Abstract

Ocean bottom pressure-gauge (OBP) records play an important role in seafloor geodesy, but oceanographic fluctuations in OBP data are a major source of noise in seafloor transient crustal deformation observations, including slow slip events (SSEs), so it is important to evaluate them properly. To extract the significant characteristics of the oceanographic fluctuations, we applied principal component analysis (PCA) to the 3-year Dense Oceanfloor Network System for Earthquakes and Tsunamis (DONET) OBP time series for 40 stations during 2016–2019. PCA can separate several oceanographic signals based on the characteristics of their spatial distributions, although transient tectonic signals could not be clearly confirmed from the observed pressure records. The higher-order modes of the principal component reflected the oceanographic variation along the sea depth, and we interpreted that they were caused by the strength or weakness and meandering of ocean geostrophic currents, based on a comparison to the global ocean model ECCO2 by "Estimating the Circulation and Climate of the Ocean" (ECCO) consortium. In addition, to evaluate the ability of PCA to separate transient crustal deformation from oceanographic fluctuations, we conducted a synthetic test assuming an SSE by rectangular faults. The assumed synthetic tectonic signal can be separated from the oceanographic signals and included in the principal component independently depending on its amplitude. We proposed a transient event-detection method based on the spatial distribution variation of a specific principal component with or without a tectonic signal. This method can detect transient tectonic signals larger than moment-magnitude scale M_W 5.9 from OBP records.

17 Key Points:

- We applied a principal component analysis to the long-term continuous data from a dense
 and wide ocean bottom pressure gauge network
- Our principal component analysis revealed the spatiotemporal characteristics of the meandering of the ocean geostrophic currents
- We propose a method to discriminate the transient tectonic signal from the bottom pressure data based on amplitudes of principal component

25 Abstract

Ocean bottom pressure-gauge (OBP) records play an important role in seafloor geodesy, but 26 oceanographic fluctuations in OBP data are a major source of noise in seafloor transient crustal 27 deformation observations, including slow slip events (SSEs), so it is important to evaluate them 28 properly. To extract the significant characteristics of the oceanographic fluctuations, we applied 29 30 principal component analysis (PCA) to the 3-year Dense Oceanfloor Network System for Earthquakes and Tsunamis (DONET) OBP time series for 40 stations during 2016–2019. PCA 31 can separate several oceanographic signals based on the characteristics of their spatial 32 distributions, although transient tectonic signals could not be clearly confirmed from the 33 observed pressure records. The higher-order modes of the principal component reflected the 34 oceanographic variation along the sea depth, and we interpreted that they were caused by the 35 strength or weakness and meandering of ocean geostrophic currents, based on a comparison to 36 the global ocean model ECCO2 by "Estimating the Circulation and Climate of the Ocean" 37 (ECCO) consortium. In addition, to evaluate the ability of PCA to separate transient crustal 38 deformation from oceanographic fluctuations, we conducted a synthetic test assuming an SSE by 39 rectangular faults. The assumed synthetic tectonic signal can be separated from the 40 oceanographic signals and included in the principal component independently depending on its 41 amplitude. We proposed a transient event-detection method based on the spatial distribution 42 43 variation of a specific principal component with or without a tectonic signal. This method can detect transient tectonic signals larger than moment-magnitude scale M_w 5.9 from OBP records. 44

45

46 Plain Language Summary

Measurement of water pressure at the seafloor can be used to detect crustal deformation in the 47 vertical direction. This technique is extremely important for understanding various crustal 48 deformations associated with earthquakes. To capture water pressure changes caused by crustal 49 deformation with high accuracy; however, it is necessary to remove the water pressure changes 50 due to ocean water. In this study, we attempted to separate these oceanic components by 51 applying principal component analysis (PCA) to seafloor-pressure gauge data from DONET, a 52 cable-based seafloor observation network deployed in southwestern Japan. As a result, PCA 53 succeeded in separating multiple spatially characterized components. The higher-order modes of 54 the principal component reflected the oceanographic variation along the sea depth, and we 55 interpreted that they were caused by the strength or weakness and meandering of ocean 56 geostrophic currents compared to the global model. In addition, numerical experiments were 57 58 conducted to understand whether crustal deformation caused by a transient fault-slip phenomenon, called as a slow slip event, can be separated by PCA. The assumed synthetic 59 tectonic signal can be separated from ocean-origin components. Furthermore, we propose a 60 transient event-detection method based on the spatial distribution variation of a specific principal 61 component with or without a tectonic signal. 62

63

64 **1 Introduction**

65 Seafloor geodetic observations are critical for accurately understanding crustal
 66 deformation associated with phenomena such as transient fault slips (e.g., Bürgmann &
 67 Chadwell, 2014). Among those seafloor geodetic instruments, the ocean bottom pressure-gauge

(OBP) is a sensor that can continuously observe vertical crustal deformation of the seafloor and 68

- tsunamis over a broad range of time scales and has been the subject of many previous studies 69
- (Transient crustal deformation: e.g., Ito et al., 2013; Ohta et al., 2012; Wallace et al., 2016; 70
- 71 Suzuki et al., 2016; Sato et al., 2017; Fukao et al., 2021; Woods et al., 2022; Tsunamis: e.g., Tsushima et al., 2012; Kubota et al., 2021). However, the water-pressure time series obtained by 72
- the OBP includes various components such as tidal impacts, instrumental drift, non-tidal 73
- oceanographic fluctuations, and crustal deformation, so addressing these influences is extremely 74
- important for extracting objective crustal deformation components. Particularly, the non-tidal 75
- oceanographic fluctuation component has a characteristic time constant of more than a few days 76
- (e.g., Dobashi & Inazu, 2021), and the time constants are similar to those of slow slip events 77
- (SSEs), resulting in transient crustal deformation events (e.g., Obara & Kato, 2016; Rousset et 78 al., 2017; Okada et al., 2022; Takagi et al., 2017). Thus, appropriate estimation and removal of 79
- non-tidal oceanographic fluctuation components are critical for the accurate identification of the 80
- tectonic components. Such non-tidal oceanographic components can be removed by applying a 81
- bandpass filter to eliminate oceanic origins, excluding specific constants (Sato et al., 2017; 82
- Wallace et al., 2016; Suzuki et al., 2016; Muramoto et al., 2019), and using a physical model to 83
- calculate the expected pressure fluctuation values and remove them from the observed time 84
- series (Inazu et al., 2012; Dobashi & Inazu, 2021). Although these methods can improve the 85
- signal-to-noise ratio of non-tidal oceanographic fluctuations, their spatiotemporal 86
- 87 characterization is required to enable smaller tectonic-induced pressure changes detection.

The spatiotemporal characteristics of these non-tidal oceanographic components recorded 88 in the OBP have been identified in several previous studies. Muramoto et al. (2019) found that 89 the oceanographic fluctuations recorded in the OBP time series off Hikurangi, New Zealand 90 [Hikurangi Ocean Bottom Investigation of Tremor and Slow Slip (HOBITSS), which extends 91 92 ~60km square; e.g., Wallace et al., 2016], became less similar as the difference in sea depth between OBP sites increased. Inoue et al. (2021) used the standard deviation of the relative 93 pressure time series between stations in the same observational network and observation period 94 95 as Muramoto et al. (2019), to evaluate the station distance and sea-depth difference in the similarity of the time series. These studies showed that the depth dependence was more 96 significant than the station-distance dependence in the OBP time series. However, the larger 97 spatial characteristics of these non-tidal oceanographic fluctuation components still need to be 98 investigated. The current interpretations and discussions of the similarity of these features at 99 similar sea-depths are also insufficient. 100

Principal component analysis (PCA) (e.g., Jolliffe, 2002) is a standard technique for 101 102 analyzing large datasets containing a high number of dimensions/features per observation, 103 increasing the interpretability of data while preserving the maximum amount of information. PCA has been employed in land-based geodesy (e.g., Munekane, 2012; Kositsky & Avouac, 104 2010), seafloor geodesy (e.g., Hino et al., 2014; Gomberg et al., 2019), oceanography (e.g., 105 Kundu et al., 1975; Kutzbach, 1967; Androsov et al., 2020), and other fields to evaluate and 106 remove common modes. Hino et al. (2014) applied PCA to the OBP time series and showed that 107 it could remove non-tidal oceanographic fluctuation components common to the entire OBP 108 network. They demonstrated that the signal-to-noise ratio of the OBP time series could be 109 improved by removing the first principal component (PC). Watts et al. (2021) applied Complex 110 PCA (Thomson & Emery, 2014; Nuryanto, 2016), which can also evaluate propagation 111 components by extending PCA to complex numbers, to four OBP time series stations and 112

evaluated its performance with respect to removing oceanographic components from the OBP 113

114 time series. These previous studies have already shown that PCA effectively removes non-tidal

oceanographic fluctuations from the OBP time series, but a spatiotemporal assessment of each of

116 the extracted components is lacking.

Given this research background, this study focuses on the OBP observation network in 117 the Dense Oceanfloor Network system for Earthquakes and Tsunamis (DONET) (Figure 1; 118 119 Kaneda et al., 2015; Kawaguchi et al., 2015) in southwest Japan, where the observation network is densely and widely distributed. In the Nankai trough region, where the DONET is installed, 120 the transient SSEs have been oftern observed and the spatiotemporal variation of the SSE 121 activities is extensively studied (e.g., Obara & Kato, 2016; Yokota & Ishikawa, 2020). Thanks to 122 the long-term continuous observations and the spatial extent of the DONET data, we can 123 quantify the spatial characteristics of non-tidal oceanographic fluctuations in further detail and 124 can evaluate the ability of PCA to separate tectonic and oceanographic signals, which have not 125 been done in the past studies. Therefore, we apply PCA to the long-term time series of the 126 DONET data, and examine its spatiotemporal characteristics. Furthermore, we discuss the 127 possibility of applying PCA to data in which transient crustal deformations are included in the 128 OBP time series to separate these features from the time series. We further propose a transient 129 event-detection method based on the spatial distribution variation of a specific principal 130

131 component.

132 2 Data and Principal component analysis

133 2.1 Seafloor pressure data and data processing

We used OBP data acquired via a cabled seismic observation system named DONET in 134 135 the Nankai Trough in southwestern Japan. The DONET observatory includes an accelerometer, broadband seismometer, pressure sensor, hydrophone, thermometer, and other sensors to observe 136 the seafloor conditions. Absolute quartz oscillation pressure sensors by Paroscientific, Inc. are 137 138 used as pressure sensors, with a sampling frequency of 10 Hz (Matsumoto & Araki, 2021). The DONET observatory consists of two cables (Figure 1) with several nodes, which are groups of 139 four or five observation sites in the vicinity. The eastern cable (DONET1, KMA to KME nodes; 140 22 stations) began monitoring in 2011, and the western cable (DONET2, MRA to MRG nodes; 141 29 stations) began monitoring in 2016 (Figure 2). For example, KMA node includes the stations 142 of KMA01-KMA04, and MRF node includes the stations of MRF22-MRF25 (Figure 2). To 143 144 ensure a sufficient time-series data length, 40 sites from June 2, 2016, to August 12, 2019, with few missing measurements, were used for the analysis (red-colored sites in Figure 1). The 145 pressure data for all the KMA sites and MRF22 were not available after October 2018 and March 146 2018, respectively. No data for the KME sites were available during the analysis period. 147

The OBP time series contains signals other than the targeted crustal deformation. The observed OBP time series can be described by Equation 1 (e.g., Ito et al., 2013; Hino et al., 2014):

151

$$\Delta p_B(t) = \Delta p_C(t) + \Delta p_T(t) + \Delta p_O(t) + \Delta p_D(t) + \varepsilon(t), \#(1)$$

152

153 where $\Delta p_B(t)$, $\Delta p_C(t)$, $\Delta p_T(t)$, $\Delta p_D(t)$, $\Delta p_D(t)$, and $\varepsilon(t)$ represent the observed 154 pressure, crustal deformation, tidal signal, non-tidal oceanographic fluctuations, instrumental drift, and other errors, respectively. The following procedure was used to extract the crustal deformation component from the OBP time series.

The original 10 Hz sampling data were down-sampled by averaging them over one hour. 157 The missing parts were linearly interpolated to use the tide-killer filter as follows: the tidal 158 component $(\Delta p_T(t))$ was removed using a low-pass filter designed for removing tidal 159 components (the 48-hour tide-killer filter designed by Hanawa & Mitsudera, 1985). This tide-160 killer filter extended the Thompson (1983) filter to 48 h. It uses a 10-day weighted moving 161 average to reduce the filter response factor to approximately zero in less than 2 days (for the 162 weighting factor, see Table3 by Hanawa & Mitsudera (1985)). The weighting factors of this filter 163 were adjusted so that the inertial motions contained in tidal currents and other oceanographic 164 phenomena near Japan could also be removed. Bayesian Tidal Analysis Program - Grouping 165 Model program (BAYTAP-G) (Tamura et al., 1991) is often used to estimate and remove tidal 166 variations from OBP time series; however, small fluctuations with a high frequency (time 167 constant of less than 2 days) remain in the time series. Here, we are interested in crustal 168 deformation in the range of a few days or more; high-frequency variations are outside the scope 169 of this study. Therefore, a simple low-pass filter was applied. The tide-killer filter produces 170 inappropriate variability when applied to a time series that does not include tidal variations. 171 Hence, the missing parts and the time series for the 5 days before and after the missing periods 172 173 were removed before the instrumental drift estimation. The instrumental drift component $(\Delta p_{\tau}(t))$ was estimated and removed using linear and exponential approximations (Watts & 174 Kontoyianiss, 1990; Polster et al., 2009); the averaged drift rate over the stations was 175 approximately several hPa per year. The missing part of the time series was reinterpolated using 176 a piecewise cubic Hermite interpolating polynomial (Fritsch & Carlson, 1980). Processed data, 177 in which tectonic and oceanographic signals remained, were used in the following analyses. 178 These processed data are called "observed data" in the sections hereafter. 179

180 2.2 Principal component analysis

We assumed that the observed data contained multiple spatially correlated non-tidal 181 182 oceanographic fluctuations signals that could be separated by PCA, which is a major multivariate analysis method that uses as few synthetic variables as possible to capture as much information 183 as possible (e.g., Jolliffe, 2002). We applied PCA to the observed data to extract non-tidal 184 oceanographic components with spatial similarities from the OBP time series. This study first 185 applied PCA to such a long-term OBP data set to extract non-tidal oceanographic components 186 for extracting crustal deformation data. We adopted the conventional PCA method for the 187 preprocessed observed data. For each extracted PC, a judgment was made on whether the 188 component should be attributed to the non-tidal oceanographic contribution based on its spatial 189 characteristics. 190

As mentioned in the introduction, a sea-depth dependence exists for the oceanographic 191 fluctuations in the OBP data (e.g., Inoue et al., 2021). To confirm these PCA effects and the 192 193 subsequent selection and removal of PCs, the relative pressure between sites in the OBP time series was calculated, and their dependence on the difference in distance and sea depth was also 194 calculated. Differences from an assumed reference site were calculated for all sites, the standard 195 deviation (SD) of the relative water-pressure time series at each site was determined and the 196 dependence on distance and sea depth between those stations was evaluated. In this paper, we 197 198 use the absolute averaged SD for overall stations (ASD) and the relative SD for each station

(RSD) to explain the PCA contributions shown as below. The ASD for the time series types of l is shown in Equation (2):

201

$$ASD^{l} = \frac{1}{N} \sum_{i=1}^{N} \sqrt{\frac{1}{T} \sum_{t=1}^{T} \left(P_{i,l}^{t} - \overline{P_{i,l}}\right)^{2}}, \#(2)$$

202

where $P_{i,l}^{t}$ indicates the pressure at time *t* at station *i*, and $\overline{P_{i,l}}$ denotes the temporal average of $P_{i,l}^{t}$. The types of l = 1, 2, ... 9 indicate the observed pressure, first PC (PC1), second PC (PC2), third PC (PC3), fourth PC (PC4), and the observed pressure after subtracting PCs 1 and 2, after subtracting PCs 1–3, after subtracting PCs 1, 2, and 4, and after subtracting PCs 1–4, respectively. The RSD at station *i* from the reference station *j* is shown in Equation (3):

208

$$RSD_{ij}^{l} = \sqrt{\frac{1}{T} \sum_{t=1}^{T} \{ \left(P_{i,l}^{t} - P_{j,l}^{t} \right) - \left(\overline{P_{i,l} - P_{j,l}} \right) \}^{2}}, \#(3)$$

209

where $P_t^{i,l}$ and $P_t^{j,l}$ indicate the pressure record at time *t* at station *i* and *j*, respectively. $\overline{P_{i,l} - P_{j,l}}$ denotes the average of the relative pressure time series between station *i* and *j*.

212

3. Results

Figure 2 shows example of the OBP time series after removing the tidal and drift 214 components from the observed time series. These time series show annual variations: a higher 215 pressure value appeared in the summer season (July to August) and a lower pressure value 216 appeared in the winter season (January to February). This annual variation is evident even before 217 2016 in DONET1 network, which is outside of the period of our analysis (KMB-KMD time 218 series in Figure 2). The annual variation has an amplitude of up to 5 hPa, and these 219 characteristics are within the same node and display similar features over a wide area. Similar 220 characteristics can be observed throughout the network, even for shorter time-constant 221 variations. In the following sections, we present the PCA results that separate these spatially 222

- 223 coherent oceanographic fluctuations.
- 3.1 Spatiotemporal characteristics of each principal component

In PCA, PC1 has the largest eigenvalue. PC1 is more highly correlated with the original features than PC2, and PC2 is better correlated than the PC3, and so on. PCA reduces the dimensionality of the data by selecting the first k PCs to represent the original data. Figure 3 (a– d) shows the extracted PCs at the DONET OBP sites. The eigenvector and eigenscore of each PC

correspond to its spatial distribution and temporal variation, respectively. The contributions of

each PC were 75.7% for PC1, 10.3% for PC2, 3.5% for PC3, and 2.5% for PC4 (Right top 230 number in Figure 3). The contribution reached 92% through PC4, and the spatial patterns and 231 other characteristics of the higher-order components after PC5 were not clear, therefore, the 232 233 sections hereafter will utilize PC1-PC4 to interpret their characteristics. PC1 and PC2 explain the majority (86.0%) of the time series characteristics; PC1 is the common component across the 234 entire observation network and includes the annual variability (Figure 3 (a) and Figure 4(a)). 235 PC2 has a spatially inclined characteristic, reversing the positive and negative eigenvector values 236 between the shallow and deep stations (Figure 3(b) and Figure 4(c)). This sea-depth-dependence 237 characteristic is clear in the time series of PC2, whose amplitude is notably large in shallow or 238 deep stations (Figure 5(b)). PC3 does not have a clear sea-depth dependency like PC2, but it does 239

have a longitudinal dependence characteristic (Figure 3(c) and Figure 4(f)). PC4 has parabolic
spatial characteristics with positive and negative eigenvector values at shallow and deep water
depths, respectively (Figure 3(d) and Figure 4(g)). Based on the characteristics of each of these
PCs, PCs 1–4 were determined to be the components that needed to be removed from the
oceanographic fluctuation components in this study.

Previous studies have noted the sea-depth dependency of the seafloor water-pressure characteristics based on actual observation data and oceanographic models (e.g., Inoue et al., 2021; Fredrickson et al., 2019). The PCA results obtained in this study were consistent with the those obtained in previous studies. The results also suggest that not only can the depth-dependent component be extracted as the main component, but it can also be separated into two different components: PC2 and PC4.

251

3.2 Contribution of the principal components in the OBP time series

To confirm how the noise in the OBP time series can be reduced using the extracted PCs, 252 the results of subtracting the PCs from the original observed data in different combinations are 253 shown in Figure 6. After removing PC1 (Figure 5(a)), which includes the annual variation 254 component, the ASD of the time series was considerably reduced from 1.98 hPa to 0.91 hPa (the 255 ASD value was reduced by 46%), while the spatially correlated variations remained (Figure 6 256 (b)). The characteristics of the remaining components are not common to the entire observation 257 network but are identified at specific sites, which suggests that they reflect depth-dependent 258 oceanographic fluctuations. Figure 6(c) shows the results obtained by subtracting PC1 and PC2 259 from observed data. In Figure 6(b), the remaining variation was eliminated, and the ASD has 260 decreased to 0.69 hPa (the ASD value was further reduced by 24%, for an overall reduction of 261 65%). Removing PCs 1–3, the ASD decreased to 0.61 hPa (Figure S1(b)), and removing PCs 1, 262 2, and 4 resulted in an ASD of 0.62 hPa (Figure S1(c)). Finally, removing PCs 1-4 resulted in an 263 ASD of 0.53 hPa (Figure S1(d)), reducing the noise level by 73% compared to the time series 264 before the PCs were removed. PCA is a method of identifying as much information as possible 265 using as few synthetic variables as possible. Naturally, subtracting the principal components with 266 high contributions from the original data reduces their noise levels; however, as previously 267 mentioned, PCs 1-4 showed distinct spatially correlated variations that could be attributed to 268 oceanic origins. Therefore, subtracting these PCs appeared to be a reasonable procedure. In 269 particular, PC1 and PC2 reflected most of the common or depth-dependent gradients of 270 oceanographic fluctuations in the OBP time series, because the sum contributions of both 271 reached 86.0%, and the sum contributions of PC3 and PC4, which also reflect the oceanic signal, 272 were only 6.0% (Figure 4). These results also suggest that PCA can efficiently remove depth-273 dependent oceanographic fluctuations, as indicated in previous studies (Muramoto et al., 2019; 274

Inoue et al., 2021; Fredrickson et al., 2019). In addition, reducing the noise level via pressure
values at individual sites rather than calculating the pressure differences between sites is
considered a significant advantage. In the next section, we confirm more detail the extent to

considered a significant advantage. In the next section, we confirm more detail
which the PCA removes these depth-dependent oceanographic fluctuations.

- 278 which the FCA femoves these depth-dependent oceanographic inditiatio
- 2793.3 Reduction of sea-depth dependency based on PCA

As mentioned in the introduction, Inoue et al. (2021) found that the characteristics of 280 oceanographic fluctuations depend on sea depth. In this section, we quantitatively discuss the 281 extent to which these depth dependencies are reduced by PCA, as described in the previous 282 sections. First, we calculated the relative pressure time series for all the stations used in the 283 analysis. Next, the RSDs were calculated and plotted as a function of the difference in depth or 284 distance between sites. Similar calculations were applied to the results obtained in the previous 285 section by subtracting the PCs to confirm their characteristics. In addition, correlation 286 287 coefficients were calculated to quantitatively evaluate the dependence.

Figure 7(a-b) shows the sea depth and distance dependency, respectively, before PCA 288 289 was applied to the time series. The results for Hikurangi, New Zealand, by Inoue et al. (2021) are also included for comparison (red dots in Figure 7(a-b)). This figure shows that the depth 290 dependence is more distinct than the distance dependence. This trend is also consistent with that 291 of off-Hikurangi margin. Figure 7(c-d) shows the correlation plot when PC1 was subtracted 292 from the original observed time series. It is interesting to note that the depth dependence visible 293 in the original time series was not reduced. This result suggests that PC1 contains a common 294 295 component throughout the observation network, which contributes little to the spatial variation of the observation data even after its influence is removed. The results of subtracting PC1 and PC2 296 are shown in Figure 7(e-f), which indicates that subtracting PC2 significantly reduced the 297 dependence on sea depth. The correlation coefficient when only PC1 was subtracted was 0.78, 298 299 which was almost halved to 0.40 when both PC1 and PC2 were subtracted. Interestingly, for distance dependence, the ASD itself decreases significantly (from 0.91 to 0.69), although the 300 value of the correlation coefficient itself does not change significantly (from 0.35 to 0.30). This 301 suggests that PC2 can adequately remove only the sea-depth-dependent component of the OBP 302 time series. The fact that the DONET observation network has a slightly elongated shape in the 303 direction of the isobaths (Figure 1) also helps ensure that the removal of the sea depth 304 dependence does not reduce the distance dependence. Figure S2(e-f) shows the results obtained 305 after subtracting PCs 1, 2, and 4. Consequently, the depth dependence was further reduced with a 306 correlation coefficient of 0.33, approximately 60% smaller than that of the original time series. 307 However, Figure S2(c-d) shows the result after subtracting PCs 1-3. PC3 does not reduce the 308 sea depth dependence (from 0.40 to 0.40), although it contributes slightly to reducing the 309 distance dependence (from 0.30 to 0.26). After removing PCs 1, 2, and 4 or PCs 1-4, the 310 correlation coefficient of the sea-depth dependence is almost equivalent to the distance 311 dependence, indicating that removing PCs 1, 2, and 4 can significantly reduce the depth 312 dependence of oceanographic fluctuations. 313

Previous studies have noted that applying PCA may reduce the detection accuracy of crustal deformation owing to the seepage of crustal deformation components into the principal components (Watts et al., 2021). Therefore, in the next section, we discuss the accuracy of crustal deformation detection by PCA using synthetic rectangular faults in the observation region.

319 4 Discussion

320

4.1 Physical oceanographic interpretation of each principal component

In the previous section, PCA was used to successfully extract components with multiple 321 spatial characteristics. The observed pressure time series include both oceanographic fluctuations 322 and tectonic signals but the oceanographic circulation models include only the oceanographic 323 fluctuations. To examine the characteristics of oceanographic fluctuations, we applied PCA to 324 325 ocean models and compared the spatial distribution of each PC with the observation. The ocean models have advantages and disadvantages in the region and time scale used herein, depending 326 on the input data and model structure (Dobashi & Inazu, 2021). We chose a single-layer ocean 327 model (SOM) (Inazu et al., 2012) and ECCO2 (Menemenlis et al., 2008) for comparison with 328 observations. SOM assumes a single-layer barotropic ocean model and is driven by atmospheric 329 pressure as well as wind stress, whereas ECCO2 assumes a multiple-layer (50 layers) baroclinic 330 331 ocean model (i.e., better vertical resolution than SOM) and is driven by wind stress, heat, and freshwater flux although the atmospheric pressure is not considered. The details of each model 332 are referenced in Table 2 by Dobashi & Inazu (2021). The expected pressure time series was 333 334 calculated based on each model. As each numerical model provides calculations for each grid, the grid nearest to the DONET observation region (77 grids in longitude of 134°E-137°E and 335 latitude of 32°N–34°N) was selected, and PCA was applied to the time series data to confirm the 336 characteristics of the model. 337

After applying PCA to SOM, the PC1 contribution reached 96.7% (Figure S3(a)). This is 338 339 clearly larger than the 75.7% observed (Figure 3), indicating that ocean variations show similar fluctuations (Figure S3). Overall, the pressure variation due to the oceanographic fluctuations is 340 expressed, but the contribution is more exaggerated than the observation. In contrast, higher-341 order terms, such as the sea-depth-dependent component identified in the observational data, 342 were poorly extracted from the SOM. Importantly, when applying PCA to ECCO2, PC1, PC2, 343 PC3, and PC4 contributed 80.8%, 9.9%, 2.9%, and 1.8%, respectively. The contribution ratio 344 and the spatial distribution (Figure S6) were similar to the observational data (Figure 3). The 345 reproduced oceanographic fluctuations calculated by ECCO2 are more realistic than SOM. 346

The extracted PC characteristics of ECCO2 were as follows. PC1 was the overall pressure variation with a large spatial scale (several hundred km extent) driven by wind stress and atmospheric pressure, which was also reproduced by SOM. PC2 was the depth-dependent component (i.e., a pattern orthogonal to isobath). PC3 and PC4 were the depth-dependent patterns but their frequency was higher than PC2 (Figure S6; Figure S8). The longitudinal dependence component seen in PC3 of the observed data is part of the parabolic component seen in PC3 or PC4 of ECCO2 and is considered to be included in these components.

Following confirmation that the PCs extracted from the observed time series were due to 354 oceanographic fluctuations, we attempted to interpret them qualitatively. The Nankai Trough, 355 where DONET stations are installed, is a channel of the Kuroshio Current (e.g., Nitani, 1972), 356 which meanders widely on time scales of several years or more (e.g., Kawabe, 1985). For 357 example, one of the largest Kuroshio meanders occurred in 2017 and continued through 2022, 358 contributing to pressure fluctuations on the seafloor (Nagano et al., 2019; 2021). Therefore, 359 oceanographic phenomena such as the strength and meandering of the Kuroshio Current should 360 be recorded in the OBP data for the DONET region. The meandering of the geostrophic current 361 362 including Kuroshio is interrelated with the mesoscale eddy (Qiu & Miao, 2000; Hasegawa et al.,

2019) with ~100 km radius and their contribution to the sea bottom pressure perturbation cannot
be well separated. Note that the sea level variation due to the meso-scale eddies is considerably
attenuated to the ocean bottom pressure variation because the sub-seasurface water column
imperfectly compensates for the pressure change by seasurface variation (Dobashi & Inazu,
2021; Hasegawa et al., 2021).

368 Based on the results of the application of PCA to the observed data and ocean models and the previous studies on oceanographic fluctuations and the Kuroshio Current (Hasegawa et al., 369 2021), we interpreted each PC in the observed data as follows. PC1 is the large spatial scale 370 variation associated with wind stress and atmospheric pressure variation. PC2 corresponds to the 371 strength and weakness and flow axis position of the geostrophic current (e.g., Kuroshio Current) 372 (Figure 8(a)). Both PC3 and PC4 can be compatible with the spatial pattern depending on the 373 location of the mesoscale eddy, which has a radius of fewer than 50km (Figure 8(b, c)). If the 374 centroid of the cold vortex is located east (Figure 8(b)) or west (Figure 8(c)) of the Kii Peninsula, 375 the longitudinal dependence variation can reflect in the observed data in DONET. When the cold 376 vortex migrates eastward or westward orthogonally to the direction of isobath (i.e., changes from 377 Figure 8(b) to (c) or Figure 8(c) to (b)), a parabolic-like spatial distribution can occur. As 378 mentioned above, the sea-surface level fluctuations are not directly reflected as seafloor pressure 379 variations, but fluctuations caused by mesoscale eddies are thought to affect ocean bottom 380 381 pressure.

In this analysis, PCA was applied to a long-term continuous time series of more than 3 382 years. However, if the components reflected in the principal components have characteristic time 383 constants, changing the time window may change the extracted components. Nevertheless, 384 applying PCA to the OBP time series shows that pressure fluctuations of oceanic origin can be 385 separated based on their spatial characteristics. This suggests that the method can improve the 386 data quality in time series when extracting pressure variations caused by crustal deformation. In 387 the next section, we discuss the potential usefulness of PCA when transient crustal deformations 388 are included in a time series. 389

390

4.2 Synthetic test for principal component analysis to observe the crustal deformation

As shown in the previous section, applying PCA to the DONET time series can separate 391 the non-tidal oceanographic fluctuations in the observed data; PC2 and PC4 could explain the 392 most depth-dependent oceanographic fluctuations in the OBP time series. In contrast, it is 393 necessary to evaluate the ability of PCA to separate transient tectonic and oceanographic signals 394 to improve the reliability of crustal deformation observations using OBPs. Watts et al. (2021) 395 performed a Complex PCA after adding a synthetic ramp function to the OBP time series of four 396 stations and found that part of the ramp signal interfered with the principal component, which 397 mainly reflects oceanographic fluctuations. This result suggests that subtracting the 398 oceanographic component from the observed time series also removes part of the tectonic signal 399 and may underestimate the amplitude of the displacement caused by the transient event. In this 400 section, we evaluate the possibility of separating tectonic and oceanographic signals by applying 401 PCA to the OBP time series. 402

403 4.2.1 Analytical overview of the synthetic test

In this section, we describe how to add a synthetic signal to the OBP time series. A rectangular fault model (Okada, 1992) was used. The results were assumed for each earthquake 406 moment magnitude (M_W 5.5–7.0, 0.1 increments) based on the scaling law proposed by Wells &

407 Coppersmith (1994). The rigidity and Posson's ratio were assumed for 30GPa and 0.25,

respectively. The fault locations were set along the plate boundary of the Phillippine Sea plate (Baba et al., 2002; Hirose et al., 2008; Iwasaki et al., 2015). The strike, dip, and rake angles of

the fault were assumed to be 250° , 8° , and 90° , respectively, assuming a reverse fault along the

411 plate boundary. The assumed fault model was horizontally spaced at 0.1° intervals. Figure S9

shows the centroid of all 548 fault planes. For each assumed fault model, the time evolution of

the fault slip was calculated using a ramp function based on the duration and total amount of slip

expected from the moment magnitude. The duration of an SSE is estimated as in Equation (4),

following the scaling law between the magnitude and duration estimated by the observed slow earthquakes (Ide et al., 2007):

 $Mo \sim T \times 10^{12-13}, \#(4)$

418

where *Mo* indicates the seismic moment [N m] and *T* indicates the duration period [s]. In this study, we calculated the value of the duration *T* using the observed SSE parameter around the Kii Peninsula investigated by Sekine et al. (2010), which is written as follows:

422

$$Mo = T \times 10^{12.2}$$
. #(5)

423

Table 1 shows the duration, length of the rectangular faults, and other parameters at representative magnitudes calculated based on the results of Wells & Coppersmith (1994) and

Equation (5). The timing of the synthetic ramp application was set so that the center of the lamp

427 coincided with the middle of the entire observation period (January 1st, 2018).

428

429

4.2.2 Extraction of transient crustal deformation by PCA

A ramp function with an amplitude duration corresponding to the fault position and 430 earthquake size was added to the observed OBP time series. PCA was applied to investigate how 431 the components that responded to the ramp function were affected by the principal components. 432 The OBP time series expected by the M_w7.0 event at 135.5°E and 33.0°N is shown in Figure 433 9(a), and the spatial distribution of seafloor vertical displacement and each PC is shown in 434 Figures 10(b-f). In this case, the vertical displacement at the station reached a 20.1 cm uplift 435 (20.1 hPa pressure decrease) at station MRE21 (Figure 9(b)). The vertical displacement 436 associated with SSE was extracted as PC1. The common, depth-dependent, and longitude-437 dependent components were extracted from PCs 2, 3, 4, and 5, respectively (Figures 10(c-f)). On 438 the other hand, when the $M_W 6.7$ event at the same location fault was assumed, a PC including 439 the assumed ramp function was classified into PCs 1 and 2 (Figure 10(b) and (c)). PCs 1 and 2 440 also included the common components, and PCs 3-5 includes depth-dependent and longitude-441 442 dependent components (Figure 10(d-f)). The assumed ramp and common components were mixed in PCs 1 and 2 because of their similar amplitude; the contribution of PC1 and PC2 were 443 53.1% and 35.6%, respectively. This result indicates that principal components were shifted to 444 higher-order modes by one before displacement by the SSE was added, for each. In this example, 445

the expected displacements were sufficiently large compared to the accuracy of the OBP 446

observations, which were classified as PC1. Figure 11 illustrates the principal components 447

- extracted for each component as the earthquake magnitude was reduced for the same fault 448
- location. From this figure, it can be observed that the displacement field expected by the SSE 449
- gradually shifts to a higher-order mode. 450

451 These results suggest that PCA can be applied to the time series of transient crustal deformations caused by SSE to extract those tectonic signals as principal components along with 452 oceanographic fluctuations. Thus, the principal components of the time series include transient 453 crustal deformation and those do not include the deformation can be compared; in other words, if 454 the difference between their spatial distributions (each eigenvector element) is significant, they 455 can be extracted. In subsequent sections, we propose a method for evaluating crustal deformation 456 using the spatial distribution of PCs estimated by PCA and evaluate its effectiveness. 457

4.2.3 Evaluation of spatial characteristics 458

We used the absolute value of the normalized inner product (NIP) of the eigenvectors to 459 estimate the spatial characteristics of the results extracted using PCA. The amplitude of each 460 OBP site for each PC corresponded to each element of the eigenvector PC. The NIP of two 461 eigenvectors of the same value is 1; if the difference between them is large, the value is close to 462 0. When the amplitude of the OBP time series due to crustal deformation is smaller, crustal 463 deformation signals and oceanographic fluctuations may be mixed in the same PC. Figure S10 464 shows the spatial distribution of PC2 for each magnitude, assuming a rectangular fault at 465 135.5°E, 33.0°N. This shows that if the event is small and the expected crustal deformation is 466 classified as PC1 and/or PC2, then PC2 includes other noise components like oceanographic 467 fluctuations. Therefore, in this section, we consider using the PC2 difference, with and without 468 synthetic crustal deformation to improve the efficiency of crustal deformation detectors using 469 PCA. Table 2 shows the NIP between the two PC2s without changing the fault location. In this 470 example, if the assumed event was a fault with a magnitude of M_W6.2 or less, the crustal 471 deformation component would be classified as PC3, in which case the NIP would be 472 approximately 1. In other cases, the expected crustal deformation components are not separated 473 into independent PCs and are mixed with other oceanographic fluctuations (M_W6.7 and M_W6.3 474 in Figure 11). For example, for M_w6.3, the NIP of PC2 was 0.78, and its spatial distribution 475 included inclined oceanographic fluctuations and crustal deformation (Figure S10). 476

477

4.3. Comprehensive synthetic test for PCA

Based on the evaluation of spatial characteristics of the results of PCA, we conduct an 478 479 analysis (assuming faults) using NIP as a proxy for each grid assuming faults, and quantitatively evaluate the magnitude of events detected by PCA. Figure 12 shows the results when 0.75 or 480 0.52 is used as the upper NIP limit threshold between PC2s (i.e., a change is detected when NIP 481 < 0.75 or NIP < 0.52). The ability to detect crustal deformation is naturally higher in the 482 neighborhood of OBP sites, and the magnitude of the moment of the lower detection limit 483 increases with distance. On the onshore side—away from the trench axis—the plate boundary is 484 relatively deeper, and the expected displacement is smaller, therefore, the lower detection limit 485 for the magnitude is larger. Alternatively, land-side crustal deformations can be observed using 486 on-land continuous GNSS (Global Navigation Satellite System) sites (e.g., GEONET; GNSS 487 Earth Observation Network System operated by the Geospatial Information Authority of Japan 488

(GSI)). In addition, the Mw6–6.5 events can be detected by only on-land GNSS (Suito, 2016).
 The accuracy of SSE detection was also examined by integrating both on-land and seafloor

491 observation networks (Agata et al., 2019), but this is beyond the scope of this study.

The lower limit of the event size at which crustal deformation can be detected strongly 492 depends on the NIP threshold. Naturally, the threshold value is smaller, and the lower limit of the 493 494 detectable M_w is larger (Figure S11). To decide the best NIP threshold for this analysis, we focused on the NIP variation depending on the M_w migration. The NIP changed with the M_w for 495 each rectangular fault point: The maximum NIP change at 135.5°E, 33.0°N is 0.38 (from 0.40 to 496 0.78) during the M_w migration between 6.4 to 6.3 (Figure S10). Similarly, comparing the pattern 497 of change in M_W and NIP for each rectangular fault, we found that NIP changed abruptly at each 498 specific M_W. This suggests that the crustal deformation component clearly migrates to higher-499 order modes as M_w is reduced for almost all fault locations in our analysis method (Figure S11). 500 We fixed every NIP change pattern by the largest change in NIP, and the average and standard 501 deviation at each M_w were examined (Figure S12). In Figure S12, the largest NIP change was set 502 as the relative M_W between 0.1 and 0.0. The NIPs above 1σ at the lower and upper side of the 503 largest NIP change were between 0.52 and 0.75. Consequently, we propose a practical NIP 504 threshold value be included in this range. Comparing the cases with NIP thresholds of 0.52 and 505 0.75, it can be seen that the lower detection limit M_W was naturally smaller for 0.75, while the 506 overall spatial distribution was generally consistent (Figure 12). This suggests that the anomaly 507 detection ability of our method is not significantly different when the threshold value is selected 508 within this range. In the case of NIP threshold value of 0.75, at the rectangular fault at 136.8°E, 509 33.1°N, the smallest event of M_w5.9 can be detected by our detection method (Figure 12). The 510 spatial distribution of the lower limit of the moment magnitude of a detectable event corresponds 511 to a pressure step with an amplitude greater than one signal-to-noise ratio at five or more 512 stations. The reason the fault at this location was on the lower limit of detection is thought to be 513 because the assumed fault depth was relatively shallow and located near the observation point. 514

515

516 **5 Conclusions**

By applying PCA to the DONET OBP time series from 2016 to 2019, we verified the 517 spatiotemporal characteristics of oceanographic fluctuations in the Nankai region of Japan. The 518 oceanographic fluctuation characteristics of sea-depth dependency found by Inoue et al. (2021) 519 appeared in the Nankai region, and were reflected in PC2 and PC4. From the spatial distribution 520 of these principal components, we inferred that these sea-depth dependencies were caused by the 521 strength and weakness or the meandering of ocean geostrophic currents and mesoscale eddies. 522 Finally, we could not detect any significant transient tectonic events in the OBP time series. This 523 suggests that the amplitude of the transient events was too small to detect, or the signal seeped 524 into the principal components interpreted as oceanographic fluctuations. 525

We added synthetic ramps, assuming an SSE of moment magnitude between 5.5 and 7.0, to the observed time series to evaluate the ability of PCA to separate the tectonic and oceanic signals. The added synthetic ramp signal can be divided into independent principal components depending on their scale. We proposed a transient event-detection method using PCA applied to the OBP time series. The lower limit of the magnitude of the detectable event depends on the NIP threshold, although the $M_W 5.9$ event can be detected from the pressure data on the rectangular fault with the best observation points. In the future, we will systematically detect 533 SSEs using this method and compare them with slow earthquake activity detected previously to

- better understand the occurrence mechanisms of slow earthquakes.

- 804 by GNSS-A. Science Advances, 6(3), eaay5786. doi: 10.1126/sciadv.aay5786.

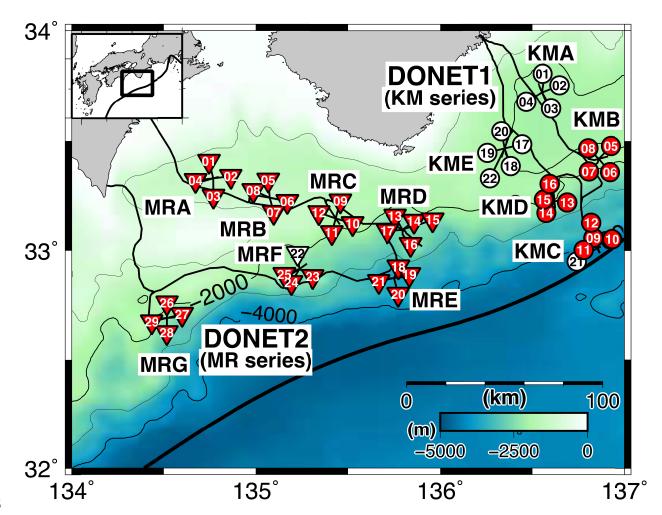

Figure 1. DONET observatory site map. Circles and triangles indicate the DONET1 and DONET2 observation sites, respectively. A group of four or five observation sites is a "node," and the node name is shown in the vicinity of each node. For example, the name of the westernmost site is MRG29. The redcolored sites are used for our principal component analysis. The bold black line indicates the Nankai

811 trough (Iwasaki et al., 2015).

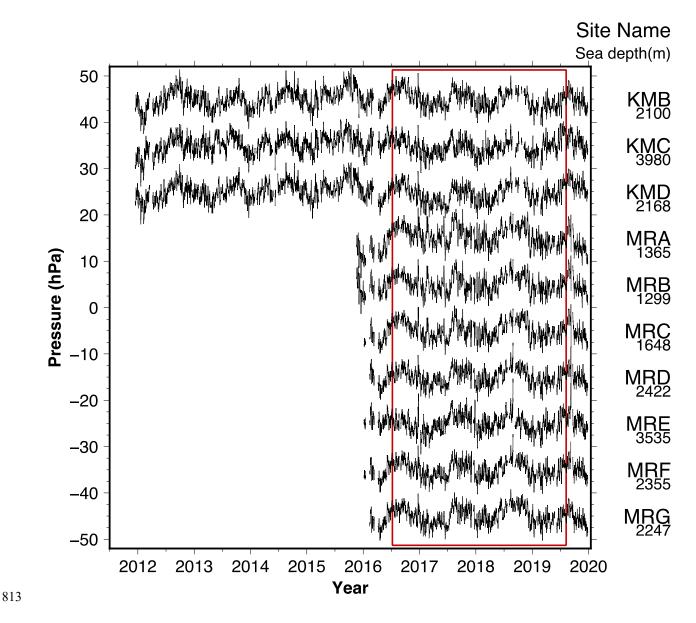

Figure 2. An averaged 8-year long-term continuous OBP time series for each node. The red rectangule indicates the analysis period in this study. The node name and the average sea depth of each nodes are

- shown on the right side of the figure.
- 817
- 818
- 819
- 820

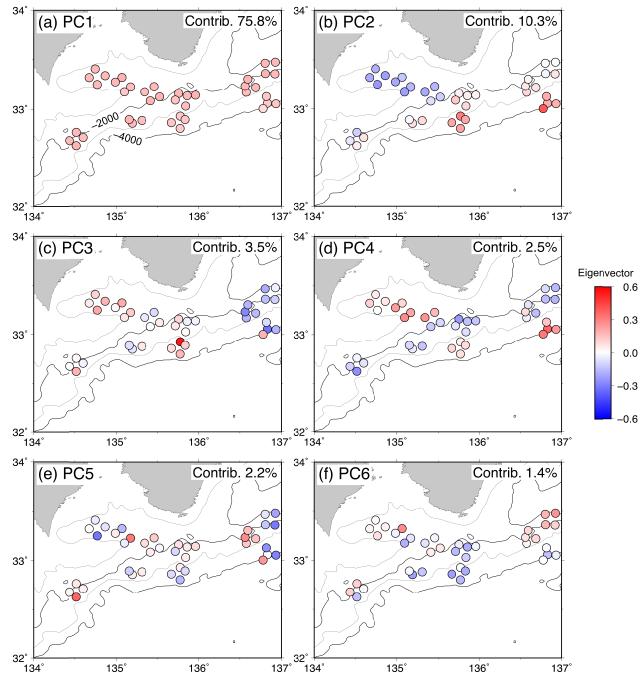

Figure 3. (a) Spatial variation of the PC1 calculated by PCA. (b) Same as (a), but for PC2. (c) Same as
(a), but for PC3. (d) Same as (a), but for PC4. (e) Same as (a), but for PC5. (f) Same as (a), but for PC6.
The contribution of each PC is shown in the right-top of the figure.

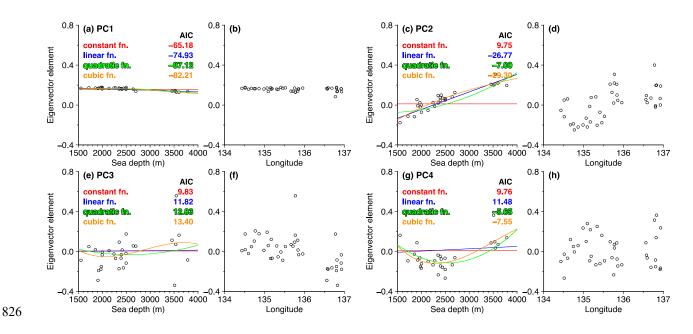

Figure 4. The PC1 variation along with (a) sea depth or (b) longitude. (c, d) Same as (a, b) but for PC2.

828 (e, f) Same as (a, b) but for PC3. (g, h) Same as (a, b) but for PC4. The red, blue, green, and orange lines

829 indicate the approximations using a constant function, a linear function, a quadratic function, and a cubic

function, respectively. The AIC (Akaike, 1973) rates of each approximation are shown in the top right
figure in (a), (c), (e), and (g).

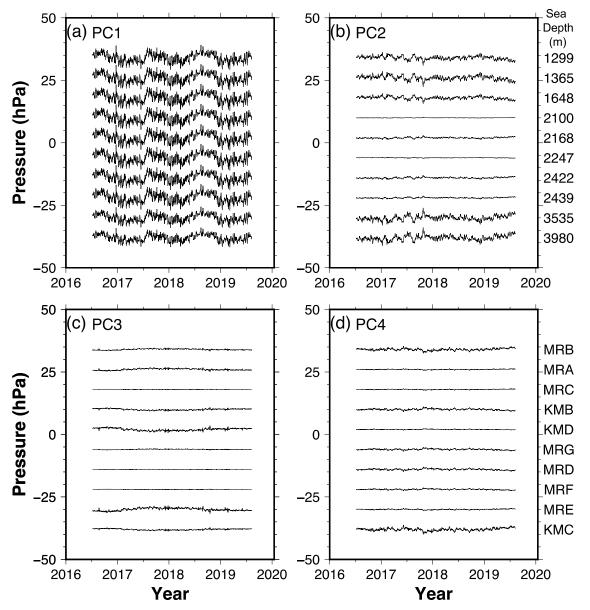

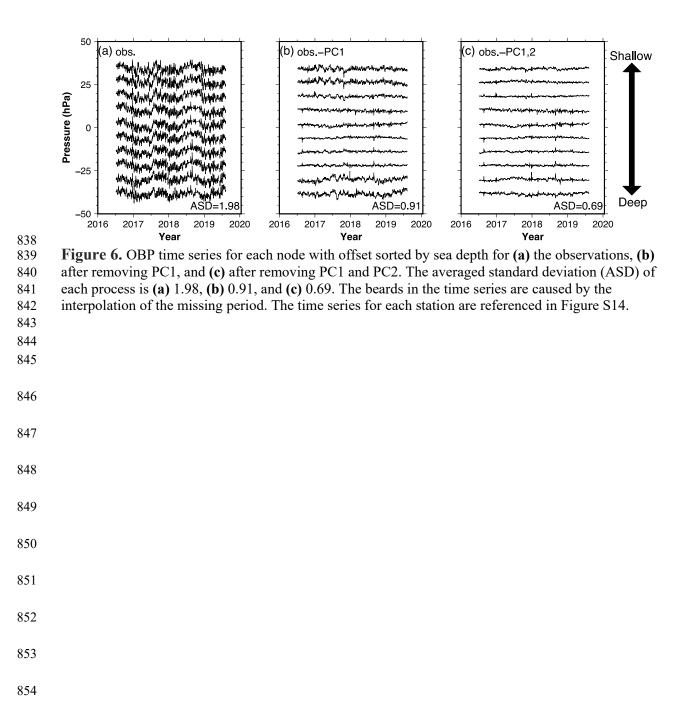

Figure 5. Each principal component time series sorted by sea-depth. The time series for (a) PC1, (b) PC2, (c) PC3, and (d) PC4. The rough sea depths and the station names are shown in the right side of (a)

and (d), respectively. The time series for each station are referenced in Figure S13.

837

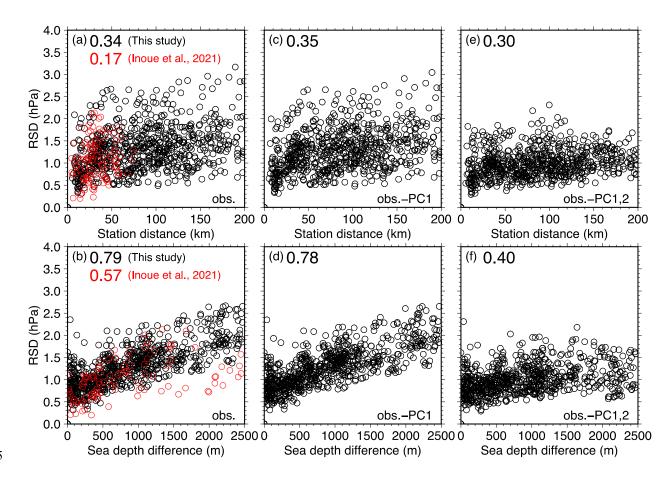

Figure 7. The correlation distribution between the standard deviation of the relative pressure time series
(RSD) and the station distance (a, c, e, g) or the sea-depth difference (b, d, f, h). The standard deviation is
calculated for (a, b) the observation, (c, d) after removing PC1, and (e, f) after removing PC1 and PC2.
Black dots indicate the correlation between the standard deviation and the distance or the sea-depth for
each relative pressure time series. Red dots indicate the same thing as the black dots but for the offHikurangi margin (Inoue et al., 2021). The upper number is the correlation coefficient between the two
axes for each figure.

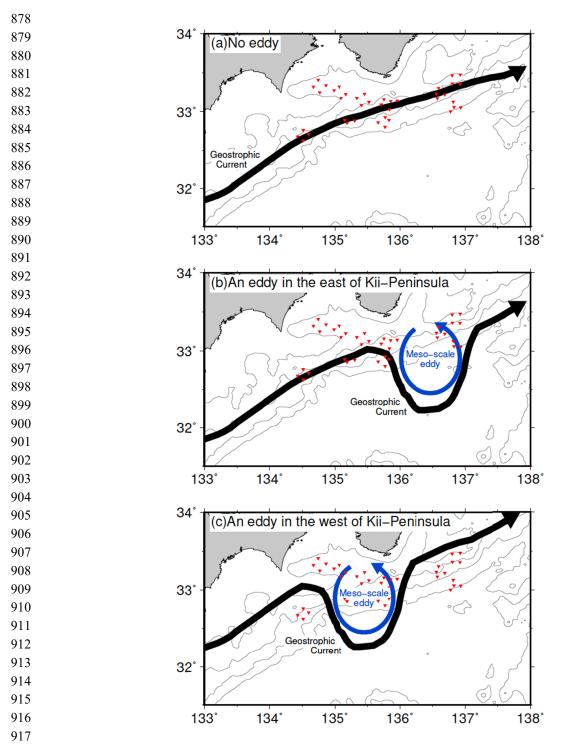

Figure 8. The sketches on the interpretation of the spatial distribution of each principal
component. (a) The geostrophic current (Kuroshio Current) without meandering and eddy. (b/c)
The geostrophic current with a mesoscale eddy (cold vortex) located in the south east/west of
Kii-Peninsula. Black bold arrow indicates the flow path of the geostrophic current. Blue arrow
indicates the image of the meso-scale eddy corresponding to the geostrophic current. Red
triangles indicate the DONET observation points used in this study.

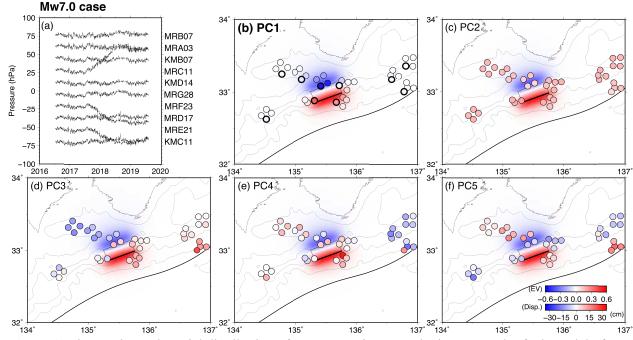

Figure 9. Time series and spatial distribution of PCA assuming a synthetic rectangular fault model of 928 929 $M_W 7.0$ centered at 135.5°E, 33.0°N. Figures with bold captions reflect the assumed synthetic ramp (In this case, (b) reflects the synthetic ramp.) (a) The pressure time series representing each node after 930 applying a synthetic ramp to the observed time series (Figure 6(a)). (b) Spatial distribution of the PC1 931 when PCA is applied to the time series in (a). The bold circles indicate the observation sites whose time 932 series are illustrated in (a). (c-f) Same as (b), but for PC2, PC3, PC4, and PC5, respectively. The 933 934 rectangular area indicates the assumed fault model, and the background color shows the vertical displacement calculated from the synthetic fault model. The thin line indicates the isobath with the 935 936 interval of 1000m.

927

938 939

940

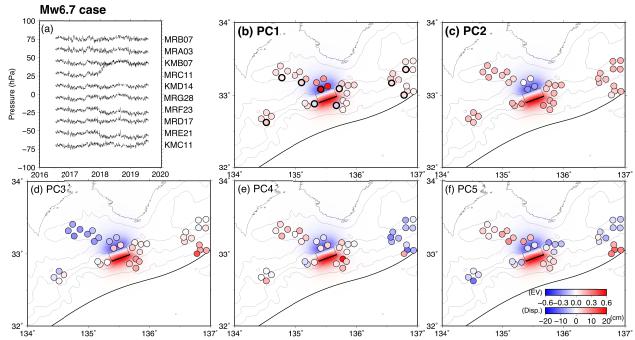

Figure 10. The views of the figures are the same as in Figure 9, but for the Mw6.7 case. In this case, (a) and (b) reflect the synthetic ramp.

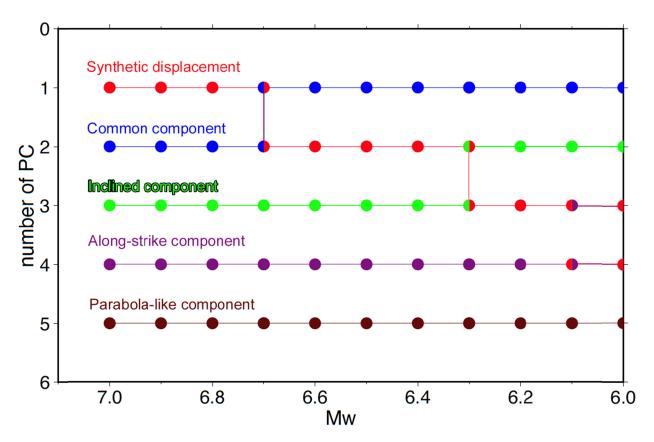

Figure 11. The PC variation per Mw based on the spatial distribution of each PC by the synthetic fault
 centered at 135.5°E, 33.0°N. As the Mw decreases, the applied synthetic displacement component
 migrates to higher-order PCs. In the Mw6.7 and Mw6.3 cases, the spatial distribution characteristics of
 PC1 and PC2 or PC2 and PC3, respectively, are mixed.

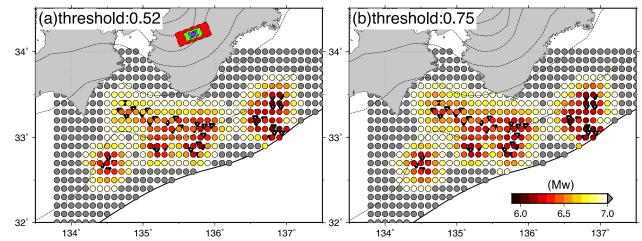

Figure 12. (a) The lower limit of the detectable Mw for each center position of the synthetic rectangular fault using only OBP data and PCA for the threshold of 0.52. (b) Same as (a), but for the threshold of 0.75. The rectangles with dotted lines indicate the case of Mw7.0 (red), Mw6.5 (green), Mw6.0 (light blue), and Mw5.5 (pink).

Mw	Duration	Duration Length		Mw	Duration	Length	Slip
	(days)	(km)	Slip (cm)		(days)	(km)	(cm)
