa·s; d ~ 11.0 μm; $\Delta\rho_m$ ~ 600 kg/m^3, g ~ 9.8 m/s^2). Apparently, the

562 transport distance (~ 53.3 μm) of this slow-extracting (~ 0.74 μm/h) melt within the longest

563 experimental time (72 h) is much shorter than the region of melt-peridotite reaction observed

564 here (Figure 1a), which implies that other mechanisms of melt extraction occur concurrently to

565 drive a higher flow velocity. In addition to the melt junctions among minerals, we also observed

566 thick melt channels (Figure 2) between some opening mineral grain boundaries in the ORL and

567 olivine + melt layer where a new crystal framework may have not been built, indicating the

568 possible existence of melt channelized flow, which has been demonstrated by some experimental

569 studies (*e.g.*, Pec et al., 2017; Zhu et al., 2011) and the field investigations on dunite channels in

570 MORB (*e.g.*, Kelemen et al., 1995). Melt velocity in these channels is suggested to be much

571 higher relative to other regions (Pec et al., 2017; Wang & Jin, 2020).

572 We then extrapolate our experimental results to the partially molten mantle. Generally,

573 the porosity (Φ) is approximately estimated to be ~ 1 – 15 % in the partially molten peridotite

574 (*e.g.*, Mei et al., 2002; Yoshino et al., 2010; Zhu et al., 2011), and the regions having high-degree

575 melt-rock reaction can obtain a higher porosity (Pec et al., 2017). Hence, the Φ in our model of

576 the molten mantle is properly set as 3 – 20 %. The observed grain size of upper mantle peridotite

577 is about mm-scale (Ave Lallemant et al., 1980; Karato, 1984), and thus the crystal radius in our

578 model is set as ~ 1.5 mm, which is about two orders of magnitude higher than the grain size (~

579 10 μm) in the experiments here. Therefore, the permeability of upper mantle peridotite should be

580 much better than the estimated situation of our experiments, and consequently, the extraction

581 velocity of melt relative to stationary crystal framework in the residual mantle increases to ~

582 4.78×10^{-6} – 5.62×10^{-5} m/s (~ 150.81 – 1,771.06 m/year) with the growth of Φ from 3 to 20 %,

583 if other parameters in equation (3) remain constant. On the other hand, the melt transport

584 velocities within the mantle were estimated to have a wide range of 1 to 1,000 m/year by

585 analyses of uranium-series (U-series) disequilibria in lavas and Icelandic deglaciation (Katz et

586 al., 2022; Rees Jones & Rudge, 2020; Rubin et al., 2005). The channelized melt flow potentially

587   has a higher melt extraction velocity, which can even reach ~ 10,000 m/year (McKenzie, 2000).

588   In contrast, recent laboratory experiments further estimate some conservative velocities of the

589   porous melt flow (~ 2.4 – 29.7 m/year, Z. Wang et al., 2020; ~ 2 – 150 m/year, Connolly et al.,

590   2009; ~ 0.5 m/year, Zhu et al., 2011). The estimated melt velocity (~ 150.81 – 1,771.06 m/year)

591   here is higher than the previous experimental results (~ 0.5 – 150 m/year), but falls into the

592   potential range of melt flowing velocity (~1 – 10,000 m/year) in the natural mantle. The wide

593   range of melt flowing velocity can be attributed to the heterogeneous grain size, various mineral

594   phases, and associated heterogeneous melt flow in natural peridotite relative to these in

595   experimental conditions.

596   The microstructure of a porous crystal framework is usually simplified as a "throat and

597   chamber" model, where the interstitial chamber pores are connected by many narrow throat

598   pores. The size distribution of these throat pores will have a great effect on the permeability of

599   the crystal framework, which in turn determines the percolation of silicate melt and the migration

600   of sulfide. Previous numerical models had demonstrated that the ratio of mean throat pore radius

601   to mineral radius decreases from 0.24 to 0.09 along with the decreasing porosity of crystal

602   framework from 35.4% to 8.3% (Sweeney & Martin, 2003). Based on this modeling result, we

603   can estimate the variations in the mean throat pore radius of the partially molten peridotite with

604   constant crystal size (~ 1.5 mm) and variable porosity due to the melt-rock reaction, which can

605   help us to trace the dynamic migration of sulfide in crystal framework.

606   5.2 Upward entrainment of fine sulfide droplets by porous melt flow

607   The physical mobility of sulfide liquids along with a sulfur-saturated silicate melt within

608   the crystal framework of partially molten peridotite largely depends on the size of sulfide

609   droplets, the permeability of crystal framework, the connectivity of melt network, and the

610   processing degree of melt-rock reaction (Z. Wang et al., 2020; Yao & Mungall, 2020). Chung &

611   Mungall (2009) simplified the downward sinking of sulfide droplets in the crystal framework,

612   and proposed that this process is mostly controlled by the relative sizes of sulfide droplets and

613   surrounding crystals within partially molten peridotite. In this regard, for the upward transport of

614   a sulfide droplet, its terminal settling velocity should be also less than the upward velocity of

615   porous melt flow, although its size has been smaller than the size of the most constricted part of

616   the melt channel or pore throat in the crystal framework. The terminal settling velocity of the

617   spherical droplet will achieve when its gravity-driven buoyance force (F_B) is balanced by the

618   vertical drag force (F_D).

619   The melt flows passing through sulfide droplets that are nearly stranded in the melt

620   channel or port throat, as a first approximation, is regarded as the flow of an incompressible fluid

621   around a circular cylindrical particle (*i.e.*, the sulfide droplet) confined by two parallel flat plates

622   (*i.e.*, the melt channel) (Figure 10a) (Lee & Fung, 1969). The drag force (F_D) acting on this

623   sulfide droplet can be expressed by a dimensionless coefficient (f_D):

624            $F_D = f_D \times 4\pi\mu_m UR$

625   (4)

626   where R is half the distance between the two plates, *i.e.*, the radius of the melt channel, and U is

627   the stokes flow velocity of melt around sulfide droplet. Based on the modeling results from Lee

628   & Fung (1969), the dimensionless coefficient, f_D, can be estimated via the ratio between R and r_s

629   which is the radius of an initial undeformed sulfide droplet before entering the melt channel

630   (Figure 10b). For simplification, here we assume that the spherical droplet has a radius (r_s)

631   equaling to or being slightly higher than R, and thus the corresponding values of f_D should

632   exceed ~ 4.8 (Figure 10b) (Lee & Fung, 1969).

633   On the other hand, dense sulfide droplet always has a trend of settling to the base of the

634   capsule due to gravity, and the corresponding buoyancy force (F_B) can be expressed as:

635            $F_B = \frac{4}{3}\pi r_s^3 g \Delta\rho_s$,

636   (5)

637   where $\Delta\rho_s = 1,700$ kg/m^3 is the density difference between sulfide and silicate melt (Kress et al.,

638   2008; Z. Wang et al., 2020). Hence, the velocity of melt flow that just successfully entrains

639   sulfide droplets whose sizes are close to that of melt channel/pore throat can be calculated via:

640            $U = \dfrac{F_D}{4\pi\mu_m R \cdot f_D} = \dfrac{F_B}{4\pi\mu_m R \cdot f_D} = \dfrac{r_s^3 g \Delta\rho_s}{3\mu_m R \cdot f_D}$,

641   (6)

642   Because the measured maximum radius of sulfide droplets in the upper peridotite part is

643   ~ 9.5 μm, the maximum value of U is estimated as ~ 170.9 μm/h (~ 1.5 m/year), when the R/r_s

644   equals 1. This value can represent the localized velocity of channelized melt flow in the regions

645   of melt-rock reaction and is nearly three orders of magnitude higher than the velocity of melt

646   porous flow (~ 0.74 μm/h) driven by compaction of crystal framework. As the melt flow velocity

647   is changeable due to the complex morphology of interconnected melt channels and variable fluid

648   dynamic environments in porous peridotite (McKenzie, 1989; Miller et al., 2014; Z. Wang et al.,

649   2020; Zhu et al., 2011), our calculation (~ 1.5 m/year) here is used as an order of magnitude

650   estimate for the velocity of melt flow around sulfide droplet through narrow pore throat in these

651   experiments.

652   When the porous melt flow in crystal mush has a small velocity, it may not have enough

653   kinetic energy to overcome the gravitational settling of large sulfide droplets. Hence, in this case

654   (the region of No. ① in Figure 11), the maximum size of the upward migrating sulfide droplet is

655   mostly controlled by the low flow velocity when the droplet size is smaller than the pore throat at

656   the high porosity of crystal mush. For the porous melt flow with a velocity of $\sim 5.1 \times 10^{-6}$ m/s ($\sim$

657   161 m/year), due to the balance between F_B and F_D, the corresponding sulfide droplet radius is

658   about 98.2 μm, which is less than the mean radius of pore throat in crystal mush with increasing

659   Φ from 3 to 20% (Figure 11). Here, the maximum radius (r_s) of sulfide droplets that can pass

660   through the crystal mush will remain at ~ 98.2 μm even though the permeability of crystal mush

661   has been highly improved due to the increasing porosity. When the velocity of porous melt flow

662   increases to $\sim 11.6 \times 10^{-6}$ m/s (~ 366 m/year), the r_s is limited by the radius of the narrow pore

663   throat at low porosity (about $\sim 9\%$), but keeps a constant value (~ 148.5 μm) at a higher porosity

664   (Figure 11). A further increase in the porous melt flow velocity (*e.g.,* $\sim 2.1 \times 10^{-5}$ m/s, ~ 662

665   m/year) will further reduce the porosity range ($> \sim 15\%$) of which the r_s is just related to the melt

666   flow velocity (Figure 11).

667   Once the melt velocity increases to $\sim 3.2 \times 10^{-5}$ m/s ($\sim 1,009$ m/year), the value of r_s due

668   to the balance between F_B and F_D will increase to ~ 246.7 μm, which is equal to the radius of

669   pore throat at $\Phi = 20\%$ (Figure 11). Hence, if the melt velocity is beyond this value, the

670   motivation of porous melt flow is no longer the restriction on the upward transport of fine sulfide

671   droplets whose sizes are less than the radius of pore throat in crystal mush with the porosity

672   range of 3-20%. Of course, this moderate flow velocity cannot provide enough power to

673   overcome the capillary forces preventing droplet deformation as the coarse sulfide droplets

674   attempt to pass into pore throats narrower than themselves. Therefore, in this situation (the No.

675   ② in Figure 11), the sizes of upward transporting sulfide droplets must be strictly no larger than

676   the pore throat size in the crystal mush. Because the mean size of the pore throat is just related to

677   the grain size and porosity of molten peridotite based on the modeling results from Sweeney &

678   Martin (2003), the value of r_s should be equal to the estimated pore throat size that increases

679   from 99.7 to 246.7 μm with the increasing porosity from 3 to 20%, which is irrelevant to the melt

680   flow velocity. Thus, the No. ② situation is represented by a black line in Figure 11, although the

681   corresponding flow velocity may vary from $\sim 3.2 \times 10^{-5}$ m/s ($\sim$ 1,009 m/year) to a much higher

682   value (*e.g.,* $\sim$ 0.08 m/s, as explained below). Hence, during the melt-peridotite reaction, the

683   accompanying melt flow in the dissolved peridotite is energetic, and its flow velocity seems to be

684   high enough to drive the upward transport of fine μm-scale sulfide droplets (Figure 10c-right

685   side; Figure 11).

686   5.3 Potentially upward transport of coarse sulfide droplet

687   When a coarse sulfide that is sufficiently larger than the minimum constriction of the

688   melt channel is gradually squeezed into the small "throat" part along with the ascending reactive

689   melt flow, the sulfide droplet will invade this throat and be changed to a pear shape having a

690   smaller radius of curvature (Figure 10c-left side). Obviously, the upward migration of this coarse

691   sulfide droplet in the partially molten peridotite becomes complicated, and the referred dynamic

692   process simplistically involves a competition between buoyancy, pressure gradient, viscous,

693   capillary, and drag forces (Yao & Mungall, 2020). This squeezing process introduces the

694   additional capillary pressure P_c, which is a measure of the pressure discontinuity existing at the

695   interface of two immiscible phases (Chung & Mungall, 2009). The additional pressure imposed

696   on this deformed sulfide droplet within the squeezing process equals the difference in capillary

697   pressure between the top and bottom interfaces of the sulfide droplet and can be calculated by:

698     $$\Delta P_c = 2\gamma_{ms} \times \left(\frac{1}{r_t} - \frac{1}{r_d}\right)$$

699   (7)

700   where γ_{ms} = 0.21 N/m is the melt-sulfide surface tension (Mungall et al., 2015), r_t is the radius of

701   the upper spheric cap, and r_d is the radius of the lower part of the pear-shaped droplet (Figure

702   10c). The droplet cannot be forced through the pore throat unless this excess pressure ΔP_c is

703   balanced by an equal or greater pressure (ΔP) exerted by ascending melt flow on the trailing

704   edge of sulfide droplet, which tends to push the droplet to rise through the melt channel.

705   Because the silicate melt flows at a low Mach number, the simple form of Bernoulli's

706   principle is valid for the quasi-incompressible flows in melt-peridotite reaction, and hence

707   pressure of flowing melt around a sulfide droplet can be highly related to the peripheral flow

708   velocity via the Bernoulli's equation (Bauman & Schwaneberg, 1994):

709               $P_1 + \frac{\rho_m U_1^2}{2} + \rho_m g h_1 = P_2 + \frac{\rho_m U_2^2}{2} + \rho_m g h_2$

710   (8)

711   where the subscripts 1 and 2 correspond to the top and bottom outside points of deformed sulfide

712   droplets along the axis of symmetry, respectively; P is the pressure caused by the flow of silicate

713   melt; ρ_m is the density of melt; h is the height of 1 and 2 relative to a reference point beneath

714   sulfide droplet. Hence, the flowing-melt-driven external pressure imposed on the deformed

715   sulfide droplet equals the difference (ΔP) between P_1 and P_2. In an extreme case, the coarse,

716   deformed sulfide droplet completely blocks the ascending melt flow, and the flow velocity at

717   bottom of droplets (U_2) is close enough to zero, leading to a maximum value of external pressure

718   difference (ΔP) that can be calculated as:

719               $\Delta P = P_2 - P_1 = \frac{\rho_m U_1^2}{2} + \rho_m g(h_1 - h_2) = \frac{\rho_m U_1^2}{2} + \rho_m g \Delta h$

720   (9)

721   where U_1 is the flow velocity of melt at the top of the sulfide droplet, and Δh is the vertical

722   distance between the top and bottom points of the droplet. Assuming that the volume of a sulfide

723   droplet is unchanged during the squeezing process, the height of this invading sulfide droplet

724   (Δh) can be described by Chung & Mungall (2009):

725               $\Delta h = r_t + r_d + \sqrt{r_d^2 - R^2} - \sqrt{r_t^2 - R^2}$

726   (10)

727   For the deformed sulfide droplet, it bears the upward pressure driven by flow melt (*i.e.,*

728   ΔP), which should balance or even exceed the total of downward capillary pressure (ΔP_c) and

729   gravity-driven pressure (P_G) for the droplet to rise through the constriction:

730               $\Delta P \geq P_G + \Delta P_C = \rho_S g \Delta h + 2\gamma_{ms} \times (\frac{1}{r_t} - \frac{1}{r_d})$

731   (11)

732 where ρ_s is the density of sulfide liquid. Thus, combining the above equations (7-10), under the

733 critical condition for migration of sulfide droplet into the pore throat to be the case ($r_t = R$)

734 (Chung & Mungall, 2009), the equation 11 substituted with the appropriate values for $\rho_m = 2,600$

735 kg/m^3 (Robertson et al., 2016) is simplified into:

736 $$1,300 \times U_1^2 \geq 16,660 \times \left(R + r_d + \sqrt{r_d^2 - R^2}\right) + 0.42 \times \left(\frac{1}{R} - \frac{1}{r_d}\right)$$

737 (12)

738 And finally, the initial radius (r_s) of this sulfide droplet before its invasion into the pore throat

739 can be calculated by Chung & Mungall (2009):

740 $$r_s = \left(0.5 \times (r_d^3 + R^3 + (r_d^2 + \frac{1}{2}R^2) \times \sqrt{r_d^2 - R^2})\right)^{1/3}$$

741 (13)

742 When the melt flows around a sulfide droplet through a narrow pore throat in the partially

743 molten peridotite, the associated velocity field is suggested to be not homogeneous. In addition,

744 it is well known that exactly deciphering the flow velocity field of silicate melt infiltrating

745 through a multi-mineral phase system plays a critically important role in understanding the

746 geodynamic properties of the partially molten upper mantle, but it is challenging and beyond the

747 scope of this study. The increases in grain size and permeability may also strongly enhance the

748 melt flow velocity in the new channel of the crystal framework. Here, the flow velocity in the

749 channel has been confirmed to be about three orders of magnitude higher than that of porous

750 flow through grain-scale percolation in our experiments, which may be extrapolated to the mm-

751 scale upper mantle peridotite. Therefore, the velocity of melt flow around a sulfide droplet in the

752 channel in upper mantle peridotite may be in the magnitude of 0.001-0.1 m/s, and thus the local

753 velocity (U_1) of focused melt flow around the top of a sulfide droplet was analogously assumed

754 as ~ 0.3 m/s and ~ 0.08 m/s here (Figure 11- region ③) for the localized high-degree melt-rock

755 reaction regions of the partially molten mantle. This range of flow velocity is also consistent with

756 the estimates from previous studies discussed in Section 5.1.

757 Equations 12 and 13 are numerically solved for the above value of U_1 by programming a

758 loop using Maple$^©$. Based on the above numerical calculation, when the velocity of focused melt

759 flow around a sulfide droplet is less than ~ 0.08 m/s, the sulfide droplet is difficult to overcome

760 the capillary pressure imposed by melt channel/pore throat with a smaller size, and will be

761   stranded in inter-grain pores. However, these flow velocities ($\sim 3.2 \times 10^{-5}$ m/s – 0.08 m/s) are

762   still large enough to drive upward transport of sulfide droplets whose radii are smaller than or

763   almost the same as the radius (R) of pore throat (Figure 11-region ②).

764   For a powerful melt flow with extremely high velocity (*e.g.*, ~ 0.3 m/s in Figure 11-

765   region ③), coarse-grained sulfide droplet overcomes the capillary pressure driven by the pore

766   throat, and its maximum radius for upward migration increases from ~ 106.8 to ~ 276.8 μm with

767   increasing the porosity from 3 % to 20 % (Figure 11-region ③), which is larger than the

768   corresponding radius of the pore throat (from ~ 99.7 to 246.7 μm). In this condition (region ③ in

769   Figure 11), the coarse sulfide droplets can pass through the pore throat narrower than themselves.

770   Although the estimates of the maximum sulfide size that are capable of upward migrating

771   through the porous molten peridotite are divided into three conditions along with the increasing

772   melt flow velocity (the regions ①-③ in Figure 11), all of them are mostly dominated by the melt

773   flow velocity, porosity, and grain size of peridotite, which would be strongly enhanced by the

774   high-degree melt-rock reaction.

775   On the other hand, based on these previous studies on the abyssal and orogenic

776   peridotites, and peridotite xenoliths (*e.g.*, Lorand & Luguet, 2016; Lorand et al., 2010; Luguet et

777   al., 2003), highly variable grain size (< 20 μm to 500 μm) of sulfides is widely observed in the

778   upper mantle, while most sulfides are likely smaller than about 100 μm in diameter. Hence, it is

779   plausible that almost all sulfide droplets are stranded among the crystal framework of the upper

780   peridotite mantle with low porosity, while the high-degree partial melting and/or melt-peridotite

781   reaction will lead to high porosity, large flow velocity, and even the new-forming melt channel,

782   which highly proposes that efficient entrainment of most sulfide droplets into ascending magma

783   flow among porous peridotite is physically possible, especially among channelized extraction of

784   silicate melt in melt-peridotite reaction. Conceivably, mechanical entrainment of sulfide droplets

785   during the melt-rock reaction would be more efficient than the transport of sulfide liquid by

786   dissolving in departing silicate melt, especially given the slow S diffusion in the basaltic melt

787   (Freda et al., 2005). The sub-continental lithospheric mantle that undergoes large-scale partial

788   melting and melt-peridotite reaction under tectonically active craton margins may be favorable

789   conjunction of these factors and potentially conducive to the entrainment of large sulfide droplets,

790   thereby contributing to the fertilization of sub-continental lithospheric mantle and the primary

791   enrichment of metal-bearing sulfides for the formation of magmatic sulfide deposits (*e.g.*, Griffin

792   et al., 2013). This may be one of the reasons to account for the issue of why the spatial and

793   temporal distribution of magmatic Ni-Cu-(PGE) sulfide deposits are genetically related to these

794   regions (Maier & Groves, 2011).

795   **6 Conclusions**

796   Reaction-infiltration of silicate melt and concomitant transport of sulfide droplets in the

797   partially molten peridotite are examined experimentally and thermodynamical-quantitatively in

798   this study, which provides important insights into the fertilization of sub-continental lithospheric

799   mantle and the efficient recycling of sulfur and metal elements from the partially molten mantle.

800   The reaction between peridotite and basalt leads to the preferential dissolution of olivine and

801   precipitation of orthopyroxene at high temperature (1,250-1,300 °C) and pressure (1.5 GPa),

802   forming an orthopyroxene-rich reaction layer (ORL) with a high growth rate ($\sim 0.78 \pm 0.05$

803    $\mu m/s^{0.5}$ at 1,250 °C) in the melt-rock interface. With increasing the degree of melt-peridotite

804   reaction, more silicate melt infiltrates through the ORL into the upper partially molten peridotite,

805   forming an olivine-melt layer above the ORL, and coarse sulfide droplets could also be entrained

806   along with the infiltration of silicate melt. Systematic variations observed in the compositions of

807   minerals and reactive melt are approximately consistent with the thermodynamically-constrained

808   mixing model. Meanwhile, the sizes of sulfide droplets have fast growth in the melt source,

809   which is partly attributed to the multiple coarsening processes (including the mechanical

810   coalescence) of sulfide droplets in the dynamic reactive melt flow.

811   Suspension and entrainment of sulfide droplets in the partially molten peridotite indicate

812   a fast-flowing velocity of reactive melt (~ 170.9 μm/h) in our experiments, which demonstrates

813   the occurrence of focused melt flows with high velocity in the reactive-forming melt channels,

814   besides the melt porous flow driven by the density difference between silicate melt and minerals

815   forming the crystal framework. It is convincible that the melt flow velocity within the melt-rock

816   reaction is potentially high enough to drive upward transport of fine sulfide droplets with smaller

817   diameters than that of the pore throat in the partially molten peridotite. In this condition, the

818   maximum size of sulfide for upward entrainment is limited by the radius of the pore throat in the

819   crystal framework of peridotite and increases with the growth of porosity during partial melting

820   and melt-peridotite reaction. Only in the channelized melt flow with extremely high velocity,

821   coarse-grained sulfide droplets could upward migrate through the pore throats narrower than

822 themselves. Hence, the high-degree melt-rock reaction regions in the upper mantle, such as the

823 sub-continental lithospheric mantle of craton margins, are likely to have wide pore throats, high

824 porosity, and even channelized melt flow with high velocity, which can potentially drive upward

825 entrainment and/or extrusion of sulfide droplets in the partially molten mantle, and thereby

826 fertilize the lithospheric mantle and lead to the endowment of Cu- and Ni-bearing sulfide for the

827 formation of associated deposits.

Figure 1. Back-scattered electron images (BSE) of sections from experiments PC520 (a) (annealing time ~ 12 h) and PC545 (b) (annealing time ~ 72 h) under the conditions of 1.5 GPa and 1,250 ℃. Dashed red and blue lines respectively denote the original and current interfaces between the melt source and peridotite before and after the melt-rock reaction. The dashed yellow line marks the top of the Opx-rich reaction layer. The position where the melt fraction at the top of the melt source decreases below 10 – 15 vol% is set as the possible lower boundary of ORL for the measurement (the dashed white line), which is approximately consistent with the original interface between the melt source and peridotite at short annealing time (< 48 h). The width of these quenched cracks needs to be subtracted. The specimen setup of these experiments

1185   is shown as the inset in the left lower part. Mineral abbreviations: Ol-olivine; Opx-
1186   orthopyroxene; SM-silicate melt; SL-sulfide liquid.

1187   **Figure 2**. Microstructures of the interface of melt-rock reaction in experiments PC545 (72 h,
1188   1,250 ℃) (a), PC528 (48 h, 1,250 ℃) (b, c), and PC527 (12 h, 1,300 ℃) (d). Detailed
1189   microstructure of the distribution of sulfide droplets and silicate melt in the partially molten
1190   peridotite is displayed in (c). Symbols are the same as in Figure 1. Mineral abbreviations: Ol-
1191   olivine; Opx-orthopyroxene; SM-silicate melt; SL-sulfide liquid. Note that some huge Opx
1192   grains are present in the Opx-rich reaction layer of experiment PC527 with high reaction
1193   temperature, potentially leading to the destruction of the layer.

1194   **Figure 3**. Plots of thicknesses of Opx-rich reaction layers (ORL) (a) and dissolution distance (b)
1195   as a function of the square root of run time. The lines show the best fit for these data. k is the
1196   diffusive dissolution or growth rate which is the slope of the linear regression line. The grey
1197   symbols and lines denoted as 3 and 4 are from Morgan & Liang (2005), and those denoted as 1,
1198   2, 5, and 6 are from C. Wang et al. (2020). The blue symbols and lines denoted as 7 are from this
1199   study. Note that the dissolution distance and the thickness of ORL may be slightly
1200   underestimated and overestimated, respectively, due to the possible gravitational settling of
1201   minerals in our experiments.

1202   **Figure 4**. Plots of melt fraction (a) and grain size of silicate minerals (b) as a function of the
1203   square root of run time in the partially molten peridotite from our experiments.

1204   **Figure 5**. Plots of grain size (μm) of sulfide droplets weighted by the area (a and c) and the area
1205   fraction of sulfide droplets (b and d) as a function of the square root of run time in the melt
1206   source (lower part) and partially molten peridotite (upper part). Inset in (a) shows the
1207   relationship between the number density of sulfide droplets in the melt source and the square
1208   root of run time. All symbols representing samples are the same as those in (c).

1209   **Figure 6**. Plots (a-g) of measured oxide abundance (in wt.%) and Mg# in olivine as a function of
1210   distance (in μm) away from the melt-rock interface. The compositional variations of MgO, Mg#,
1211   and FeO are also simulated thermodynamically as a function of the melt-peridotite ratio in (h).
1212   These measured compositions of olivine approaching to the interface are roughly consistent with

1213 those results simulated thermodynamically (the gray shadow region in h), when the melt-rock

1214 ratio ranges from 1 to 1.5 (Table S6). At low pressure (PC559, 0.5 GPa), the compositions of

1215 olivine recrystallized in the melt source during the melt-rock reaction are present as PC559-

1216 Lower (hollow black square). The compositions of olivine grains within the low-temperature

1217 hot-press experiment (PC537) were almost constant across the partially molten peridotite region

1218 and thus can be used as the reference line (purple dotted lines) to show the composition

1219 variations of olivine in those high-temperature reaction experiments. The gray shadow regions in

1220 (a)-(g) denote the region that has a vigorous melt-peridotite reaction, whose width is not in

1221 accordance with the actual distance.

1222 **Figure 7**. Plots (a-g) of oxide abundance (in wt.%) and Mg# in clinopyroxene as a function of

1223 distance (in μm) away from the melt-rock interface. The compositional variations of MgO,

1224 Al_2O_3, and CaO are also simulated thermodynamically as a function of the melt-peridotite ratio

1225 in (h). The legends are the same as in Figure 6.

1226 **Figure 8**. Plots of oxide abundance (in wt.%) (a-e), sulfur content (f), and viscosity (μ_m) (g) of

1227 silicate melt versus the run time in melt-rock interface and lower melt source of these reaction

1228 experiments. The ranges of composition variations of SiO_2, Al_2O_3, FeO, CaO, and MgO

1229 simulated thermodynamically are denoted as shadow gray regions in (a)-(e) when the melt-

1230 peridotite ratio varies from 1 to 1.5. The shadow gray region in (f) is the calculated SCSS based

1231 on the models from Chowdhury & Dasgupta (2020) and Smythe et al. (2017), and the SCSS

1232 value at t = 0 is calculated by using the compositions of starting materials under conditions of

1233 1,250 °C and 1.5 GPa. The composition of sulfides in starting materials (Table S3) was used to

1234 estimate the SCSS in experiments PC559 and PC560. Produced phase proportions of different

1235 silicate minerals during the melt-rock reaction are simulated thermodynamically as a function of

1236 melt-peridotite ratio in (h). A lower melt viscosity (~ 0.25 Pa·s) of the carbonate-bearing

1237 experiment (PC560) is roughly estimated by using a model from Di Genova et al. (2014)

1238 considering the effect of CO_3^{2-} (~ 2 wt.%) and denoted as a hollow inverted triangle in (g). Cpx-

1239 clinopyroxene, Opx-orthopyroxene.

1240   **Figure 9**. Normalized 3D size distributions of sulfide droplets in melt source. The size of sulfide

1241   droplets (r) and frequency (f) have been normalized to average size ($r*$) and maximum frequency

1242   (f_{max}), respectively.

1243   **Figure 10**. Schematic map illustrating the fluid flow around a circular cylindrical particle

1244   confined by two parallel flat plates (a), the dimensionless coefficients f_D is shown as a function

1245   of the R/r_s ratio (b) (modified from Lee & Fung, 1969), and the extrusion and entrainment of

1246   large (left side) and small (right side) sulfide droplets driven by focused melt flow (c). In (a), the

1247   two parallel flat plates and a circular cylindrical particle are considered as the walls of the pore

1248   throat/melt channel and sulfide droplet, respectively.

1249   **Figure 11**. Plots of the radius (r_s) of initial undeformed sulfide droplets that could extrude the

1250   pore throat as a function of the porosity (Φ) of the partially molten mantle. The relationship

1251   between r_s and Φ is divided into three parts according to the relative size of sulfide droplets'

1252   radius (r_s) and the pore throat's minimum constriction (R). The description of these three regions

1253   can be found in the main text.

1254   **Table 1.** Experimental conditions and the observed lithologies.
