Abstract

Relating the mass eruption rate (MER) of explosive eruptions to column height in the atmosphere is key to reconstructing past eruptions and forecasting volcanic hazards. Using 134 eruptive events from the Independent Volcanic Eruption Source Parameter Archive (IVESPA v1.0), we explore the canonical MER-height relationship for four measures of column height: spreading level, sulfur dioxide height, and top height from both directly observed plumes and those reconstructed from deposits. These relationships show significant differences and should be chosen carefully for operational and research applications. The roles of atmospheric stratification, wind, and humidity remain challenging to assess across the large range of eruptive conditions in this database, ultimately resulting in empirical relationships outperforming analytical models that account for atmospheric conditions. This finding reveals the complexity of the height-MER relation that is difficult to constrain based on available heterogeneous observations, which reinforces the need for improved datasets to develop eruptive column models.

Key Points:

- Using 134 volcanic events, we constrain empirical scaling relationships between mass eruption rate and four metrics of column height

- We do not detect a clear influence of atmospheric stratification, wind, and humidity on scaling relationships in this global database

- We discuss limitations of global data and discrepancies between scaling models and the observed behavior of explosive eruptions in nature

Abstract

Relating the mass eruption rate (MER) of explosive eruptions to column height in the atmosphere is key to reconstructing past eruptions and forecasting volcanic hazards. Using 134 eruptive events from the Independent Volcanic Eruption Source Parameter Archive (IVESPA v1.0), we explore the canonical MER-height relationship for four measures of column height: spreading level, sulfur dioxide height, and top height from both directly observed plumes and those reconstructed from deposits. These relationships show significant differences and should be chosen carefully for operational and research applications. The roles of atmospheric stratification, wind, and humidity remain challenging to assess across the large range of eruptive conditions in this database, ultimately resulting in empirical relationships outperforming analytical models that account for atmospheric conditions. This finding reveals the complexity of the height-MER relation that is difficult to constrain based on available heterogeneous observations, which reinforces the need for improved datasets to develop eruptive column models.

Plain Language Summary

Explosive volcanic eruptions expel gas and particles in the form of a volcanic column (or plume) that rises into the atmosphere. Two important metrics characterizing these eruptions are the maximum rise height and the eruptive intensity, i.e. the rate at which material is expelled from the eruptive vent. Understanding the relationship between these parameters is critical for reconstructing past volcanic events and managing hazards during volcanic crises. In this study, we use a new database of well-characterized eruptions to constrain simple relationships between column height and eruptive intensity. We distinguish four different measurements of column height: the maximum height reached by emitted particles from observations and from analysis of deposits, the height at which ash spreads in the atmosphere, and the height reached by volcanic sulfur gases. We show that each height category has a distinct relationship with the eruption intensity, enabling volcanologists and risk managers worldwide to use the relationship most appropriate to the measurements available to them. Despite the improved level of detail, our dataset cannot resolve any systematic influence of atmospheric conditions such as wind and humidity on eruption column height, highlighting that the second-order complexity of individual eruptions cannot be captured by simplified relationships.

1. Introduction

Mass eruption rate (MER) and eruptive column (also known as volcanic plume) height are critical for forecasting volcanic ash transport and dispersion during an eruption (e.g., Mastin et al., 2022). MER and height also help quantify the scale of an eruption (Newhall and Self, 1982; Carey and Sigurdsson, 1989; Crosweller et al., 2012). Although column height can often be directly observed, MER is more challenging to constrain (Pioli and Harris, 2019). Satellite, radar, cameras, or infrasound sensors have been used to directly estimate MER in near real-time (e.g., Bear-Crozier et al., 2020; Freret-Lorgeril et al., 2021; Mereu et al., 2022), but these pioneering applications are either not operational or limited to a few of the world's best-monitored volcanoes (e.g. Etna volcano, Italy). Therefore, computationally inexpensive empirical scaling relationships and one-dimensional (1D) eruptive column models remain the most common tools to estimate MER based on observed height. The scaling models are particularly widely applied owing to their simplicity.

The canonical scaling model is an empirical power law relationship between MER and column height (Morton et al., 1956, Wilson et al., 1978; Sparks et al., 1997, Mastin et al., 2009). Development of these empirical relationships - and the validation of eruptive column models in general (e.g. 1D and 3D) - is limited by datasets with a narrow range of eruptive and atmospheric parameters, absent or sparse information on uncertainty, and the accidental use of dependent data, e.g., when MER is estimated from the column height itself. To address these issues, the Eruption Source Parameters working group of the Commission on Tephra Hazard Modeling of the International Association of Volcanology and Chemistry of the Earth's Interior (IAVCEI) developed the Independent Volcanic Eruption Source Parameter Archive (IVESPA, Aubry et al. 2021). Here, we use IVESPA to explore new empirical relationships between MER and the height of both tephra and SO_2 eruption columns. We also compare these results with analytical scaling models that account for atmospheric conditions.

2. Overview of IVESPA

We use version 1.0 of IVESPA (http://www.ivespa.co.uk/), which is described in Aubry et al. (2021). The database contains 134 eruptive events, i.e. eruption or eruption phases for which we have estimates of tephra fall deposit mass, eruption duration, atmospheric conditions, and

97   column height. Among these events, 111 are small- moderate, 18 are Subplinian and 5 are

98   Plinian (using the Bonadonna and Costa 2013 classification). IVESPA uses the following height

99   metrics (see sketch in Figure 2 in Aubry et al., 2021):

100 • H_{top} , the height of the top of the tephra column, available for 130 events

101 • H_{spr} , the spreading height of the tephra cloud, available for 41 events

102 • H_{SO2} , the height of SO_2 injection, available for 28 events.

103 The measurement techniques used to estimate heights (e.g., satellite, ground-based radar or lidar,

104 visual observations) are reported although a single best estimate based on all available

105 measurements is provided. Estimates of heights, mass of tephra, and duration are independent,

106 e.g. no tephra mass was estimated by inverting information from column height. We define the

107 MER as the mass of tephra fallout, derived from mapping the tephra fallout deposits and

108 empirical fitting of the thinning trends (e.g., Bonadonna and Costa, 2012), divided by the

109 eruptive event duration. As defined, MER is thus a time-averaged value, and we denote it $\overline{MER}$.

110 For consistency, IVESPA provides height estimates that are also aimed to be representative of a

111 time-averaged value, denoted by $\overline{H}_{top}$, $\overline{H}_{spr}$ and $\overline{H}_{so2}$.

112 IVESPA parameters are assigned uncertainties aimed to be representative of a 95% confidence

113 level. Both the best estimates and uncertainties are assigned an interpretation flag value between

114 0 (no interpretation) and 2 (significant interpretation of the data source(s)). Atmospheric profiles

115 from two climate reanalyses are provided and are time-averaged over each event duration.

116 IVESPA also contains vertically averaged (between the vent and $\overline{H}_{top}$) values of the horizontal

117 wind speed ($\overline{W}$) and stratification (Brunt-Väisälä frequency, $\overline{N}$). The mean value from both

118 atmospheric reanalyses is used as the best estimate, and their difference (halved) as the

119   uncertainty. Table S1 contains all parameters used in this study and their calculation is detailed

120   in Supporting Information S1 unless directly provided in IVESPA.

121   Top column heights are commonly estimated from deposits using isopleth contours (e.g. Carey

122   and Sparks, 1986), which are excluded from IVESPA. However, for this study we compile an

123   additional suite of top heights determined from isopleths, which are available for 18 eruptive

124   events in IVESPA. This enables us to test whether $\overline{MER}$-height relationships derived from

125   directly observed column heights are consistent with isopleth-derived heights. We denote

126   isopleth-derived heights $H_{iso,top}$ and do not bar the symbol because they are commonly

127   representative of the maximum rather than time-averaged column height (e.g., Burden et al.,

128   2011). For consistency, we use $H_{iso,top}$ estimated using the Carey and Sparks (1986) method

129   rather than more recent and comprehensive methods (Rossi et al., 2019) that account e.g. for

130   wind impact but have been applied to a limited number of events. Supporting Information S2 and

131   Table S2 provide detail on $H_{iso,top}$ data collection.

132   **3. Results**

133   **3.1 Empirical scaling relationships specific to different column height metrics**

134

Figure 1. $\overline{H}_{top}$ (a), $\overline{H}_{spr}$ (b), $\overline{H}_{SO2}$ (c) and $H_{iso,top}$ (d) as a function of $\overline{MER}$. Thick continuous

lines are the power law fit relationship between heights and $\overline{MER}$, with shading showing the

confidence interval, and the thin dashed lines showing the prediction interval. The confidence

interval reflects the uncertainty on the fitted model parameters and can be used to test if two

models are significantly different. The prediction interval reflects both the uncertainty on the

model parameters and the model error and should be used when making a prediction with the

model. All uncertainties are at the 95% confidence level. The bold dotted lines show the best

linear fit relationship between the logarithm $\overline{MER}$ and the logarithm of heights (logarithm refers

to base 10 logarithm in this study). Information on all newly calibrated fits are provided in

tabular form in Table S3. Panels e-f show comparison of the fit relationships for the four heights

145 considered, along with select relationships from previous studies (Wilson and Walker, 1987;

146 Mastin et al., 2009), for the power law (e) and log-linear (f) fits. Select events on panels a-d are

147 labelled using their IVESPA identifiers (see Table S1 for full details): BEZ=Bezymianny,

148 CHA=Chaitén, COT=Cotopaxi, ETN=Etna, HEL=St. Helens, MER=Merapi, NEV=Nevado del

149 Ruiz, PIN=Pinatubo, POP=Popocatépetl, STR=Stromboli.

150 Figure 1 a–d shows how $\overline{H}_{top}$ (a), $\overline{H}_{spr}$ (b), $\overline{H}_{so2}$ (c) and $H_{iso,top}$ (d) relate to $\overline{MER}$, and

151 corresponding empirical power law relationships using a least-squares fit. $\overline{MER}$ values in the

152 IVESPA database range from $2 \times 10^1 - 2 \times 10^8$ kg s^{-1} (median: 1.6×10^6 kg s^{-1}), which is a larger

153 range with a higher proportion of low-intensity events compared to previous studies (e.g., Mastin

154 et al. (2009) provide a $\overline{MER}$ range of $6 \times 10^3 - 2 \times 10^8$ kg s^{-1} with median of 10^7 kg s^{-1}). Defining

155 $\overline{MER}$ using the total mass of tephra (i.e., including pyroclastic density current contributions

156 instead of fallout only) results in lower coefficients of determination (R^2, Figure S1). For the

157 $\overline{MER} - \overline{H}_{top}$ fit constrained by 130 events, we find best-fit relationships between the $\overline{MER}$ in kg

158 s^{-1} and $\overline{H}_{top}$ in km above vent level (a.v.l.) of:

159 $\overline{H}_{top} = 0.345 \times \overline{MER}^{0.226}$ (Equation 1)

160 with the $\overline{MER}$ as independent variable, and

161 $\log(\overline{MER}) = 2.83 + 3.54 \times \log(\overline{H}_{top})$, equivalent to $\overline{H}_{top} = 0.159 \times \overline{MER}^{0.283}$ (Equation 2)

162 with $\overline{H}_{top}$ as the independent variable and using a log-linear fit. Parameters in Equation 1 are

163 most sensitive to events with high $\overline{MER}$ values (Figure S2). Best fits for all other types of height

164 are provided in Figure 1 e–f and Table S3, which aims to facilitate use of our new empirical fits,

165 in particular by Volcanic Ash Advisory Centres (VAACs) and Volcano Observatories (VOs).

166 With the exception of $H_{iso,top}$, log-linear fits obtained using any of the considered heights as the

167 independent variable predict significantly lower heights for low $\overline{MER}$ and significantly higher

168   heights for high $\overline{MER}$ compared to equivalent power law fits calibrated with the $\overline{MER}$ as the

169   independent variable (Figure 1.a-d).

170   Figures 1 e–f highlight important differences between empirical fits for different height metrics.

171   For a given $\overline{MER}$ value, the predicted $H_{iso,top}$ tends to be significantly higher than the predicted

172    $\overline{H}_{top}$ (average $H_{iso,top}/\overline{H}_{top}$ ratio across IVESPA events = 1.45, see Figure S3). This is consistent

173   with the expectation that isopleth-based height reflects an upper bound of the top height, whereas

174   IVESPA top heights aim to reflect a time-averaged value. In addition, the method of Carey and

175   Sparks (1986) tends to overestimate plume height in eruptions in significant wind (Rossi et al.,

176   2019). Unsurprisingly, predicted $\overline{H}_{spr}$ tends to be lower than predicted $\overline{H}_{top}$, with the average

177    $\overline{H}_{spr}/\overline{H}_{top}$ ratio of 0.76 in IVESPA matching exactly that predicted by theory for buoyant

178   plumes rising in quiescent stratified environments (Morton et al., 1956; Figure S3). Predicted

179    $\overline{H}_{top}$ and $\overline{H}_{SO2}$ are generally not significantly different (average $\overline{H}_{SO2}/\overline{H}_{top}$ ratio is 0.97 in

180   IVESPA, see Figure S3).

181   The widely used empirical scaling of Mastin et al. (2009) compares best with our $\overline{H}_{top}$ fit,

182   although it is closer to our $H_{iso,top}$ fit at high $\overline{MER}$s for the power law fit (Fig. 1.e). This finding

183   is not surprising as although the plume height type is unspecified in Mastin et al. (2009), most

184   heights in the literature generally reflect top height values, and Mastin et al. (2009) included

185   isopleth-based column heights in their compilation (unlike IVESPA). Although there are

186   statistically significant differences between the Mastin et al. (2009) and our new top height fits

187   (up to 15% for predicted $\overline{H}_{top}$ and up to 0.6 for predicted $\log(\overline{MER})$, i.e. a factor of 4 for $\overline{MER}$),

188   these differences are small relative to the prediction errors of these empirical laws. The relative

189   root mean squared error (RMSE) on $\overline{H}_{top}$ (predicted from $\overline{MER}$) is 53% for Equation 1, 57% for

190   Equation 2 and 60% for Mastin et al. (2009) (Figure S4.a). When using these relationships and

191   observed $\overline{H}_{top}$ to invert for $\overline{MER}$, duration or tephra fallout mass (Fig. S4.b-d), the RMSE on a

192   logarithmic scale is 0.81 for Equation 1, 0.76 for Equation 2 and 0.80 for Mastin et al. (2009).

193   The new empirical relationships for $\overline{H}_{top}$ (Equations 1-2) are thus broadly consistent with Mastin

194   et al. (2009). However, we show that the optimal parameter values of empirical scaling

195   relationships and corresponding predictions differ greatly depending on the height metric (i.e.

196    $\overline{H}_{top}, \overline{H}_{spr}, \overline{H}_{SO2}$ or $H_{iso,top}$).

3.2 Accounting for atmospheric conditions using analytical scaling models

198   Unlike the empirical relationships shown in Figure 1, several analytical (derived from buoyant

199   plume theory) scaling models explicitly account for atmospheric stratification ($\overline{N}$) and horizontal

200   wind speed $\overline{(W)}$. Here use IVESPA to evaluate five of these models (Morton et al., 1956,

201   Hewett et al., 1971, Degruyter and Bonadonna, 2012, Woodhouse et al., 2013 and Aubry et al.,

202   2017; see details in Table 1 and Supporting Text S3). Table 1 ("unweighted" column) provides

203   the adjusted R^2 when using the $\overline{MER}$ and atmospheric conditions as independent variables, and

204    $\overline{H}_{top}$ as the dependent variable. The only model that outperforms the empirical relationship

205   between $\overline{H}_{top}$ and $\overline{MER}$ (Equation 1, $R^2 = 0.67$) is another empirical power law between $\overline{H}_{top}$,

206    $\overline{MER}, \overline{N}$ and $\overline{W}$ ($R^2 = 0.75$). However, the obtained exponent for $\overline{N}$ is 1.1, meaning that higher

207   column heights are obtained for stronger stratification values, which is an unphysical result

208   (Morton et al., 1956). The analytical scaling models have R^2 values between 0.32 and 0.52, much

209   smaller than the empirical power law. This finding cannot be explained by the fact that we use

210   the same dataset to calibrate Equation 1 and calculate corresponding R^2 because the Mastin et al.

211   (2009) relationship also has a higher R^2 (0.62) than analytical scalings despite being calibrated

212   against a much smaller dataset (Aubry et al., 2021).

213   The poor performance of analytical scaling relationships could be explained by poorly

214   constrained parameter values in IVESPA, or the fact that specific eruptions dominate the

215   database. To explore these possibilities, in Table 1, we give different weight to events in the

216   database according to their characteristics (Supporting Information S4):

217   ● In column 4 ("Eruption"), we give the same weight to each eruption in IVESPA (e.g., the

218   18 events from the 1989-1990 Mt Redoubt eruption have the same weight as the two

219   events from the 1991 Mt. Pinatubo eruption).

220   ● In column 5 ("Uncertainty"), weights are inversely proportional to the uncertainty on the

221   observed and predicted $\overline{H}_{top}$ values for each event, the former being linked to $\overline{MER}$

222   uncertainty.

223   ● In column 6 ("Interpretation flag"), less weight is given to events that required significant

224   interpretation of the literature to attribute $\overline{H}_{top}$ and $\overline{MER}$ values.

225   ● In column 7 ("All"), the events are weighted according to the product of weights in

226   columns 4-6 to account for all three factors above.

227   We find that these weighting procedures do not change the main results: i) the empirical power

228   law fit between $\overline{H}_{top}$ and $\overline{MER}$ still outperforms the analytical scaling models in terms of R^2; and

229   ii) the best-performing model is still the empirical power law that includes $\overline{N}$ and $\overline{W}$ terms, and

230   gives a positive (unphysical) exponent for $\overline{N}$. When weighting the eruptive events by parameter

231   uncertainty, the performance of all scaling models improves, with greater improvement among

232   the analytical models accounting for atmospheric conditions. For example, the difference in R^2

233   values between the power-law fit and the best analytical scaling (Degruyter et al., 2012) when

234   applying all weighting procedures is 0.06, whereas it is 0.19 unweighted. For the power law fit,

235   the $\overline{MER}$ exponent varies between 0.21 and 0.25 depending on the weighting procedures applied

236   and is thus relatively robust. However, for more complex models, fit parameters are very

237   sensitive to the weighting. For example, the calibrated value of entrainment coefficient ratio β/α

238   in the Aubry et al. (2017) scaling model ranges between -0.43 (an unphysical value) and 4.4.

239   Laboratory studies suggest that the ratio of β/α should be 0.6- 20 (see Aubry and Jellinek, 2018,

240   and references therein). We note that the Hewett et al. (1971) scaling model consistently has the

241   smallest R^2 values, and we always find unphysical parameter values for the Woodhouse et al.

242 (2013) scaling model, possibly due to their use of a simplified linear wind profile (see Figure
243 S5).

248   parameter values deemed non-physical. For all other models, bold text highlights the one that has

249   the highest R^2 value.

250   **4. Discussion**

251   **4.1 Influence of atmospheric conditions**

252   Using 25 eruptive events, Mastin (2014) demonstrated that a 1D plume model accounting for

253   atmospheric conditions was not as good as an empirical power-law in predicting $\overline{MER}$ from

254   column height. Despite having improved data compilation methodologies and over 5 times more

255   events in IVESPA (Aubry et al., 2021), we reach similar conclusions as the simple $\overline{MER}$-$\overline{H}_{top}$

256   empirical power law outperforms analytical scaling models accounting for atmospheric

257   conditions (Table 1). To understand this result, we define the standardized $\overline{H}_{top}$ as the ratio of

258   the observed $\overline{H}_{top}$ to that predicted by Equation 1 (i.e. $\overline{H}_{top}/[0.0345\overline{MER}^{0.226}]$). This variable

259   expresses how high $\overline{H}_{top}$ is relative to the value expected from the $\overline{MER}$ alone. Figure 2a

260   suggests that the standardized $\overline{H}_{top}$ does not depend on the Brunt Väisälä frequency $\overline{N}$ in

261   IVESPA, whereas some of the results in Table 1 even suggest that $\overline{H}_{top}$ increases with $\overline{N}$

262   (empirical power-law with $\overline{N}$ and $\overline{W}$ terms). These results contradict theoretical and experimental

263   evidence that $\overline{H}_{top}$ should decrease in a more strongly stratified atmosphere (e.g. Morton et al.,

264   1956; Woods, 1988), and explain the poor performance of analytical scaling models in which

265    $\overline{H}_{top}$ is proportional to $\overline{N}^{-0.75}$ (Table 1). One potential explanation is that $\overline{N}$ generally increases

266   with altitude (Figure S5a) and in turn with $\overline{H}_{top}$ and $\overline{MER}$. If $\overline{N}$ is normalised for each event by

267   the value obtained from the average atmospheric profile across IVESPA (which removes the

268   dependence of $\overline{N}$ on vent and column altitude), it becomes negatively although insignificantly

269   correlated with the standardized $\overline{H}_{top}$ (Figure S6.a).

270   Figure 2b shows that the standardized top height decreases with stronger horizontal wind

271   speed $\overline{W}$, as expected from laboratory experiments (e.g., Hewett et al., 1971; Carazzo et al.,

272   2014) and a few well-observed eruptions (e.g., Poulidis et al., 2019). The two variables are not

273   significantly correlated despite the large range of $\overline{W}$ values in IVESPA (3–41 m s^{-1}). We also do

274 not detect any influence of relative humidity (Figure 3c), despite model predictions that the

275 atmospheric water vapour entrained into a volcanic plume and the associated latent heat and

276 buoyancy flux should boost $\overline{H}_{top}$ by over 5 km for small-moderate eruptions in a wet tropical

277 atmosphere (e.g., Woods, 1993; Glaze et al., 1997; Herzog et al., 1998; Tupper et al., 2009).

278 Although several studies have noted that tropical volcanic plumes commonly reach the

279 tropopause (e.g., Tupper and Wunderman, 2009; Carboni et al., 2016), without any constraint on

280 MER as in this study, the role of humidity can only be speculated. Removing the influence of

281 altitude on $\overline{W}$ and relative humidity (Figure S5) only marginally increases their apparent

282 influence on the standardized top height (Figure S6).

283 Last, we tested the influence of volcanic plume morphology (i.e., weak, bent-over and spreading

284 downwind only, versus strong, spreading both upwind and downwind). This parameter is

285 explicitly constrained for 44 events in IVESPA, so we complement it by calculating

286 $\Pi = \left(\dfrac{\alpha}{\beta}\right)^2 \dfrac{\overline{H}_{top}\,\overline{N}}{1.8\,\overline{W}}$ (Equation 3)

287 for each event. Π is a non-dimensional parameter defined by the ratio of the wind entrainment

288 and plume rise timescales (Degruyter and Bonadonna, 2012) and has been shown to relate to the

289 plume morphology for a handful of eruptions (e.g., Bonadonna et al., 2015b). We use α=0.1 and

290 β=0.55 (Aubry and Jellinek, 2018) in Equation 3. Π values in IVESPA range from 0.02 to 1.1

291 with weak plumes associated with lower values. Both types of plumes are found for $0.03 < \Pi <$

292 0.35 (Figures 2d and S3), suggesting a transition from weak to strong plumes at a critical value

293 of $\Pi \approx 0.1$, in agreement with the values used operationally at Mount Etna (Scollo et al., 2019).

294 Despite the absence of any clear relationship between the standardized $\overline{H}_{top}$ and Π in Fig. 2d, the

295 variables are significantly correlated, which hints to a small but discernible influence of the

296 plume morphology on the $\overline{H}_{top}$ - $\overline{MER}$ relationship.

297

Figure 2. Standardized $\overline{H}_{top}$ (i.e. ratio of observed $\overline{H}_{top}$ and that predicted by Equation 1 based

299 on $\overline{MER}$ value) plotted as a function of $\overline{N}$ (a), $\overline{W}$ (b), average relative humidity (c), and Π (d).

300 Linear trends are highlighted by the dotted dashed lines with correlation coefficient r annotated

301   on each panel (bold if significant at the 95% confidence level). GRI= Grímsvötn,

302   MIY=Miyakejima, RED=Redoubt; see Figure 1 for other acronyms.

4.2 Influence of location and column height measurement technique

304   Figure 3a shows the distribution of standardized $\overline{H}_{top}$ for 10 geographical regions. Across these

305   regions, the median standardized $\overline{H}_{top}$ varies between 0.72 and 1.24, i.e. the median $\overline{H}_{top}$ differs

306   from the median value predicted using Equation 1 by -28% (Redoubt) to +24% (Central

307   America). The distributions of standardized $\overline{H}_{top}$ for these two regions significantly differ

308   compared to all other regions. Differences across the 10 considered regions might reflect a range

309   of factors including atmospheric conditions or the prevalence of certain magma or edifice types.

310   Non-physical factors might also be at play, e.g. the prevalence of island volcanoes which would

311   affect tephra fallout mass and $\overline{MER}$ estimates due to limited deposition on land. Even when

312   subdivided into 10 geographical areas, most still contain 10-24 events. We can thus calibrate

313   region or volcano-specific $\overline{H}_{top}$ - $\overline{MER}$ relationships and show select examples in Figure 3.c.

314   Figure 3.b shows the distribution of standardized $\overline{H}_{top}$ for 8 different combinations of

315   measurement technique used to measure $\overline{H}_{top}$. Standardized $\overline{H}_{top}$ issued from satellite-only

316   measurements or a combination of satellite and ground-based instrumental measurements (e.g.,

317   radar) are higher than for other measurement techniques (p-value<0.1), consistent with Tupper

318   and Wunderman (2009). In contrast, when visual measurements (ground or aircraft) were used

319   alone or in combination with satellite imagery, the standardized $\overline{H}_{top}$ tends to be lower (p-

320   value<0.15). Figure 3d shows that the unique $\overline{H}_{top}$ -$\overline{MER}$ relationships for these two categories

321   (satellite versus ground based measurements) differ significantly at most $\overline{MER}$ values, although

322   the predicted $\overline{H}_{top}$ differ at most by 2 km for $\overline{MER}<10^8$ kg/s. The dependence of standardized

323    $\overline{H}_{top}$ on other parameters was explored with examples for duration and median grain size shown

324   in Figure S7. The 17 events with a duration smaller than 10 times the plume rise timescale tend

325   to have smaller standardized $\overline{H}_{top}$ (Figure S7.a) but giving these short-duration events less

326   weights does not change Table 1 results.

327   Last, for each sub-category shown in Figure 3a and 3b, we annotate the correlation coefficient

328   between the logarithm of the standardized $\overline{H}_{top}$ and that of the wind speed $\overline{W}$. This correlation is

329   only significant for the subgroup of satellite and ground-based $\overline{H}_{top}$ measurement ($r = -0.87$).

330   Negative correlations are expected, but we find a positive correlation for some event groups, e.g.,

331   for Icelandic eruptions ($r = 0.34$, Figure 3.a). This finding further emphasises the difficulty of

332   detecting atmospheric influence on the $\overline{H}_{top}$-$\overline{MER}$ relationship in IVESPA v1.0.

333

Figure 3. Distribution of the standardized $\overline{H}_{top}$ for specific volcanic regions (a) or $\overline{H}_{top}$

measurement techniques (b). Box plots show the minimum, quartiles, and maximum values.

336   Three values are annotated for each subgroup: the number of events (n), the p-value resulting

337   from a Mann-Whitney U-test testing the probability that values from the subgroup differ

338   significantly from the values from all other subgroups (p), and the correlation coefficient

339   between the logarithm of the standardized $\overline{H}_{top}$ and the logarithm of $\overline{W}$ (r, in bold if significant

340   at the 95% level). Panels c-d are similar to Figure 1.a, but show $\overline{H}_{top}$ -$\overline{MER}$ power law fits

341   calibrated for select subgroups of regions (c) or measurement techniques (d). CNG= Cerro

342   Negro, SHM= Soufrière Hills Montserrat; see Figures 1-2 for other labels.

343   **4.3 Measuring eruptions for estimating MER-H relationships**

344   The challenging detection of atmospheric influences on the MER-column height relationship in

345   IVESPA v1.0 may be due to the use of 0D scaling models, and future studies could investigate

346   application of more sophisticated eruptive column models (e.g.. 1D, 3D) or data analysis

347   techniques (e.g. machine learning) to IVESPA. However, our study hints at developments of

348   IVESPA, and eruptive data more generally, that will help build a better understanding of the

349   relationship between MER and column height. First, Figure 3.b shows that future versions of

350   IVESPA should separate column heights according to measurement type instead of providing

351   one height value and a list of measurements type used to derive it. Second, Figure 3.a and other

352   studies suggest that compiling information such as magma composition or type (e.g. Trancoso et

353   al., 2022) and conduit information (e.g. Gouhier et al., 2019) would help constrain other factors

354   modulating the relationship between height and MER. In terms of atmospheric conditions, one

355   open question is how well large-scale reanalysis datasets resolve meterological variability at the

356   scale of volcanic edifices. Last, a challenging question is whether the use of time-averaged

357   eruption source parameters enable detection of atmospheric influence on plume dynamics in a

358   database with such a variety of eruptions. Advances in near real-time measurements of MER

359   (Caudron et al., 2015; Freret-Lorgeril et al., 2018, 2021; Bear-Crozier et al., 2020; Mereu et al.

360   2022) might unlock the potential to provide time series of parameters for both height and MER

361   for many events. Such collection of time series would provide a step change in assessing MER –

362   column height relationships.

5 Conclusions

364   We used the new Independent Volcanic Eruption Source Parameter Archive (IVESPA, Aubry et

365   al., 2021) to explore the empirical power law relationship linking eruptive column height to

366   MER. A key improvement over previous work is that our new relationships are specific to the

367   type of column height considered, i.e. the height of the SO_2 cloud ($\overline{H}_{SO2}$), the spreading height of

368   the tephra cloud ($\overline{H}_{spr}$), and the top height of the ash cloud directly measured ($\overline{H}_{top}$) or derived

369   from the deposit ($H_{iso,top}$) with significant differences among these four metrics (Figure 1 and

370   S3). We recommend that users such as VAACs or VOs apply the relationship most adapted to

371   their available height measurement type, and we provide extensive details on each calibrated

372   relationship and their uncertainties in Table S3. The newly calibrated power law relationship

373   between $\overline{H}_{top}$ and $\overline{MER}$ (Equation 1) still results in discrepancies of 50% for predicted $\overline{H}_{top}$, and

374   a factor of ~6 for predicted $\overline{MER}$ (Figures 1 and S4). Despite such large discrepancies, this

375   empirical power law outperforms analytical scaling models accounting for atmospheric

376   conditions (Table 1). This is an interesting result given the extensive body of literature

377   describing the influence of wind, humidity, and atmospheric stratification on eruption column

378   behaviour. Our inability to detect a statistically significant influence of these atmospheric

379   properties on column heights in the improved database suggests several possibilities. First,

380   further improvements to IVESPA might be needed such as better consistency and distinctions in

381   methods used to estimate $\overline{H}_{top}$ (e.g. satellite, radar, visual) and $\overline{MER}$ (e.g. empirical model used

382   to fit thinning trends). Second, analysis of the $\overline{H}_{top}$-$\overline{MER}$ relationship using more sophisticated

383   models than scaling relationships, such as 1D and 3D plume models, may be required. And third,

384   we may simply be identifying an inherent limitation in the accuracy with which we capture time-

385   averaged plume heights or erupted mass by deposit mapping. In other words, defining a

386   relationship based on widely varying magmatic conditions, eruption styles, atmospheric

387 conditions, and measurement techniques helps reveal first-order controls on column height, but
388 obscures the nuances of eruption behaviour that are apparent on a case-by-case basis.

Open Research

404 All data used in this study is available from the Independent Volcanic Eruption Source Parameter
405 Archive (IVESPA) Version 1.0 at http://ivespa.co.uk/data.html . IVESPA is curated by the
406 IAVCEI Commission on Tephra Hazard Modelling and supported by the British Geological
407 Survey.

30   **Key Points:**

31   - Using 134 volcanic events, we constrain empirical scaling relationships between mass
32   eruption rate and four metrics of column height

33   - We do not detect a clear influence of atmospheric stratification, wind, and humidity on
34   scaling relationships in this global database

35   - We discuss limitations of global data and discrepancies between scaling models and the
36   observed behavior of explosive eruptions in nature

37

Abstract

Relating the mass eruption rate (MER) of explosive eruptions to column height in the atmosphere is key to reconstructing past eruptions and forecasting volcanic hazards. Using 134 eruptive events from the Independent Volcanic Eruption Source Parameter Archive (IVESPA v1.0), we explore the canonical MER-height relationship for four measures of column height: spreading level, sulfur dioxide height, and top height from both directly observed plumes and those reconstructed from deposits. These relationships show significant differences and should be chosen carefully for operational and research applications. The roles of atmospheric stratification, wind, and humidity remain challenging to assess across the large range of eruptive conditions in this database, ultimately resulting in empirical relationships outperforming analytical models that account for atmospheric conditions. This finding reveals the complexity of the height-MER relation that is difficult to constrain based on available heterogeneous observations, which reinforces the need for improved datasets to develop eruptive column models.

Plain Language Summary

Explosive volcanic eruptions expel gas and particles in the form of a volcanic column (or plume) that rises into the atmosphere. Two important metrics characterizing these eruptions are the maximum rise height and the eruptive intensity, i.e. the rate at which material is expelled from the eruptive vent. Understanding the relationship between these parameters is critical for reconstructing past volcanic events and managing hazards during volcanic crises. In this study, we use a new database of well-characterized eruptions to constrain simple relationships between column height and eruptive intensity. We distinguish four different measurements of column height: the maximum height reached by emitted particles from observations and from analysis of deposits, the height at which ash spreads in the atmosphere, and the height reached by volcanic sulfur gases. We show that each height category has a distinct relationship with the eruption intensity, enabling volcanologists and risk managers worldwide to use the relationship most appropriate to the measurements available to them. Despite the improved level of detail, our dataset cannot resolve any systematic influence of atmospheric conditions such as wind and humidity on eruption column height, highlighting that the second-order complexity of individual eruptions cannot be captured by simplified relationships.

68   **1. Introduction**

69   Mass eruption rate (MER) and eruptive column (also known as volcanic plume) height are

70   critical for forecasting volcanic ash transport and dispersion during an eruption (e.g., Mastin et

71   al., 2022). MER and height also help quantify the scale of an eruption (Newhall and Self, 1982;

72   Carey and Sigurdsson, 1989; Crosweller et al., 2012). Although column height can often be

73   directly observed, MER is more challenging to constrain (Pioli and Harris, 2019). Satellite, radar,

74   cameras, or infrasound sensors have been used to directly estimate MER in near real-time (e.g.,

75   Bear-Crozier et al., 2020; Freret-Lorgeril et al., 2021; Mereu et al., 2022), but these pioneering

76   applications are either not operational or limited to a few of the world's best-monitored

77   volcanoes (e.g. Etna volcano, Italy). Therefore, computationally inexpensive empirical scaling

78   relationships and one-dimensional (1D) eruptive column models remain the most common tools

79   to estimate MER based on observed height. The scaling models are particularly widely applied

80   owing to their simplicity.

81   The canonical scaling model is an empirical power law relationship between MER and column

82   height (Morton et al., 1956, Wilson et al., 1978; Sparks et al., 1997, Mastin et al., 2009).

83   Development of these empirical relationships - and the validation of eruptive column models in

84   general (e.g. 1D and 3D) - is limited by datasets with a narrow range of eruptive and atmospheric

85   parameters, absent or sparse information on uncertainty, and the accidental use of dependent

86   data, e.g., when MER is estimated from the column height itself. To address these issues, the

87   Eruption Source Parameters working group of the Commission on Tephra Hazard Modeling of

88   the International Association of Volcanology and Chemistry of the Earth's Interior (IAVCEI)

89   developed the Independent Volcanic Eruption Source Parameter Archive (IVESPA, Aubry et al.

90   2021). Here, we use IVESPA to explore new empirical relationships between MER and the

91   height of both tephra and SO_2 eruption columns. We also compare these results with analytical

92   scaling models that account for atmospheric conditions.

93   **2. Overview of IVESPA**

94   We use version 1.0 of IVESPA (http://www.ivespa.co.uk/), which is described in Aubry et al.

95   (2021). The database contains 134 eruptive events, i.e. eruption or eruption phases for which we

96   have estimates of tephra fall deposit mass, eruption duration, atmospheric conditions, and

97   column height. Among these events, 111 are small- moderate, 18 are Subplinian and 5 are

98   Plinian (using the Bonadonna and Costa 2013 classification). IVESPA uses the following height

99   metrics (see sketch in Figure 2 in Aubry et al., 2021):

100   • H_{top}, the height of the top of the tephra column, available for 130 events

101   • H_{spr}, the spreading height of the tephra cloud, available for 41 events

102   • H_{SO2}, the height of SO_2 injection, available for 28 events.

103   The measurement techniques used to estimate heights (e.g., satellite, ground-based radar or lidar,

104   visual observations) are reported although a single best estimate based on all available

105   measurements is provided. Estimates of heights, mass of tephra, and duration are independent,

106   e.g. no tephra mass was estimated by inverting information from column height. We define the

107   MER as the mass of tephra fallout, derived from mapping the tephra fallout deposits and

108   empirical fitting of the thinning trends (e.g., Bonadonna and Costa, 2012), divided by the

109   eruptive event duration. As defined, MER is thus a time-averaged value, and we denote it $\overline{MER}$.

110   For consistency, IVESPA provides height estimates that are also aimed to be representative of a

111   time-averaged value, denoted by $\overline{H}_{top}$, $\overline{H}_{spr}$ and $\overline{H}_{so2}$.

112   IVESPA parameters are assigned uncertainties aimed to be representative of a 95% confidence

113   level. Both the best estimates and uncertainties are assigned an interpretation flag value between

114   0 (no interpretation) and 2 (significant interpretation of the data source(s)). Atmospheric profiles

115   from two climate reanalyses are provided and are time-averaged over each event duration.

116   IVESPA also contains vertically averaged (between the vent and $\overline{H}_{top}$) values of the horizontal

117   wind speed ($\overline{W}$) and stratification (Brunt-Väisälä frequency, $\overline{N}$). The mean value from both

118   atmospheric reanalyses is used as the best estimate, and their difference (halved) as the

119 uncertainty. Table S1 contains all parameters used in this study and their calculation is detailed

120 in Supporting Information S1 unless directly provided in IVESPA.

121 Top column heights are commonly estimated from deposits using isopleth contours (e.g. Carey

122 and Sparks, 1986), which are excluded from IVESPA. However, for this study we compile an

123 additional suite of top heights determined from isopleths, which are available for 18 eruptive

124 events in IVESPA. This enables us to test whether $\overline{\text{MER}}$-height relationships derived from

125 directly observed column heights are consistent with isopleth-derived heights. We denote

126 isopleth-derived heights $H_{iso,top}$ and do not bar the symbol because they are commonly

127 representative of the maximum rather than time-averaged column height (e.g., Burden et al.,

128 2011). For consistency, we use $H_{iso,top}$ estimated using the Carey and Sparks (1986) method

129 rather than more recent and comprehensive methods (Rossi et al., 2019) that account e.g. for

130 wind impact but have been applied to a limited number of events. Supporting Information S2 and

131 Table S2 provide detail on $H_{iso,top}$ data collection.

132 **3. Results**

133 **3.1 Empirical scaling relationships specific to different column height metrics**

134

Figure 1. $\overline{H}_{top}$ (a), $\overline{H}_{spr}$ (b), $\overline{H}_{SO2}$ (c) and $H_{iso,top}$ (d) as a function of $\overline{MER}$. Thick continuous

lines are the power law fit relationship between heights and $\overline{MER}$, with shading showing the

confidence interval, and the thin dashed lines showing the prediction interval. The confidence

interval reflects the uncertainty on the fitted model parameters and can be used to test if two

models are significantly different. The prediction interval reflects both the uncertainty on the

model parameters and the model error and should be used when making a prediction with the

model. All uncertainties are at the 95% confidence level. The bold dotted lines show the best

linear fit relationship between the logarithm $\overline{MER}$ and the logarithm of heights (logarithm refers

to base 10 logarithm in this study). Information on all newly calibrated fits are provided in

tabular form in Table S3. Panels e-f show comparison of the fit relationships for the four heights

145   considered, along with select relationships from previous studies (Wilson and Walker, 1987;

146   Mastin et al., 2009), for the power law (e) and log-linear (f) fits. Select events on panels a-d are

147   labelled using their IVESPA identifiers (see Table S1 for full details): BEZ=Bezymianny,

148   CHA=Chaitén, COT=Cotopaxi, ETN=Etna, HEL=St. Helens, MER=Merapi, NEV=Nevado del

149   Ruiz, PIN=Pinatubo, POP=Popocatépetl, STR=Stromboli.

150   Figure 1 a–d shows how $\overline{H}_{top}$ (a), $\overline{H}_{spr}$ (b), $\overline{H}_{so2}$ (c) and $H_{iso,top}$ (d) relate to $\overline{MER}$, and

151   corresponding empirical power law relationships using a least-squares fit. $\overline{MER}$ values in the

152   IVESPA database range from 2×10^1–2×10^8 kg s^{-1} (median: 1.6×10^6 kg s^{-1}), which is a larger

153   range with a higher proportion of low-intensity events compared to previous studies (e.g., Mastin

154   et al. (2009) provide a $\overline{MER}$ range of 6×10^3–2×10^8 kg s^{-1} with median of 10^7 kg s^{-1}). Defining

155    $\overline{MER}$ using the total mass of tephra (i.e., including pyroclastic density current contributions

156   instead of fallout only) results in lower coefficients of determination (R^2, Figure S1). For the

157    $\overline{MER} - \overline{H}_{top}$ fit constrained by 130 events, we find best-fit relationships between the $\overline{MER}$ in kg

158   s^{-1} and $\overline{H}_{top}$ in km above vent level (a.v.l.) of:

159    $\overline{H}_{top} = 0.345 \times \overline{MER}^{0.226}$ (Equation 1)

160   with the $\overline{MER}$ as independent variable, and

161    $\log(\overline{MER}) = 2.83 + 3.54 \times \log(\overline{H}_{top})$, equivalent to $\overline{H}_{top} = 0.159 \times \overline{MER}^{0.283}$ (Equation 2)

162   with $\overline{H}_{top}$ as the independent variable and using a log-linear fit. Parameters in Equation 1 are

163   most sensitive to events with high $\overline{MER}$ values (Figure S2). Best fits for all other types of height

164   are provided in Figure 1 e–f and Table S3, which aims to facilitate use of our new empirical fits,

165   in particular by Volcanic Ash Advisory Centres (VAACs) and Volcano Observatories (VOs).

166   With the exception of $H_{iso,top}$, log-linear fits obtained using any of the considered heights as the

167   independent variable predict significantly lower heights for low $\overline{MER}$ and significantly higher

168   heights for high $\overline{\text{MER}}$ compared to equivalent power law fits calibrated with the $\overline{\text{MER}}$ as the

169   independent variable (Figure 1.a-d).

170   Figures 1 e–f highlight important differences between empirical fits for different height metrics.

171   For a given $\overline{\text{MER}}$ value, the predicted $H_{\text{iso,top}}$ tends to be significantly higher than the predicted

172    $\overline{H}_{\text{top}}$ (average $H_{\text{iso,top}}/\overline{H}_{\text{top}}$ ratio across IVESPA events = 1.45, see Figure S3). This is consistent

173   with the expectation that isopleth-based height reflects an upper bound of the top height, whereas

174   IVESPA top heights aim to reflect a time-averaged value. In addition, the method of Carey and

175   Sparks (1986) tends to overestimate plume height in eruptions in significant wind (Rossi et al.,

176   2019). Unsurprisingly, predicted $\overline{H}_{\text{spr}}$ tends to be lower than predicted $\overline{H}_{\text{top}}$, with the average

177    $\overline{H}_{\text{spr}}/\overline{H}_{\text{top}}$ ratio of 0.76 in IVESPA matching exactly that predicted by theory for buoyant

178   plumes rising in quiescent stratified environments (Morton et al., 1956; Figure S3). Predicted

179    $\overline{H}_{\text{top}}$ and $\overline{H}_{\text{SO2}}$ are generally not significantly different (average $\overline{H}_{\text{SO2}}/\overline{H}_{\text{top}}$ ratio is 0.97 in

180   IVESPA, see Figure S3).

181   The widely used empirical scaling of Mastin et al. (2009) compares best with our $\overline{H}_{\text{top}}$ fit,

182   although it is closer to our $H_{\text{iso,top}}$ fit at high $\overline{\text{MER}}$s for the power law fit (Fig. 1.e). This finding

183   is not surprising as although the plume height type is unspecified in Mastin et al. (2009), most

184   heights in the literature generally reflect top height values, and Mastin et al. (2009) included

185   isopleth-based column heights in their compilation (unlike IVESPA). Although there are

186   statistically significant differences between the Mastin et al. (2009) and our new top height fits

187   (up to 15% for predicted $\overline{H}_{\text{top}}$ and up to 0.6 for predicted log($\overline{\text{MER}}$), i.e. a factor of 4 for $\overline{\text{MER}}$),

188   these differences are small relative to the prediction errors of these empirical laws. The relative

189   root mean squared error (RMSE) on $\overline{H}_{\text{top}}$ (predicted from $\overline{\text{MER}}$) is 53% for Equation 1, 57% for

190   Equation 2 and 60% for Mastin et al. (2009) (Figure S4.a). When using these relationships and

191   observed $\overline{H}_{\text{top}}$ to invert for $\overline{\text{MER}}$, duration or tephra fallout mass (Fig. S4.b-d), the RMSE on a

192   logarithmic scale is 0.81 for Equation 1, 0.76 for Equation 2 and 0.80 for Mastin et al. (2009).

193   The new empirical relationships for $\overline{H}_{\text{top}}$ (Equations 1-2) are thus broadly consistent with Mastin

194   et al. (2009). However, we show that the optimal parameter values of empirical scaling

195   relationships and corresponding predictions differ greatly depending on the height metric (i.e.

196    $\overline{H}_{top}$, $\overline{H}_{spr}$, $\overline{H}_{SO2}$ or $H_{iso,top}$).

3.2 Accounting for atmospheric conditions using analytical scaling models

198   Unlike the empirical relationships shown in Figure 1, several analytical (derived from buoyant

199   plume theory) scaling models explicitly account for atmospheric stratification ($\overline{N}$) and horizontal

200   wind speed $\overline{(W)}$. Here use IVESPA to evaluate five of these models (Morton et al., 1956,

201   Hewett et al., 1971, Degruyter and Bonadonna, 2012, Woodhouse et al., 2013 and Aubry et al.,

202   2017; see details in Table 1 and Supporting Text S3). Table 1 ("unweighted" column) provides

203   the adjusted R^2 when using the $\overline{MER}$ and atmospheric conditions as independent variables, and

204    $\overline{H}_{top}$ as the dependent variable. The only model that outperforms the empirical relationship

205   between $\overline{H}_{top}$ and $\overline{MER}$ (Equation 1, $R^2 = 0.67$) is another empirical power law between $\overline{H}_{top}$,

206    $\overline{MER}$, $\overline{N}$ and $\overline{W}$ ($R^2 = 0.75$). However, the obtained exponent for $\overline{N}$ is 1.1, meaning that higher

207   column heights are obtained for stronger stratification values, which is an unphysical result

208   (Morton et al., 1956). The analytical scaling models have R^2 values between 0.32 and 0.52, much

209   smaller than the empirical power law. This finding cannot be explained by the fact that we use

210   the same dataset to calibrate Equation 1 and calculate corresponding R^2 because the Mastin et al.

211   (2009) relationship also has a higher R^2 (0.62) than analytical scalings despite being calibrated

212   against a much smaller dataset (Aubry et al., 2021).

213   The poor performance of analytical scaling relationships could be explained by poorly

214   constrained parameter values in IVESPA, or the fact that specific eruptions dominate the

215   database. To explore these possibilities, in Table 1, we give different weight to events in the

216   database according to their characteristics (Supporting Information S4):

- In column 4 ("Eruption"), we give the same weight to each eruption in IVESPA (e.g., the 18 events from the 1989-1990 Mt Redoubt eruption have the same weight as the two events from the 1991 Mt. Pinatubo eruption).

- In column 5 ("Uncertainty"), weights are inversely proportional to the uncertainty on the observed and predicted $\overline{H}_{top}$ values for each event, the former being linked to $\overline{MER}$ uncertainty.

- In column 6 ("Interpretation flag"), less weight is given to events that required significant interpretation of the literature to attribute $\overline{H}_{top}$ and $\overline{MER}$ values.

- In column 7 ("All"), the events are weighted according to the product of weights in columns 4-6 to account for all three factors above.

227   We find that these weighting procedures do not change the main results: i) the empirical power

228   law fit between $\overline{H}_{top}$ and $\overline{MER}$ still outperforms the analytical scaling models in terms of R^2; and

229   ii) the best-performing model is still the empirical power law that includes $\overline{N}$ and $\overline{W}$ terms, and

230   gives a positive (unphysical) exponent for $\overline{N}$. When weighting the eruptive events by parameter

231   uncertainty, the performance of all scaling models improves, with greater improvement among

232   the analytical models accounting for atmospheric conditions. For example, the difference in R^2

233   values between the power-law fit and the best analytical scaling (Degruyter et al., 2012) when

234   applying all weighting procedures is 0.06, whereas it is 0.19 unweighted. For the power law fit,

235   the $\overline{MER}$ exponent varies between 0.21 and 0.25 depending on the weighting procedures applied

236   and is thus relatively robust. However, for more complex models, fit parameters are very

237   sensitive to the weighting. For example, the calibrated value of entrainment coefficient ratio β/α

238   in the Aubry et al. (2017) scaling model ranges between -0.43 (an unphysical value) and 4.4.

239   Laboratory studies suggest that the ratio of β/α should be 0.6- 20 (see Aubry and Jellinek, 2018,

240   and references therein). We note that the Hewett et al. (1971) scaling model consistently has the

241   smallest R^2 values, and we always find unphysical parameter values for the Woodhouse et al.

242 (2013) scaling model, possibly due to their use of a simplified linear wind profile (see Figure
243 S5).

Table 1. Adjusted R^2 and calibrated parameter values for tested scaling models, for various weights applied to each IVESPA event (see sections 3.2 and S4). * indicate analytical models. Physical parameters V^*, W_s, W^* and β/α and functional expressions f_{D12}, f_{W13} and f_{A17} are provided in Supporting Information S3. Orange shading highlights models with calibrated

248   parameter values deemed non-physical. For all other models, bold text highlights the one that has

249   the highest R^2 value.

4. Discussion

4.1 Influence of atmospheric conditions

252   Using 25 eruptive events, Mastin (2014) demonstrated that a 1D plume model accounting for

253   atmospheric conditions was not as good as an empirical power-law in predicting $\overline{MER}$ from

254   column height. Despite having improved data compilation methodologies and over 5 times more

255   events in IVESPA (Aubry et al., 2021), we reach similar conclusions as the simple $\overline{MER}$-$\overline{H}_{top}$

256   empirical power law outperforms analytical scaling models accounting for atmospheric

257   conditions (Table 1). To understand this result, we define the standardized $\overline{H}_{top}$ as the ratio of

258   the observed $\overline{H}_{top}$ to that predicted by Equation 1 (i.e. $\overline{H}_{top}/[0.0345\overline{MER}^{0.226}]$). This variable

259   expresses how high $\overline{H}_{top}$ is relative to the value expected from the $\overline{MER}$ alone. Figure 2a

260   suggests that the standardized $\overline{H}_{top}$ does not depend on the Brunt Väisälä frequency $\overline{N}$ in

261   IVESPA, whereas some of the results in Table 1 even suggest that $\overline{H}_{top}$ increases with $\overline{N}$

262   (empirical power-law with $\overline{N}$ and $\overline{W}$ terms). These results contradict theoretical and experimental

263   evidence that $\overline{H}_{top}$ should decrease in a more strongly stratified atmosphere (e.g. Morton et al.,

264   1956; Woods, 1988), and explain the poor performance of analytical scaling models in which

265    $\overline{H}_{top}$ is proportional to $\overline{N}^{-0.75}$ (Table 1). One potential explanation is that $\overline{N}$ generally increases

266   with altitude (Figure S5a) and in turn with $\overline{H}_{top}$ and $\overline{MER}$. If $\overline{N}$ is normalised for each event by

267   the value obtained from the average atmospheric profile across IVESPA (which removes the

268   dependence of $\overline{N}$ on vent and column altitude), it becomes negatively although insignificantly

269   correlated with the standardized $\overline{H}_{top}$ (Figure S6.a).

270   Figure 2b shows that the standardized top height decreases with stronger horizontal wind

271   speed $\overline{W}$, as expected from laboratory experiments (e.g., Hewett et al., 1971; Carazzo et al.,

272   2014) and a few well-observed eruptions (e.g., Poulidis et al., 2019). The two variables are not

273   significantly correlated despite the large range of $\overline{W}$ values in IVESPA (3–41 m s^{-1}). We also do

274   not detect any influence of relative humidity (Figure 3c), despite model predictions that the

275   atmospheric water vapour entrained into a volcanic plume and the associated latent heat and

276   buoyancy flux should boost $\overline{H}_{top}$ by over 5 km for small-moderate eruptions in a wet tropical

277   atmosphere (e.g., Woods, 1993; Glaze et al., 1997; Herzog et al., 1998; Tupper et al., 2009).

278   Although several studies have noted that tropical volcanic plumes commonly reach the

279   tropopause (e.g., Tupper and Wunderman, 2009; Carboni et al., 2016), without any constraint on

280   MER as in this study, the role of humidity can only be speculated. Removing the influence of

281   altitude on $\overline{W}$ and relative humidity (Figure S5) only marginally increases their apparent

282   influence on the standardized top height (Figure S6).

283   Last, we tested the influence of volcanic plume morphology (i.e., weak, bent-over and spreading

284   downwind only, versus strong, spreading both upwind and downwind). This parameter is

285   explicitly constrained for 44 events in IVESPA, so we complement it by calculating

286    $\Pi = \left(\frac{\alpha}{\beta}\right)^2 \frac{\overline{H}_{top}\,\overline{N}}{1.8\,\overline{W}}$ (Equation 3)

287   for each event. Π is a non-dimensional parameter defined by the ratio of the wind entrainment

288   and plume rise timescales (Degruyter and Bonadonna, 2012) and has been shown to relate to the

289   plume morphology for a handful of eruptions (e.g., Bonadonna et al., 2015b). We use α=0.1 and

290   β=0.55 (Aubry and Jellinek, 2018) in Equation 3. Π values in IVESPA range from 0.02 to 1.1

291   with weak plumes associated with lower values. Both types of plumes are found for $0.03 < \Pi <$

292   0.35 (Figures 2d and S3), suggesting a transition from weak to strong plumes at a critical value

293   of $\Pi \approx 0.1$, in agreement with the values used operationally at Mount Etna (Scollo et al., 2019).

294   Despite the absence of any clear relationship between the standardized $\overline{H}_{top}$ and Π in Fig. 2d, the

295 variables are significantly correlated, which hints to a small but discernible influence of the

296 plume morphology on the $\overline{H}_{top}$ - $\overline{MER}$ relationship.

297

Figure 2. Standardized $\overline{H}_{top}$ (i.e. ratio of observed $\overline{H}_{top}$ and that predicted by Equation 1 based

299 on $\overline{MER}$ value) plotted as a function of $\overline{N}$ (a), $\overline{W}$ (b), average relative humidity (c), and Π (d).

300 Linear trends are highlighted by the dotted dashed lines with correlation coefficient r annotated

301   on each panel (bold if significant at the 95% confidence level). GRI= Grímsvötn,

302   MIY=Miyakejima, RED=Redoubt; see Figure 1 for other acronyms.

4.2 Influence of location and column height measurement technique

304   Figure 3a shows the distribution of standardized $\overline{H}_{top}$ for 10 geographical regions. Across these

305   regions, the median standardized $\overline{H}_{top}$ varies between 0.72 and 1.24, i.e. the median $\overline{H}_{top}$ differs

306   from the median value predicted using Equation 1 by -28% (Redoubt) to +24% (Central

307   America). The distributions of standardized $\overline{H}_{top}$ for these two regions significantly differ

308   compared to all other regions. Differences across the 10 considered regions might reflect a range

309   of factors including atmospheric conditions or the prevalence of certain magma or edifice types.

310   Non-physical factors might also be at play, e.g. the prevalence of island volcanoes which would

311   affect tephra fallout mass and $\overline{MER}$ estimates due to limited deposition on land. Even when

312   subdivided into 10 geographical areas, most still contain 10-24 events. We can thus calibrate

313   region or volcano-specific $\overline{H}_{top}$ - $\overline{MER}$ relationships and show select examples in Figure 3.c.

314   Figure 3.b shows the distribution of standardized $\overline{H}_{top}$ for 8 different combinations of

315   measurement technique used to measure $\overline{H}_{top}$. Standardized $\overline{H}_{top}$ issued from satellite-only

316   measurements or a combination of satellite and ground-based instrumental measurements (e.g.,

317   radar) are higher than for other measurement techniques (p-value<0.1), consistent with Tupper

318   and Wunderman (2009). In contrast, when visual measurements (ground or aircraft) were used

319   alone or in combination with satellite imagery, the standardized $\overline{H}_{top}$ tends to be lower (p-

320   value<0.15). Figure 3d shows that the unique $\overline{H}_{top}$ -$\overline{MER}$ relationships for these two categories

321   (satellite versus ground based measurements) differ significantly at most $\overline{MER}$ values, although

322   the predicted $\overline{H}_{top}$ differ at most by 2 km for $\overline{MER}<10^8$ kg/s. The dependence of standardized

323    $\overline{H}_{top}$ on other parameters was explored with examples for duration and median grain size shown

324   in Figure S7. The 17 events with a duration smaller than 10 times the plume rise timescale tend

325   to have smaller standardized $\overline{H}_{top}$ (Figure S7.a) but giving these short-duration events less

326   weights does not change Table 1 results.

Last, for each sub-category shown in Figure 3a and 3b, we annotate the correlation coefficient
between the logarithm of the standardized $\overline{H}_{top}$ and that of the wind speed $\overline{W}$. This correlation is
only significant for the subgroup of satellite and ground-based $\overline{H}_{top}$ measurement ($r = -0.87$).
Negative correlations are expected, but we find a positive correlation for some event groups, e.g.,
for Icelandic eruptions ($r = 0.34$, Figure 3.a). This finding further emphasises the difficulty of
detecting atmospheric influence on the $\overline{H}_{top}$-$\overline{MER}$ relationship in IVESPA v1.0.

Figure 3. Distribution of the standardized $\overline{H}_{top}$ for specific volcanic regions (a) or $\overline{H}_{top}$
measurement techniques (b). Box plots show the minimum, quartiles, and maximum values.

336   Three values are annotated for each subgroup: the number of events (n), the p-value resulting

337   from a Mann-Whitney U-test testing the probability that values from the subgroup differ

338   significantly from the values from all other subgroups (p), and the correlation coefficient

339   between the logarithm of the standardized $\overline{H}_{top}$ and the logarithm of $\overline{W}$ (r, in bold if significant

340   at the 95% level). Panels c-d are similar to Figure 1.a, but show $\overline{H}_{top}$ -$\overline{MER}$ power law fits

341   calibrated for select subgroups of regions (c) or measurement techniques (d). CNG= Cerro

342   Negro, SHM= Soufrière Hills Montserrat; see Figures 1-2 for other labels.

343   **4.3 Measuring eruptions for estimating MER-H relationships**

344   The challenging detection of atmospheric influences on the MER-column height relationship in

345   IVESPA v1.0 may be due to the use of 0D scaling models, and future studies could investigate

346   application of more sophisticated eruptive column models (e.g.. 1D, 3D) or data analysis

347   techniques (e.g. machine learning) to IVESPA. However, our study hints at developments of

348   IVESPA, and eruptive data more generally, that will help build a better understanding of the

349   relationship between MER and column height. First, Figure 3.b shows that future versions of

350   IVESPA should separate column heights according to measurement type instead of providing

351   one height value and a list of measurements type used to derive it. Second, Figure 3.a and other

352   studies suggest that compiling information such as magma composition or type (e.g. Trancoso et

353   al., 2022) and conduit information (e.g. Gouhier et al., 2019) would help constrain other factors

354   modulating the relationship between height and MER. In terms of atmospheric conditions, one

355   open question is how well large-scale reanalysis datasets resolve meterological variability at the

356   scale of volcanic edifices. Last, a challenging question is whether the use of time-averaged

357   eruption source parameters enable detection of atmospheric influence on plume dynamics in a

358   database with such a variety of eruptions. Advances in near real-time measurements of MER

359   (Caudron et al., 2015; Freret-Lorgeril et al., 2018, 2021; Bear-Crozier et al., 2020; Mereu et al.

360   2022) might unlock the potential to provide time series of parameters for both height and MER

361 for many events. Such collection of time series would provide a step change in assessing MER –
362 column height relationships.

5 Conclusions

364 We used the new Independent Volcanic Eruption Source Parameter Archive (IVESPA, Aubry et
365 al., 2021) to explore the empirical power law relationship linking eruptive column height to
366 MER. A key improvement over previous work is that our new relationships are specific to the
367 type of column height considered, i.e. the height of the SO_2 cloud ($\overline{H}_{SO2}$), the spreading height of
368 the tephra cloud ($\overline{H}_{spr}$), and the top height of the ash cloud directly measured ($\overline{H}_{top}$) or derived
369 from the deposit ($H_{iso,top}$) with significant differences among these four metrics (Figure 1 and
370 S3). We recommend that users such as VAACs or VOs apply the relationship most adapted to
371 their available height measurement type, and we provide extensive details on each calibrated
372 relationship and their uncertainties in Table S3. The newly calibrated power law relationship
373 between $\overline{H}_{top}$ and $\overline{MER}$ (Equation 1) still results in discrepancies of 50% for predicted $\overline{H}_{top}$, and
374 a factor of ~6 for predicted $\overline{MER}$ (Figures 1 and S4). Despite such large discrepancies, this
375 empirical power law outperforms analytical scaling models accounting for atmospheric
376 conditions (Table 1). This is an interesting result given the extensive body of literature
377 describing the influence of wind, humidity, and atmospheric stratification on eruption column
378 behaviour. Our inability to detect a statistically significant influence of these atmospheric
379 properties on column heights in the improved database suggests several possibilities. First,
380 further improvements to IVESPA might be needed such as better consistency and distinctions in
381 methods used to estimate $\overline{H}_{top}$ (e.g. satellite, radar, visual) and $\overline{MER}$ (e.g. empirical model used
382 to fit thinning trends). Second, analysis of the $\overline{H}_{top}$-$\overline{MER}$ relationship using more sophisticated
383 models than scaling relationships, such as 1D and 3D plume models, may be required. And third,
384 we may simply be identifying an inherent limitation in the accuracy with which we capture time-
385 averaged plume heights or erupted mass by deposit mapping. In other words, defining a
386 relationship based on widely varying magmatic conditions, eruption styles, atmospheric

387   conditions, and measurement techniques helps reveal first-order controls on column height, but

388   obscures the nuances of eruption behaviour that are apparent on a case-by-case basis.

Acknowledgments

Open Research

404   All data used in this study is available from the Independent Volcanic Eruption Source Parameter

405   Archive (IVESPA) Version 1.0 at http://ivespa.co.uk/data.html . IVESPA is curated by the

406   IAVCEI Commission on Tephra Hazard Modelling and supported by the British Geological

407   Survey.

Contents of this file

Text S1 to S4
Figures S1 to S7

Additional Supporting Information (Files uploaded separately)

Table S1. Data used in our study. Most parameters are directly taken from IVESPA version 1.0 (see https://ivespa.co.uk). Explanation on the other parameters is provided in supporting information S1-S2.

Table S2. Data compiled for isopleth height $H_{iso,top}$ estimates for IVESPA events.

Table S3. Data for empirical fits presented in Figure 1, including best fit relationships, and predictions and uncertainties for a range of $\overline{H}_{top}$ and $\overline{MER}$ values. The first sheet provides details on the following eight sheets, each of which is associated with a specific empirical fit

(four types of height, and either power law fit with $\overline{\text{MER}}$ as independent variable or log-linear fit with $\overline{\text{H}}_{\text{top}}$ as independent variable).

Introduction

This supporting information file provides details on all data derived from but not explicitly included in the IVESPA archive (S1) as well as isopleth-based height (S2). It also provides information on the analytical relationships considered in Table 1 (S3) and the fitness metrics used to compare them (S4). Figure S1-S8 mostly provide sensitivity tests on the calibration of the $\overline{\text{H}}_{\text{top}}$ - $\overline{\text{MER}}$ empirical fits, or on the dependence of the $\overline{\text{H}}_{\text{top}}$ residuals on atmospheric and eruption source parameters. This file also provides caption of additional supporting information tables (all in .xlsx format) which contain all the data used in our study (Table S1-S2) as well as information and data on all empirical fits presented in Figure 1 (Table S3).

S1. Additional parameters not explicitly provided in IVESPA

Mass eruption rate uncertainty

We define the $\overline{\text{MER}}$ as the mass of tephra fallout divided by eruption duration. For the former parameter, we only used estimates derived from mapping of the tephra fallout deposits and empirical fitting of the thinning trends. In IVESPA, unlike other parameters like height and duration, we allowed for different values of lower and upper bound uncertainty for the mass of tephra fallout because this parameter commonly shows strongly asymmetric probability distributions for its true value (Bonadonna et al., 2015c). Accordingly, in this study, we also provide a lower and upper bound uncertainty for $\overline{\text{MER}}$ which are calculated as:

$$\left(\frac{\Delta\overline{\text{MER}}_{l,u}}{\overline{\text{MER}}}\right)^2 = \left(\frac{\Delta M_{l,u}}{M}\right)^2 + \left(\frac{\Delta D}{D}\right)^2 \qquad (S.1)$$

Where Δ refers to the uncertainty, l and u subscript to the lower or upper bound uncertainty, and M and D are the mass of tephra fallout and duration, respectively.

Furthermore, we did not systematically assign an uncertainty to the mass of tephra fallout because uncertainty information on TEM in the published record is commonly not provided and hard to infer from contextual information. Accordingly, we do not attribute a $\overline{\text{MER}}$ uncertainty for events that do not have a tephra fallout mass uncertainty.

Atmospheric parameters

IVESPA contains time-averaged atmospheric profiles from two different atmospheric reanalysis families (i.e. produced either by the European Centre for Medium-Range Weather Forecasts or by the National Oceanic and Atmospheric Administration) for all events (see Aubry et al., 2021). The main IVESPA spreadsheet also contains derived atmospheric parameters, namely the vertically-averaged (between vent and top height) values of Brunt-Väisälä frequency and horizontal wind speed. For this study, we additionally calculate the following derived atmospheric parameters:

- Vertically averaged relative humidity: For each event, we interpolate relative humidity at 1000 regularly spaced altitudes using a piecewise cubic Hermite interpolating polynomial function, after removing non-attributed values for high altitudes for the NOAA reanalyses. We exclude all values at altitudes smaller than the vent height or higher than $\overline{H}_{top}$ (or $\overline{H}_{spr}$ if $\overline{H}_{top}$ is not constrained, or $\overline{H}_{SO2}$ if neither $\overline{H}_{top}$ nor $\overline{H}_{spr}$ are constrained), and calculate the average of remaining values.
- Vertically averaged wind shear ($\overline{\frac{dW}{dz}}$): We first interpolate horizontal wind speed values in the same way as relative humidity. We then calculate the absolute value of the vertical derivative of horizontal wind speed at each height, and calculate the vertically averaged value in the same way as relative humidity. The absolute value of the wind speed derivative with height is used because the magnitude of wind shear controls atmospheric stability and turbulence, and in turn potential impacts on entrainment in the volcanic column.
- Vent-level atmospheric properties: Vent-level atmospheric pressure, temperature and relative humidity are required to calculate the plume buoyancy flux (S5). We simply obtain these by interpolating corresponding atmospheric profiles at vent altitude for each event, using a piecewise cubic Hermite interpolating polynomial function. For atmospheric pressure, we interpolate the logarithm of pressure because pressure varies exponentially with altitude.

All these additional parameters are provided in Table S1. As for all other atmospheric parameters, we use the mean of the values obtained from the two reanalyses as the best estimate, and half of their difference as the uncertainty at 95% confidence level.

S2. Isopleth-based heights

Information on all isopleth-based height H_{iso} collected are provided in Table S2. The comment column summarizes information found in the literature and justifies any choice made in attributing a value to parameters in this table. The IVESPA ID columns shows the identifier of the IVESPA event to which a value of H_{iso} was attributed. When H_{iso} values of distinct units belonging to a single IVESPA event exist, we averaged these values. When a single H_{iso} value encompasses eruption phases that are distinct events in IVESPA, we attributed that same value to all corresponding IVESPA events.

Information on all found $H_{iso,top}$ estimates are reported in comment column of Table S2, but only estimates made using the Carey and Sparks (1986) method were used to constrain values of $H_{iso,top}$ used in our study. This ensures consistency in the isopleth-based height estimates used as more recent methods account more comprehensively for factors influencing the relationship between clast size measurement (used to build isopleth contour) and volcanic column height. For example, in comparison to Carey and Sparks (1986), Rossi et al. (2019) use exact (volcano-specific) atmospheric conditions, account for the effect of wind on plume dynamics, and improve parameterization of particle sedimentation among other advancements.

Isopleth-based height are measured relative to the altitude where the clasts were sampled, which can sometimes span a large range. Consequently, to obtain heights above sea (a.s.l.) and vent (a.v.l.) levels, the average height at which the clasts were sampled is required and reported in Table S2. Information on the average altitude at which clast were sampled is often not reported explicitly in the literature. In such cases, we made a rough estimate of this altitude by combining maps showing sample location, which are more often included in the literature, with topographic maps either included in the source reporting isopleth-based height or from the internet. In a few cases, authors do not report the sampling altitude but provide $H_{iso,top}$ relative to vent level. In

such cases and for convenience, we report a sampling altitude equal to the vent altitude and a plume height above sampling level equal to that above vent level found in the literature. These cases are clearly flagged in the comment column of table 2.

$H_{iso,top}$ uncertainties reported either correspond to uncertainties reported in the literature or assessed from the difference between estimates found in distinct sources (in all cases, using only information related to $H_{iso,top}$ estimates using the method of Carey and Sparks, 1986). In many cases, we could not provide any uncertainty estimates. In comparison to heights reported in IVESPA, $H_{iso,top}$ estimates were often constrained from a single reference, and no more than 2-3. They also did not undergo the same quality-control procedure as key eruption source parameters in IVESPA (i.e., two members of the IVESPA working group independently making estimates based on their own literature search before comparing their values and reaching a consensus). We thus expect that both the $H_{iso,top}$ best estimate and uncertainty are less reliable than other parameters reported in IVESPA.

S3. Scalings relating height and mass eruption rate

In table 1, we calibrate and compare the performance of eight different scalings relating $\overline{H}_{top}$ to the $\overline{MER}$. For four of them, the expressions are fully detailed in Table 1. Here we detail the expressions of the other three (Degruyter and Bonadonna, 2012; Woodhouse et al., 2013; Aubry et al., 2017), which all take the form

$$\overline{H}_{top} = a \times \overline{MER}^{0.25} \times \overline{N}^{-0.75} \times f \quad (S.2)$$

Where f is a function of atmospheric parameters, entrainment parameters and eruption source parameters, and a is a fit parameter.

We use a fit parameter a in equation S.2 instead of the published theoretical pre-factor values for these scalings because they are originally formulated using the plume buoyancy flux instead of $\overline{MER}$ (with these two parameters being proportional), because the prefactors might depend on poorly constrained entrainment coefficient values, and because the scalings were derived under idealized assumptions (e.g. point source, Boussinesq flow) not met for volcanic plumes. Consequently, it is unrealistic to expect theoretical prefactors to be realistic for our study.

In its original form, the Degruyter and Bonadonna (2012) scaling expresses $\overline{MER}$ as a 4th degree polynomial function of $\overline{H}_{top}$. There is no analytical solution for expressing $\overline{H}_{top}$ as a function of $\overline{MER}$ instead, but Aubry et al. (2017) shows that the numerical solution is well approximated ($R^2 > 0.99$) by Equation S.2 with:

$$f = f_{DB12} = \frac{1 + 0.17 \frac{\beta^2}{\alpha^{3/2}} V^* + 0.00061 \left(\frac{\beta^2}{\alpha^{3/2}} V^* \right)^2}{1 + 0.48 \frac{\beta^2}{\alpha^{3/2}} V^* + 0.0072 \left(\frac{\beta^2}{\alpha^{3/2}} V^* \right)^2} \quad (S.3) ,$$

where β is the wind entrainment coefficient, α is the radial entrainment coefficient, and $V^* = \frac{W}{(FN)^{1/4}}$ with F the plume buoyancy flux, W the vertically averaged wind speed, and N the vertically averaged Brunt Vaisala frequency. Because we only have constraints on $\overline{MER}$ for most

events in IVESPA, we calculate V^* as $\frac{W}{(MER\ N)^{1/4}}$ and f_{DB12} as $\frac{1+0.17b\ V^*+0.00061(b\ V^*)^2}{1+0.48b\ V^*+0.0072(b\ V^*)^2}$ where b is a parameter, proportional to $\frac{\beta^2}{\alpha^{3/2}}$ and to the ratio of the buoyancy flux to the mass eruption rate. We calibrate b as part of the fitting procedure and deem any negative value unphysical.

The Woodhouse et al. (2013) scaling follows Equation S.2 with:

$$f = f_{W13} = \frac{1+\left(0.87+0.5\frac{\beta}{\alpha}\right)W_s}{1+\left(1.09+0.32\frac{\beta}{\alpha}\right)W_s+\left(0.06+0.03\frac{\beta}{\alpha}\right)W_s^2}\ \ (S.4)\ ,$$

where $W_s = \frac{1}{N}\overline{\frac{dW}{dz}}$. With estimates of α and β ranging between 0.05-0.17 and 0.1-1 respectively (see Aubry et al., 2017, 2018 and references therein), the ratio $\frac{\beta}{\alpha}$ is expected to be between 0.59 and 20, and we deem any calibrated value outside 0.3-40 unphysical in Table 1.

Last, the Aubry et al. (2017) scaling follows Equation S.2 with

$$f = f_{A17} = \frac{1}{\sqrt{1+\frac{\beta}{\alpha}W^*}}\ \ (S.5)\ ,$$

where $W^* = \frac{\overline{W}}{U_0}$ with U_0 the column exit velocity at vent level. As for the Woodhouse et al. (2013) scaling, we deem any calibrated value of $\frac{\beta}{\alpha}$ outside 0.3-40 unphysical in Table 1. U_0 is constrained for only 10 events (out of 134) in IVESPA, but the exit water vapor fraction (n_0) and temperature (T_0) are known for 73 and 38 events respectively (Aubry et al., 2021). We thus use the model of Woods and Bower (1995) to calculate the exit velocity as $U_0 = 1.85\sqrt{Rn_0T_0}$ with R the specific gas constant (461.5 J/kg/K). For events with no constraint on n_0 or T_0, we use values of these parameters equal to the average for events for which they are constrained (i.e. 2.7 wt.% for n_0 and 1250 K for T_0).

S4. Scaling calibration, fitness metric and weights

We calibrate all scalings in Table 1 using Matlab non-linear regression model fit function fitnlm (https://uk.mathworks.com/help/stats/fitnlm.html) minimizing the coefficient of determination $R^2 = 1 - \frac{SSE}{SST}$ with SSE being the sum of squares error and SST the sum of squared total

(adjusted R^2 values, accounting for the number of independent variables in the models, are presented in Table 1). Furthermore, we use weights in SSE and SST calculations e.g.:

$$\text{SSE} = \sum_i w_i \left(y_i^{pred} - y_i^{obs} \right)^2 \quad \text{(S.6)}.$$

Where i denotes an IVESPA event, w the value of the weight, y^{pred} the model-predicted value of the dependent variable y and y^{obs} its observed value (in the case of Table 1, y is $\overline{H}_{top}$).Weights w are always normalized so that $\sum_i w_i = 1$, and for simplicity we omit this normalization in the following weight definitions (Equations S.7-S.10).

In column 3 of Table 1 (labeled "none"), there is no weight applied in R^2 calculation i.e.

$$w_i = 1 \quad \text{(S.7)}.$$

In column 4 of Table 1 (labeled "eruption"), we give the same weight to each eruption in IVESPA i.e.

$$w_i = \frac{1}{n_i} \quad \text{(S.8)},$$

where n_i is the number of IVESPA events belonging to the same eruption as event i. This prevents eruptions with many events from having disproportionate weights and biasing model calibration and comparison. For example, the Redoubt 1989-1990 eruption has 18 events, representing 14% of the IVESPA events with a top column height estimate.

In column 5 of Table 1 (labeled "uncertainty"), weights are inversely proportional to uncertainties on the difference between the observed and model-predicted height i.e.

$$\frac{1}{w_i} = \left(\Delta\overline{H}_{top} \right)^2 + \left(0.226 \times \frac{\Delta\overline{MER}}{\overline{MER}} \times \left(0.3448 \times \overline{MER}^{0.226} \right) \right)^2 \quad \text{(S.9)},$$

Where $\Delta\overline{H}_{top}$ is the uncertainty on the observed top height and the second term is our chosen expression for the squared uncertainty on the scaling-predicted top height. This definition enables less weight to be given to events with higher uncertainty on the observed height and that predicted by scalings from the $\overline{MER}$. The second term in equation S.9 should be specific to each scaling, e.g. the predicted top height uncertainty will depend on wind uncertainty for the Degruyter and Bonadonna (2012) scaling (Equation S.3), and it should also depend on the final expression of the model calibrated after fitting procedure. However, as we are comparing the different scaling models, the same set of weights should be applied to them all in calculating R^2 values, and prior knowledge of the weights are also needed for model calibration. As a simplification, the second term in Equation S.9 is thus the squared uncertainty on the empirical power-law fit obtained for top height with no weighting (i.e. $\overline{H}_{top} = 0.3448 \times \overline{MER}^{0.226}$) using standard error propagation rules. Simplifying assumptions also had to be made to calculate the error on the $\overline{MER}$, $\Delta\overline{MER}$, **using Equation S.1**. Given the different upper and lower bound error on the mass of tephra fallout, we calculate $\Delta M/M$ as the mean of relative errors calculated using

the lower and upper bounds. For events with no attributed lower and/or upper bound uncertainty on M, we assume a difference by a factor of 3 between the best estimate and the lower and/or upper bound estimate.

In column 6 of Table 1 (labeled "Flag"), weights are inversely proportional to the sum of the interpretation flags on the best estimates of $\overline{H}_{top}$ (I_H) and $\overline{MER}$ (chosen as the maximum of the interpretation flag on the best estimate of M and D, I_M and I_D) i.e.

$$\frac{1}{w_i} = 1 + I_H + \max(I_M, I_D) \quad (S.10).$$

Weight values in Equation S.10 can thus vary between 0.2 and 1 given interpretation flags take values between 0 (no interpretation) and 2 (significant interpretation). This definition enables less weight to be given to IVESPA events that required significant interpretation to define eruption source parameter values.

In column 7 of Table 1 (labeled "all"), the weights applied are the products of the weights for columns 4-6 (Equations S.8-10), enabling simultaneous application of lower weight to events that belong to the same eruptions, events that have large uncertainty and events that required significant literature interpretation during data collection.

Figure S1. $\overline{H}_{top}$ as a function of $\overline{MER}$ and corresponding power law fit for all IVESPA events with $\overline{MER}$ as an independent variable. In panel b, the $\overline{MER}$ is the same as throughout the manuscript i.e. it is calculated using the tephra fallout deposit mass. In panel a, the $\overline{MER}$ is calculated using the total tephra deposit mass, i.e. the sum of fallout and pyroclastic density current deposits.
Figure S2. $\overline{H_{top}}$ as a function of $\overline{MER}$ and corresponding power law fits with $\overline{MER}$ as an independent variable. The black dotted line shows the fit for all events from Figure 1.a. Coloured lines show the fit for specific subgroup of events determined: according to the $\overline{MER}$ value (a), or excluding events from specific volcanoes or from select high- $\overline{MER}$ eruptions with high uncertainties on $\overline{H_{top}}$ and/or $\overline{MER}$ (b).
Figure S3. Ratios $\overline{H_{spr}}/\overline{H_{top}}$ (a), $\overline{H_{SO2}}/\overline{H_{top}}$ (b), and $H_{iso,top}/\overline{H_{top}}$ (c) as a function of the Π parameter. The thick horizontal line show the mean ratio value and the dotted line shows the y=1

line. Blue circles, purple squares and yellow triangles correspond to weak, strong and unknown plume morphology.

Figure S4. Predicted vs observed $\overline{H}_{top}$ (a), $\overline{MER}$ (b), duration (c) and total erupted mass (TEM) (d) when using our new power law fit (dark blue circles), log-linear fit (light blue triangles) or Mastin et al. (2009) power law fit (red squares) to link $\overline{MER}$ and $\overline{H}_{top}$. Dotted lines show the 1:1 line. Panel a uses the $\overline{MER}$ as the independent variable, whereas panels b-d use $\overline{H}_{top}$ as the independent variable. In panel c, the observed tephra fallout mass is divided by the $\overline{H}_{top}$-derived $\overline{MER}$ to predict duration. In panel d, the $\overline{H}_{top}$-derived $\overline{MER}$ is multiplied by the observed duration to predict tephra fallout mass.
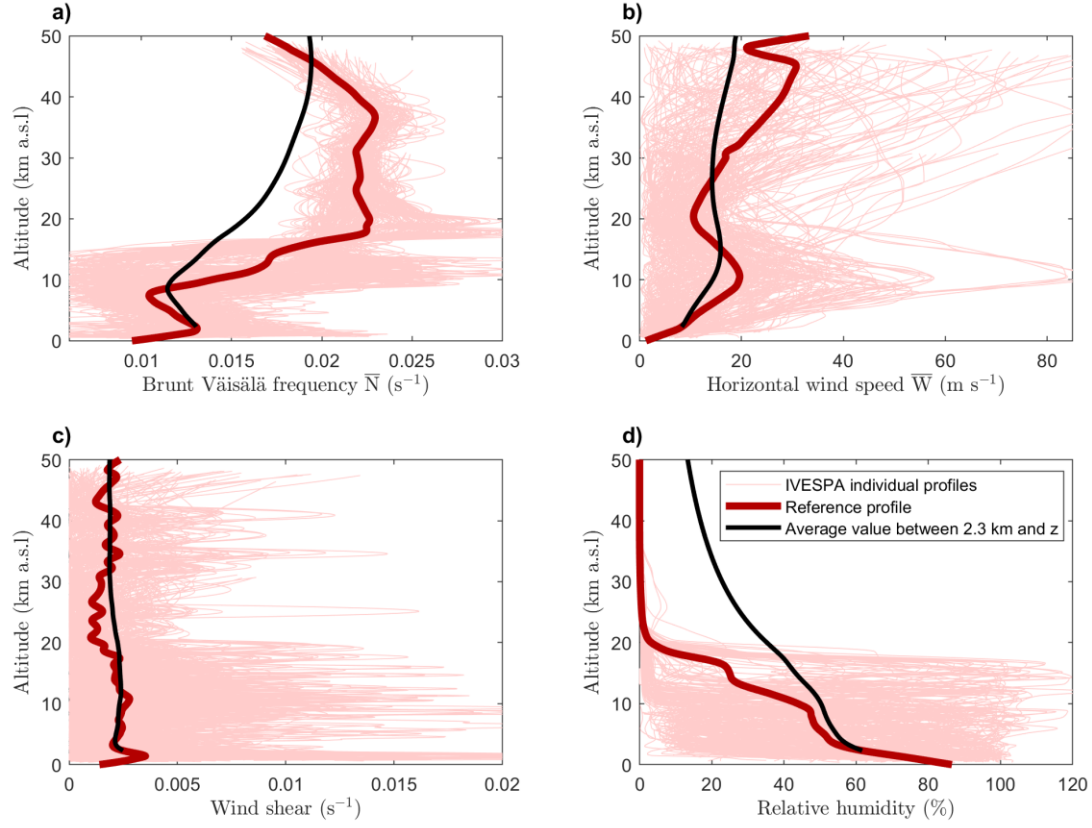

Figure S5. Profiles of Brunt Väisälä frequency (a), horizontal wind speed (b), wind shear (c) and relative humidity (d) for all IVESPA events for both families of atmospheric reanalyses. The thick red line shows the average across all events, smoothed over 2 km, which we refer to as the reference profile. The continuous black line shows the vertically averaged value of the reference profile between 2.3 km (the mean vent altitude in IVESPA) and the altitude shown on the y-axis.
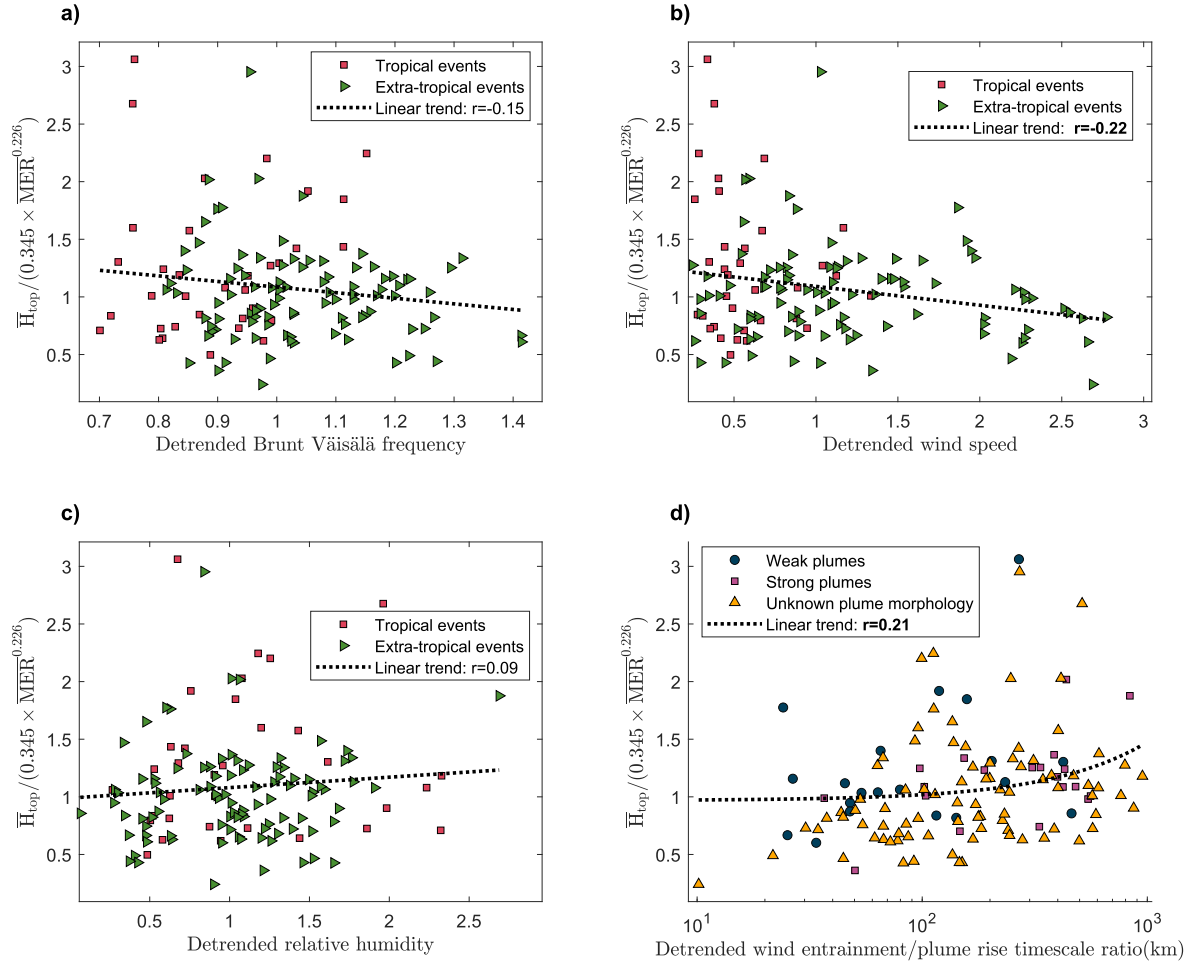

Figure S6. Same as Figure 2, but showing standardized $\overline{H}_{top}$ as a function of detrended atmospheric parameters instead of raw atmospheric parameters. We define detrended atmospheric parameters as the ratio of the vertically averaged value for the considered event to the vertically averaged value for all events, i.e. the vertically averaged value of the reference profile (Figure S5; all vertical averages are between the vent altitude and $\overline{H}_{top}$ specific to the event). Detrended atmospheric conditions thus reflect how vertically averaged conditions deviate from the expected average value for the event vent altitude and $\overline{H}_{top}$, i.e. they should only reflect variations in atmospheric conditions related to the volcano location, eruptive event season, and meteorological variability.
Figure S7. Same as Figure 2, but showing standardized $\overline{H}_{top}$ as a function of the logarithm of the ratio event duration/plume rise timescale (a) and the median grain size from the total grain-size distribution (TGSD) in Φ units (b). The plume rise timescale is defined as $1/\overline{N}$ following buoyant plume rise theory (Morton et al., 1956). Given the grain size diameter d, the grain size in Φ unit is defined as $-\log_2(d)$.
