Abstract

At the heart of the vision of sustainable development and intergenerational responsibility lies the prudent use of natural resources. Agriculture is a key sector both in terms of resources consumed and of goods and services provided. Recently Its intensification and expansion have been studied and their sustainability evaluated, often with a particular focus on water management. While, in literature, possible agricultural strategies have been based on local water availability and, in some cases, downstream effects of such strategies have been evaluated, a method to identify and quantify hydrologically sustainable land use and crop use changes directly accounting for downstream effects is yet to be defined. Here we propose a framework to assess hydrological sustainability of land use and crop use changes, preventing both in situ and downstream effects. We apply this framework on the case study of coffee plantations expansion in Kenya, a sector that is seeing, and is planned to see, a rapid growth, given its potential in promoting agricultural, economic, and social development, not without risks associated to hydroclimatic change. We simulate the hydrological alterations caused by coffee plantation expansion onto available suitable areas, and use these simulations to identify areas where the expansion does not generate water scarcity either in situ or downstream. The assessment of hydrological suitability proves effective in preventing water availability reduction. Areas selected for expansion present similar total water footprints as currently used areas, but with higher precipitation-generated water availability. The proposed methodology identifies and quantifies areas in a physically robust, and thus transparent, way, also maintaining flexibility to the selected expansion scenario and low data intensity. This makes this framework a potentially easily replicable methodology for planning sustainable agricultural development within planetary boundaries.

A blue water scarcity-based method for hydrologically sustainable agricultural expansion design

Key points

A new methodology for designing sustainable agricultural expansion while preventing water scarcity is developed

The method selects, among areas with high water availability, those not onsetting water scarcity either locally nor downstream

An application on coffee expansion in Kenya identifies more areas than foreseen by policy, leaving action space for further selection criteria

Abstract

At the heart of the vision of sustainable development and intergenerational responsibility lies the prudent use of natural resources. Agriculture is a key sector both in terms of resources consumed and of goods and services provided. Recently Its intensification and expansion have been studied and their sustainability evaluated, often with a particular focus on water management. While, in literature, possible agricultural strategies have been based on local water availability and, in some cases, downstream effects of such strategies have been evaluated, a method to identify and quantify hydrologically sustainable land use and crop use changes directly accounting for downstream effects is yet to be defined. Here we propose a framework to assess hydrological sustainability of land use and crop use changes, preventing both in situ and downstream effects. We apply this framework on the case study of coffee plantations expansion in Kenya, a sector that is seeing, and is planned to see, a rapid growth, given its potential in promoting agricultural, economic, and social development, not without risks associated to hydroclimatic change. We simulate the hydrological alterations caused by coffee plantation expansion onto available suitable areas, and use these simulations to identify areas where the expansion does not generate water scarcity either in situ or downstream. The assessment of hydrological suitability proves effective in preventing water availability reduction. Areas selected for expansion present similar total water footprints as currently used areas, but with higher precipitation-generated water availability. The proposed methodology identifies and quantifies areas in a physically robust, and thus transparent, way, also maintaining flexibility to the selected expansion scenario and low data intensity. This makes this framework a potentially easily replicable methodology for planning sustainable agricultural development within planetary boundaries.

Introduction

The focal point of sustainable development is the rational use of resources, aimed not only at satisfying current needs, but also at guaranteeing the fulfilment of the needs of future generations, who indeed occupy

26   a prominent place in this vision (Brundtland, 1987). Water resources are at the core of many of the main

27   global and regional challenges our planet is facing. Freshwater is mentioned as one of the Planetary

28   Boundaries (Gerten et al., 2013; Gleeson et al., 2020; Rockström et al., 2009), it constitutes the main object

29   in one of the United Nations (UN) Sustainable Development Goals (SDGs), SDG6, while appearing in other

30   four (SDGs 3,11,12,15) and being indirectly involved in at least other two (SDGs 2,7) (UN, 2020). In fact, it is

31   well known that freshwater is an essential ecosystem service flow(Gerten et al., 2013), a fundamental

32   resource for the production of food and energy (D'Odorico et al., 2018; FAO & Food and Agriculture

33   Organization of the United Nations, 2014), and the constitutor of many basic human services (UNDP, 2016).

34   Among other sectors, agriculture plays a key role in meeting the food, fibre, and energy demand, but it is also

35   the largest natural resources consumer, in particular concerning freshwater use. In fact, 70% of the world

36   water use is linked to agriculture (Siebert & Döll, 2010), and this amount is expected to increase even more

37   in order to meet the future rise in demand driven by population growth, energy policies and changing dietary

38   habits (Godfray et al., 2010).

39   Accurately assessing demand for freshwater resources – both in terms of timing and magnitude – is critical

40   for understanding the water sustainability of agriculture. A better understanding of agricultural water needs

41   could be used to identify those places where water demand and its variability could potentially increase or

42   compromise the reliability of crop production, and for formulating solutions to promote sustainable water

43   management.

44   Recent studies have quantified the sustainably attainable additional food production (Rosa et al., 2018, 2020)

45   and evaluated possible crop production optimization strategies based on local water availability (K. F. Davis

46   et al., 2017, 2019). Other studies analysed the downstream effects of such mechanisms (Chiarelli, Passera,

47   Rulli, et al., 2020; Galli et al., 2022). However, there still is the need to establish a method which enables to

48   identify and evaluate, globally and locally, under what conditions certain land use and crop use choices and

49   changes may be sustainable. From a hydrological point of view, land use and crop use change impact the

50   water balance in more than one way. The most direct impact is likely the localized increase in water scarcity

51   because of an increase in blue water demand associated to irrigation, with the same water availability. In a

52   more indirect way, land use and crop use change produce variations in water scarcity because the higher

53 evapotranspiration rates of the new agricultural areas reduce the formation of blue water (Ricciardi et al.,

54 2022). Also, water scarcity can propagate downstream. Assuming, for the sake of simplicity, to divide a

55 watershed in an upstream region and a downstream region, increased demand, or decreased formation, of

56 blue water upstream can produce water scarcity downstream, if upstream blue water was originally used

57 downstream. These upstream-downstream effects of water scarcity can arise also in absence of upstream

58 water scarcity: even limiting new upstream irrigation water uses to the amount that does not generate water

59 scarcity where it is used, this new water use produces downstream water scarcity if that volume originally

60 flowed downstream and was used to satisfy the downstream blue water demand(Chiarelli et al., 2022). How

61 can the knowledge of these mechanisms be leveraged to design sustainable agricultural expansion and

62 intensification? While water scarcity assessments can provide the quantitative base for a more hydrologically

63 conscious formulation of sustainable development policies, strategies, and solutions (Z. Hussain et al., 2022),

64 the challenge is to go beyond providing ready-to-use assessments of baseline water scarcity indicators and

65 basing policy recommendations on their interpretation. Can water scarcity assessments be used to further

66 bridge this science-policy gap, directly basing sustainability policies on water scarcity related targets? The

67 answer to this question, besides being of value within science, can play an essential role in economic and

68 political decision making. Economic development strategies must be considered according to, among other

69 criteria, sustainability and resource-based feasibility. In this context, the matter of cash crops is highly

70 debated, as their water requirements have often proved to be higher than those of the main food crops

71 (Chiarelli, Passera, Rulli, et al., 2020). Therefore, a thorough sustainability assessment of such policies is

72 needed to avoid transitory benefits which may otherwise worsen the water scarce conditions in the country

73 on the long terms. Investigations on the potential increase of cash crop production require attention to the

74 natural resources (i.e. suitable land and water) demand and availability as well as to the direct and indirect

75 effects of natural resources use.

76 Here we propose a methodology to assess hydrological sustainability of land use and crop use changes,

77 evaluating both in situ and downstream effects of water use. We apply this framework on the expansion of

78 coffee cultivations an example of a water intensive cash crop whose expansion in subtropical countries has

79 seen a rapid and ongoing boom (FAO, 2019a). We select Kenya as a case study, where coffee also has a

80   recognized potential in promoting agricultural, economic, and social development (International Coffee

81   Organization, 2019). Coffee is also the most water-intensive crop in Kenya (in terms of water volume per

82   produced tonne), the third crop by total volumetric water consumption, and the most important component

83   of the Kenyan virtual water export (Mekonnen & Hoekstra, 2011). The coffee production and export sector

84   in Kenya, among the biggest in Africa, currently employs around 5 million people (L. A. S. Hussain et al., 2020).

85   In contrast to many other coffee exporting countries, in Kenya smallholders account for most of the

86   production. Some 700,000 small scale farmers, organized in hundreds of cooperatives to which they sell their

87   cherries, account for 80% of the country's coffee production (Mugo et al., 2019). The rest are around 3,000

88   large coffee estates, selling their own coffee directly (L. A. S. Hussain et al., 2020). The Kenyan government

89   recently approved a plan for the development and expansion of agriculture, including coffee plantations, in

90   order to promote agricultural and economic development (Agriculture and Food Authority (AFA), 2018b).

91   Growth rates for the coffee sector in Kenya are increasing, moving from a less than 10% growth in 2017/18

92   with respect to the previous season(Agriculture and Food Authority (AFA), 2018a) to an almost 30% increase

93   in 2020/21 with respect to the previous season (Agriculture and Food Authority (AFA), 2021). Part of this

94   increase in production is associated to agricultural expansion(Agriculture and Food Authority (AFA), 2021).

95   However, policy plans like this often miss an in-depth hydrological analysis of the impacts connected to the

96   expansion of such water-demanding crops, especially in light of the well-known environmental impacts of

97   agricultural expansion, often deemed higher than those, for instance, of yield gap closure by agricultural

98   intensification (D'Odorico et al., 2018). Water scarcity- and food insecurity-related consequences of poorly

99   planned agricultural policies may derail the very same plan they arose from. Evidences of such backfiring can

100   be observed, for instance, in the United Arab Emirates, where agricultural development and production saw

101   a rapid boom in the early 2000s only to come to a quick stop shortly after, caused by the progressive fossil

102   ground water depletion (Sherif et al., 2021). A similar situation has been observed in India since the late 60s

103   (K. F. Davis et al., 2018). The then adopted self-sufficiency policy in cereal production, has led, in the following

104   decades, to a steady lowering of the groundwater table (Rodell et al., 2009). Kenya is facing a situation of

105   acute water and food insecurity, which will be worsened by hydroclimatic change (Ngaira, 2009). Therefore,

106   boosting coffee production in Kenya would will improve the livelihoods of local people and generate export

107   revenue only if it is planned within resource boundaries.

108   On one hand, coffee is a plant with well-defined optimal growing conditions, regarding a broad spectrum of

109   climatic, morphological, chemical and pedologic parameters (Allen et al., 1998; IIASA & FAO, 2012). All these

110   parameters have to be taken into account to maximize the yield. On the other hand, increased coffee

111   production is associated to increased natural resource consumption, expecially water (Mekonnen &

112   Hoekstra, 2011). To guarantee the environmental sustainability of the additional coffee production, it must

113   not induce resource scarcity as much as it must not conflict with demands for the same resources coming

114   from crucial activities. To assess whether it is possible to expand coffee plantation in a sustainable way, we

115   start the crop expansion from the suitable areas for coffee cultivation as reported by the Global

116   Agroecological Zones Data Portal (GAEZ) (FAO, 2021). Then, we use hydrological modeling of water scarcity

117   to narrow down the selection of these areas to those not generating water scarcity, not only locally (i.e.

118   where coffee is or may be actually cultivated), but also in the downslope and downstream areas.

119   Methods

120

121   Kenya is an African country extending over 580370km^2 in the Eastern part of the continent, on the Indian

122   Ocean coast. The population of Kenya was estimated as 51 million in 2018 and it is expected to have a sharp

123   growth in the next decades since it will more than double (UN, 2019). 37.5 million people live in rural areas,

124   and almost 70% of the economically active population worked in the agricultural sector in 2014 (FAO, 2016a).

125   The high diversity of the Kenyan morphology, the presence of the ocean and of major inland water bodies,

126   and the low latitudes create a climate that ranges from arid to equatorial through humid subtropical in the

127   uplands (Kottek et al., 2006). The rain pattern is bimodal, with a first rainy season from March to May and a

128   second one from October to December. The concentration of water towers in the central-western area of

129   the country generates inhomogeneity in the catchments' water availability, and most of the catchments are

130   shared with neighbouring countries (FAO, 2015, 2016b). The total actual renewable water resources (TRWR)

131   correspond to a per capita value of 617 m3/year, which is just above the 500m3/year absolute water scarcity

132   threshold (Falkenmark, M, 1989; FAO, 2016b).

133   According to (FAO, 2019b), it is estimated that in Kenya the area harvested with coffee in 2018 was 115570

134   ha, having agricultural yield of 0.358 ton/ha and crop production of 41375 tonnes.

135   We base our analysis of the sustainable coffee extensification on spatially distributed agro-hydrological

136   simulations for different land use scenarios in Kenya. To guarantee effectivity while countering the risk of

137   resource depletion, the extensification of coffee cultivation is designed considering the plant characteristics

138   and optimal growing conditions. The elevation is needed to guarantee the ideal temperature range that

139   delays the bean ripening increasing coffee quality and prevent pests (A. P. Davis et al., 2012; Jaramillo et al.,

140   2011). A higher temperature would affect the plant's photosynthesis, resulting in stress, whereas lower

141   temperatures increase the risk of frosting. The slope is required to improve air drainage and reduce frost

142   damage (Valipour & Eslamian, 2014), but it has to be gentle to prevent soil erosion. The correct aspect assures

143   a good sun exposure. The application of lime can be effective to overcome the limitations concerning soil

144   type and characteristics. The pH is important for the plant yield: a too acid soil can undermine the presence

145   of phosphorus and other fundamental nutrients. Coffee land suitability data based on these factors are

146   retrieved from the GAEZ project (FAO, 2021; IIASA & FAO, 2012), which provides crop-specific global

147   suitability maps. These maps are calculated from the crop yield. Among all, we consider three significant

148   levels of suitability: very high, high and moderate, corresponding respectively to a yield higher than 80%, 60%

149   and 40% of the maximum attainable yield. These three levels of suitability (moderate, high, very high) are

150   combined with the remaining available shrub areas obtained from the Copernicus Land Service Land Cover

151   data (Buchhorn et al., 2019). We consider for expansion only areas that have at least a given suitability and

152   are not used for equally important activities, e.g., as pasturelands or protected areas. In this way, we define

153   two initial extensification alternatives: current areas (used as baseline), additional areas with at least

154   moderate suitability and no competing uses.

155   First, we expand coffee cultivation under current climate on suitable areas and evaluate the effect of such

156   expansion on water availability. Crop specific cultivated areas (including coffee) are retrieved from the MIRCA

157   dataset, updated to around year 2000 (Portmann et al., 2010). The land classification for uncultivated areas

158   is obtained from the GlobCover 2009 project (Bontemps et al., 2009). Whenever the cultivated areas from

159   GlobCover do not match the MIRCA croplands, GlobCover data are proportionally rescaled. Crop calendars

160   and crop vegetative phases are taken from (Siebert & Döll, 2010). Soil data come from FAO's Harmonized

161   World Soil Database (FAO et al., 2012).

162   Crop water use (including coffee) is calculated using the physically based and spatially distributed agro-

163   hydrological model WATNEEDS (Chiarelli, Passera, Rosa, et al., 2020). The water footprint approach of this

164   model partitions crop water requirements in green water and blue water: the crop water requirement is the

165   volume of water needed to support a crop's evapotranspiration, green water is the fraction provided through

166   precipitation and blue water is the remainder, provided through groundwater resources and/or irrigation.

167   The model is centred on a vertical water balance equation, solved at a daily time scale and at 5 arc-minutes

168   (around 10 km) resolution in order to obtain the crop water requirements (CWR) through the estimation of

169   crop evapotranspiration. The vertical water balance is reported in Equation 1 by means of soil moisture

170   accounting. In a single cell, the soil moisture is calculated for each crop and land use i at each day t as:

171

$$S_{i,t} = S_{i,t-1} + \Delta t \cdot (P_{eff} + I_{i,t} - ET_{a,i,t} - D_{i,t} - R_{i,t}) \tag{1}$$

172

173   where $S_{i,t-1}$ is the soil moisture in the previous time step, Δt is the duration of the time step, equal to one

174   day. P_{eff} is the effective precipitation, calculated starting from CHIRPS data (Climate Hazards Group, 2015)

175   and assuming that 5% of the precipitation is immediately partitioned to runoff (Hoogeveen et al., 2015).

176    $ET_{a,i,t}$ is the actual evapotranspiration, calculated starting from the potential evapotranspiration, i.e. the

177   product of reference evapotranspiration and crop coefficient (Allen et al., 1998). Reference

178   evapotranspiration is retrieved from the CRU TS3.10 Dataset (Harris et al., 2014), which uses the Penman-

179   Monteith equation. For rainfed crops, when the crop water requirement exceeds the readily available water,

180   i.e. the water the plant can uptake from the root zone without entering crop water stress, the crop coefficient

181   is opportunely reduced by a stress factor. For irrigated crops, this excess demand with respect to the available

182   water is supplied by irrigation. $D_{i,t}$ is the deep percolation below the root area, occurring when soil moisture

183   exceeds field capacity, i.e. the maximum volume of water that can be retained by the soil. $R_{i,t}$ is the sub-

184   surface runoff, occurring when the excess in soil moisture cannot be uptaken exclusively by deep percolation

185   because it would require an infiltration rate higher than the maximum.

186   The results are then monthly aggregated.

187   The model is run in current (baseline conditions) and considering the replacement of coffee in all areas where

188   suitability of coffee is at least moderate and no competing uses where identified. Basing on the results of

189   these two scenarios, blue water scarcity (Equation 2) is computed as the ratio between demand and

190   availability of freshwater:

191

$$BWS = \frac{Dom + Ind + Agr}{0.2R + \langle 0.2R_{up} - (Dom + Ind + Agr)_{up} \rangle} \tag{2}$$

192

193   Where Dom, Ind and Agr are domestic, industrial, and agricultural blue water demands, respectively.

194   Agricultural blue water is given as an output by the soil water balance, whereas industrial and domestic water

195   footprints are retrieved from (Hoekstra & Mekonnen, 2012). Local blue water availability is calculated from

196   runoff R, also an output of the hydrological model, constrained by environmental flow requirements through

197   the 0.2 factor in Equation 2, representing a fixed unconstrained runoff fraction of 20% (Rosa et al., 2018). To

198   model the impact of upstream users on downstream areas, the local blue water availability in a grid cell is

199   summed to the net blue water availability from the upstream grid cells. Net blue water availability is

200   calculated as the cumulated surplus of upstream cells with respect to their water demand. The pointy

201   brackets in Equation 2 represent a conditional statement by which, if in a cell the sum of water availability in

202   the cell and surplus water coming from upstream areas exceeds human demand, this excess is passed onto

203   downstream cells, whereas if the demand is higher than the availability all the water is consumed in the cell

204   and no surplus is passed onto downstream cells. By calculating blue water scarcity in the current scenario

205   and in the coffee expansion scenario, and comparing the two sets of results, we can evaluate the impact of

206   this agricultural expansion on water scarcity. In particular, we measure the impact as variation in yearly blue

207   water scarcity months, i.e. months during which the blue water scarcity index has a value greater than 1. This

208   means the demand of water is higher than the availability, and thus that this demand cannot be satisfied, or

209   at least not without depleting environmental flows. Starting from this impact assessment we build up an

210   iterative procedure to design agricultural expansion with no tangible water scarcity effects. A simplified

211   example of this procedure is represented in Figure 1. The two sets of water scarcity data are therefore used

212   as boundary conditions: the modified blue water scarcity, accounting for agricultural expansion, is the initial

213   condition for the iterative procedure, and the baseline situation, before the expansion, is considered as the

214   target. The steps of the procedure are the following:

215   1. **Identification of new water scarce areas.** We compare the initial (new) and target (baseline) blue

216   water scarcity months data. Areas having a number of months higher in the new situation than in

217   the baseline (red areas in Figure 1, map b) are areas where the coffee expansion produced the onset

218   of water scarcity for at least one month in the average year.

219   2. **Identification of upstream areas responsible for the onset of blue water scarcity** (Figure 1, map c).

220   Each pixel experiencing changes in blue water scarcity months is snapped to the closest subbasin

221   outlet. The watershed is reconstructed for each of these outlets, and the coffee expansion areas

222   within these watersheds are identified.

223   3. **Reduction of the irrigated crop expansion** (Figure 1, map d). In each irrigated crop expansion pixel

224   that generates water scarcity, the blue water allocated to coffee in expansion areas is reduced by a

225   fraction of the currently allocated value. This means that, along iterations, blue water allocation

226   decreases following an exponential decay to reach asymptotically zero. To limit iterations, pixels are

227   shut off once they reach a cut-off value of blue water allocation, meaning that no expansion is

228   allowed to take place (Figure 1, map f), and in the following iteration the soil water balance values

229   for those pixels are taken from the baseline scenario and not from the expansion scenario.

230   4. **Decision.** After step 3 we return to step 1, comparing target (baseline) blue water scarcity to blue

231   water scarcity calculated from the redesigned expansion resulting from step 3. The possible cases

232   are the following:

233   a. **Variations in water scarcity, some expansion areas still active** (Figure 1, map d). This means

234   that there are still some areas generating downstream water scarcity effects, for which the

235   blue water contribution has to be reduced, so we go through steps 2 and 3 again (Figure 1,

236   maps e and f).

237   **b.** **No variations in water scarcity, no expansion areas active.** This means that any expansion

238   intervention in the area will lead to the onset of water scarcity somewhere, so the expansion

239   is completely unfeasible, and we exit the process.

240   **c.** **No variations in water scarcity, some expansion areas still active** (Figure 1, map f). This

241   means that the remaining expansion areas can satisfy their blue water demand without

242   generating blue water scarcity, so, to this extent, the expansion is hydrologically sustainable,

243   and we exit the process.

244   For the specific application of coffee in Kenya, the procedure has been run using a 0.1 cut-off fraction,

245   meaning pixels are shut off if less than 10% of the blue water required can be provided. Concerning the

246   reduction factor, we ran the procedure with different factors ranging from 0.5 to 0.75, obtaining substantially

247   equivalent results, but, clearly, with longer computational times for higher factors, as more iterations are

248   needed in that case to reach the target values.

249

250
251   *Figure 1. Graphic schematization of the followed methodology for a single catchment. In this simplified representation, agricultural*

252   *areas are shut off after one reduction of water contribution (paler brown areas), and a solution is found after two iterations.*

Results

254   Land use and water requirements for the main crops (cultivated areas greater than 50000ha) are reported in

255   Table 1. Land use data are computed from the maps by GlobCover (Bontemps et al., 2009), while water

256   volumes are calculated from the results of the soil water balance. Maize, pulses, and coffee are the most

257   widespread crops harvested in Kenya. Crop production in Kenya is mainly rainfed, with only less than 5% of

258   crop being irrigated (approximatively 77000 ha, 20% of which for coffee). Almost 150 thousand hectares are

259   harvested with coffee in Kenya, 10% of which are irrigated. Coffee is a relatively water intense crop in Kenya,

260   being the fifth crop by harvested area, but the third by green water requirement and the first by blue water

261   requirement. The high volumes of blue water are also related to the value of coffee as a crop, as irrigation is

262   associated to a cost that must be compensated by the revenues. However, crop yield of coffee in Kenya

263   amounts to 0.34t/ha, which is a very low value if compared to top producer countries' values (e.g. it is 1/10

264   of Malaysia crop yield) (FAO, 2019a).

265

266 *Table 1. Harvested area and yearly crop water requirements for Scenario 1*

Crop	Area [ha]	Green Water [Mm^3]	Blue Water [Mm^3]
Maize	1574203	4444	7
Pulses	1202510	3050	0
Others annual	368562	853	54
Others perennial	261613	1722	51
Coffee	149316	1021	95
Wheat	141242	426	0
Sorghum	134094	382	0
Potatoes	113930	252	0
Millet	96552	265	0
Cassava	93443	414	0
Sugar cane	53227	343	11

267

268 We choose to consider all expansion areas as irrigated areas, under the hypothesis of maximizing the

269 productivity of the new areas by closing the crop yield gap trough irrigation (Rosa et al., 2018a). Therefore,

270 when comparing water requirements in expansion scenarios with current water requirements, we consider

271 those of irrigated coffee areas.

272

273 The blue water scarcity-based design of coffee harvest expansion in Kenya renders a positive outcome,

274 meaning that areas are identified where the expansion of coffee cultivation does not generate additional

275 water scarcity. The total areas available for expansion extend over 3.38Mha, of which 2.27Mha are at least

276 moderately suitable to the cultivation of coffee. The iterative procedure narrows this pool down to 0.24Mha

277 that can be harvested in conditions of hydrological sustainability. The spatial distribution of these areas,

278 visible in Figure 2, helps better understand how these areas are identified. The map in Figure 2 shows where

279   the areas are located avoiding to show, for the sake of completeness in the visualization, the 'intensity' of

280   the expansion, i.e. how many hectares are used for expansion in each of the mapped pixels. However, the

281   general trend in this sense can be inferred qualitatively by comparing the extent with the totals. Areas

282   currently harvested with coffee amount to 0.15Mha, of which only one tenth are irrigated. They appear in

283   Figure 2 to be mostly located in the Southwest of Kenya. These are the hilly areas where Kenya's water towers

284   are located(FAO, 2015), having many of the characteristics that make an area suitable for the cultivation of

285   coffee. In fact, coffee thrives best in elevated areas, that ensure mild temperatures even in tropical climates,

286   so to avoid at the same time frosting and heat stress. Also the mild slope of these mountainous areas helps

287   preventing frosting, while ensuring sufficient drainage without setting on erosion (FAO, 2021; Valipour &

288   Eslamian, 2014). The areas available for expansion with at least moderate suitability, labelled 'Suitable areas'

289   in Figure 2, extend from these mountainous regions onto the neighbouring ones, especially southwards, i.e.

290   towards areas where the humid climate is preserved, while northwards the climate becomes progressively

291   arid (Kottek et al., 2006). While, visually, current and suitable areas extend over similar regions, suitable areas

292   are more than 20 times higher than current areas. This means that suitable areas represent shares of

293   expansion pixels that are much higher than the common coffee harvested pixel share. It is rather unrealistic

294   to consider these areas available for expansion as a whole, i.e. to project agricultural expansion on the total

295   of these areas. This is why they are used here only for the sake of hydrological characterization, and as an

296   initial pool from which to choose expansion areas, i.e. as a set of areas that are equally (un)sustainable *a*

297   *priori*, from the land use and crop suitability point of view, from which to select only those that are also

298   hydrologically sustainable. These hydrologically sustainable areas, i.e. areas using water without conflicting

299   with pre-existing water uses, labelled 'Sustainable areas' in Figure 2, are more strictly located in the region

300   currently harvested with coffee than the suitable superset. In many cases, they overlap with currently

301   harvested pixels. In these cases, shares of available areas are converted to coffee cultivation in pixels where

302   coffee cultivations where already pre-existing. This is probably the less impacting type of expansion from the

303   environmental, social and landscape point of view, as we project new coffee plantations where they are

304   already present in the mix, rather than introducing them as a new species, agricultural system, and landscape

305   element.
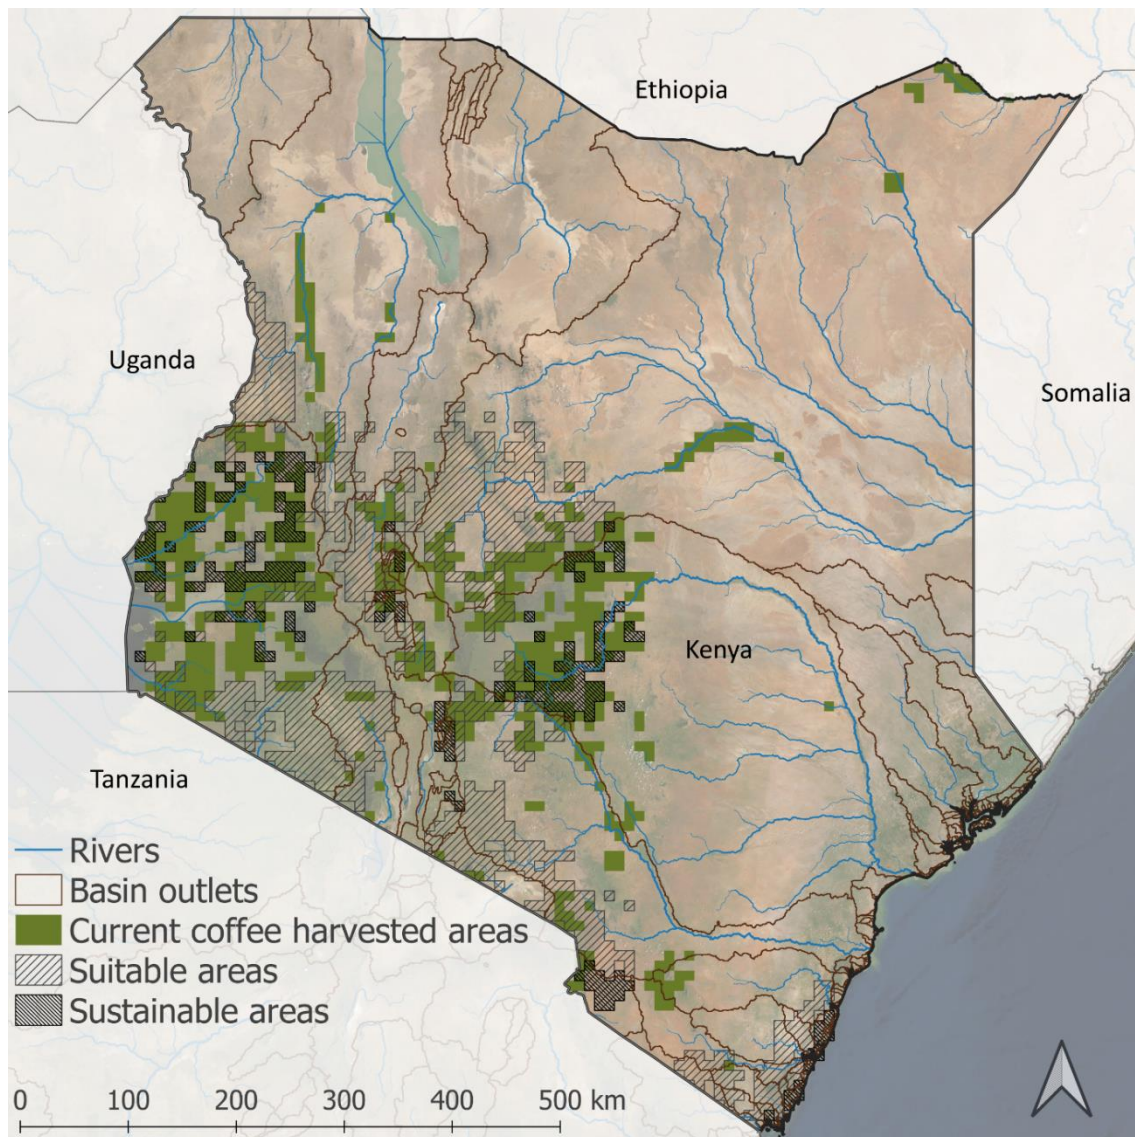

Figure 2. Current coffee harvested areas in Kenya, and suitable and hydrologically sustainable areas for the agricultural expansion of coffee cultivation.

The sustainable expansion areas amount, as already mentioned, to 0.24Mha, which is more than the current coffee harvested areas in Kenya. The fact that they extend over a smaller region than current coffee harvested areas means that, as for the suitable areas, sustainable areas occupy larger shares of the pixels they are in than current coffee harvested areas. In terms of how the iterative procedure works, this means that the areas in many of the pixels in the initial pool of available areas are either used almost completely or completely shut off. In essence, in areas where water is available, it is also sufficient for relatively larger expansion schemes, while in many other regions water scarcity is very sensitive to land use change. The fact that sustainable areas are mostly located in co-presence with existing areas also shows that, to some degree,

317   the existing agricultural system has adapted to the local water availability spatiotemporal gradients. Indeed,

318   the only sustainable expansion areas located far from existing ones are on the southern coast of Kenya. In

319   this case, being close to river outlets of small coastal basins (Figure 2), excess water has no downstream

320   users, therefore the model identifies them as areas not producing any downstream water scarcity effects.

321   Table 2 and Figure 3 show how increasing the areas for coffee production results in significantly higher water

322   requirements. First of all, even though coffee cultivation in Kenya is primarily rainfed, blue water

323   requirements occupy a significant share of the crop water requirement. Interestingly, green water use in

324   rainfed areas is lower than in irrigated areas, more likely due to a lack in availability than to a lower demand

325   of the plant. This is probably one of the main factors underlying the low yield of coffee in Kenya. The cascading

326   effects of expanding coffee plantations by cultivating suitable areas without hydrological constraints can be

327   evaluated both from the partition of water requirements in Figure 3 and from the water scarcity map in

328   Figure 4. Coffee in suitable expansion areas would have a higher crop water requirement than currently

329   irrigated coffee. The green water contribution to this requirement is slightly higher, in absolute terms, in

330   suitable expansion areas, but the higher total water requirement counters this effect, leading to an overall

331   higher blue water consumption. This, combined with the high extent of these new agricultural areas,

332   produces strong variations in blue water scarcity. Figure 4 shows maps of yearly months of water scarcity,

333   i.e. months during which the demand for blue water exceeds the availability. The left map shows water

334   scarcity months when coffee cultivation expands onto suitable areas, while the right map shows water

335   scarcity months when coffee cultivation expands onto sustainable areas, i.e., the areas that are obtained at

336   the end of the iterative procedure. Because the iterative procedure is designed to find expansion areas that

337   produce negligible variations in blue water scarcity, the blue water scarcity map for sustainable areas is

338   visually equivalent to current actual blue water scarcity, before expansion, and thus can be used for

339   comparatively analysing both the performance of sustainable areas with respect to suitable areas, and of

340   suitable areas with respect to the baseline condition. On average, suitable areas suffer from water scarcity

341   almost three times longer than areas where coffee is currently cultivated. While there are some areas where

342   this effect is lower than average, some clusters emerge in Figure 4, where blue water scarcity increases

343   dramatically, moving for instance from 0-1 months/year to 10-11months/year. These extensive and intense

344   increases in blue water scarcity, mostly localized within the expansion areas, expand also downstream, which

345   can also be inferred from the visual comparison of the two maps in Figure 4. By comparing the two maps, is

346   becomes evident how, for instance, coffee expansion on suitable areas without hydrological constraints

347   would produce a far-reaching depletion effect on the Ewaso-Ngiro river, flowing from West to East in the

348   centre of the country. Indeed, while in the right map the trace of the river is evident, as a stream of pixels

349   with lower water scarcity months values than the surrounding pixels, this stream disappears in the left map,

350   showing how the pixels where the Ewaso-Ngiro flows do not benefit anymore, in terms of water availability,

351   from the presence of the river. The Ewaso-Nigro then flows into Somalia. This means that, in a scenario where

352   coffee expansion significantly depletes the river's resources, transnational issues may arise if the depletion

353   reaches the border, thus impacting Somalia's water scarcity situation. The blue water scarcity-based crop

354   expansion design, instead, allows to accurately target areas preventing this water resource depletion. What

355   is interesting to observe, in this regard, from Figure 3, is that, even though coffee has a slightly higher crop

356   water requirement in sustainable areas than in both current irrigated and suitable expansion areas, the

357   relative contribution of green water to this requirement is much higher. If we compute green water scarcity

358   as the ratio of blue water consumption with respect to the total water requirement, we obtain values of 0.47,

359   0.45 and 0.39 for current, suitable and sustainable areas respectively. This means that, while suitable areas

360   are very similar to current ones in terms of green water scarcity, harvesting on sustainable areas implies

361   having a 15% lower green water scarcity in these areas than in current areas. Moreover, the fact that

362   sustainable areas use much more green water (100mm more than sustainable areas, 163mm more than

363   current irrigated areas) does not mean that sustainable areas are more green water intensive, but rather that

364   more green water is available in these areas. As mentioned before, agricultural expansion can increase water

365   scarcity both through the increase in blue water demand given by irrigation and through the decrease in blue

366   water availability caused by lower generation of runoff. In the case of sustainable expansion areas, the lower

367   blue water demand and the higher green water availability create a synergy that reduced both this effect,

368   allowing to harvest and irrigate new areas without generating water scarcity not only in the areas themselves,

369   but also downstream. An important addition to this is that, even though substantially reduced with respect

370   to the total suitable areas, sustainable areas for expansion exceed expansion policy forecasts for coffee in

371   Kenya. Therefore, there is space of action that remains available to further limit the expansion according to

372   other important criteria to be accounted for when designing the implementation of such policies. On the

373   other hand, as already mentioned, these areas are in proximity of existing coffee plantations, and existing

374   plantations are to the largest share not irrigated, despite the high water intensity of coffee. Therefore, being

375   the procedure based on water before being based on land, the results also show that, alternatively to pure

376   expansion, there is also room for increasing production by combining, in a well calibrated manner,

377   intensification of existing plantations through irrigation and expansion on new areas.

378   *Table 2. **Harvested areas and relative blue and green water consumptions for current conditions and in irrigated expansion areas.***

expansion, or expansion on hydrologically sustainable areas.

Discussion

In this study, we propose a replicable and scalable methodology to evaluate the hydrological sustainability of agricultural expansions, in an integrated way with respect to both the ecological and socio-economic value of water, and accounting for both local and downstream effects of water withdrawals. We use this methodology to directly design agricultural expansion interventions in a hydrologically sustainable way. We find that selecting areas not only based on the optimal suitability criteria of the target crop, but also on local water availability and its timing, helps preventing water scarcity in areas that include, but also go beyond those directly interested by the expansion. Our research highlights the potential water competition rising for coffee intensification and expansion, as we evaluate the cumulative effects on water withdrawal.

As this work aimed at flexibility and generalizability of the methodology, some limitations arise from the simplifications introduced to reach these aims. For what concerns the hydrological implementation of coffee expansion, our results reflect an ideal situation in which irrigation always provides the whole amount of crop water needs that is not supplied by rainfall. In practice, different irrigation techniques can be adopted, e.g. supplemental irrigation and deficit irrigation. However, at the initial planning stage in which the scope of this paper is located, the best practice is to design strategies considering the whole resource demand. It is also important to take into account the whole water demand when evaluating water scarcity, which is by definition a demand-supply based index. Analogously, we accounted only for the consumptive use of water, thus avoiding the losses associated to irrigation application (i.e. transport of water, leakages) for two reasons. First, it is common practice in water footprint assessments to consider only consumptive water use because other losses are supposed to re-enter the hydrological cycle (Hoekstra & Mekonnen, 2012). Second, irrigation application losses depend strongly on the type of irrigation and of water source, and these can be very different in a sector in which the farming method ranges from small subsistence farming to large estates (Allen et al., 1998; FAO, 2015; Jägermeyr et al., 2015). The iterative procedure progressively reduces the blue water allocated to expansion areas. When it reaches a low threshold and blue water scarcity effects are still detected, it means that the expansion areas are causing water scarcity not by putting additional demand onto blue water resources, but by reducing, through the additional transpiration due to change in land use,

415 the formation of (available) blue water. In these cases, following the proposed methodology, the pixel is 'shut

416 off', meaning no expansion is allowed in the pixel at all. A conceptually refined alternative to this approach

417 could be to directly reduce the expansion area instead of reducing the blue water contribution to this area.

418 While this approach may seem more straightforward from a theoretical point of view, its application might

419 be more complex. In fact, it would require either to iteratively run a water balance model, with high

420 computational costs, or to reconstruct the cell-specific land and crop use matrix after the hydrological

421 simulation, instead of simulating the water balance of the given (current or modified) land use matrix.

422 Agricultural expansion plans and policies tend to be connected to the risk of Large-Scale Land Acquisition,

423 especially for commercial agriculture in institutionally fragile states (Lanz et al., 2018; Rulli et al., 2013; Rulli

424 & D'Odorico, 2014). This risk also applies to coffee expansion in Kenya. While our results show that

425 sustainable expansion of coffee areas is possible mostly in proximity of already existing coffee areas, thus

426 suggesting the risk of monocultures, it does so only in limited extents, in certain regions of the country. This

427 is still a rightful constraint to the scale of possible agricultural development policies, but it can also serve as

428 a bulwark against LSLA risk, in the sense that it intrinsically excludes the possibilities of very large

429 monocultural plantations. In fact, such an analysis can fit well into a wider context of agricultural

430 development, one that includes the conservation of biodiversity and landscape diversity among its

431 objectives. The projection of several small to medium scale patches for the expansion of coffee harvesting in

432 regions that are already familiar with this sector is also coherent with the socio-economic structure of the

433 coffee production chain in Kenya, based mostly on networks of small producers. The creation of structured

434 policies in that sense may help safeguard this business structure, preventing the risk of abandonment of

435 agricultural land, an emerging trend following the increasing average age of the farmers (Ngeywo et al.,

436 2015). This aspect increases in relevance in the light of the fact that a large share of the population is involved

437 in the coffee production system, and women play a central role. In fact, even though women provide roughly

438 two thirds of the workforce employed in coffee farms, they occupy only 5% of the managing positions in

439 coffee cooperatives, with most of them being widows inheriting the farm (International Coffee Organization,

440 2019; Onyalo, 2019). Therefore, if the already existing coffee production boosting policies are backed up by

441 actions towards the involvement of women in coffee management activities, this may also help to achieve

442   gender equality and reduce injustice, in line with the 5th and 10th Sustainable Development Goals, respectively

443   (United Nations General Assembly, 2015).

444   While the scope of our study is to assess and size potential areas for agricultural expansion, intensification is

445   often seen by the research and policy agendas as a more sustainable way to increase agricultural production

446   (Tilman et al., 2011). However, a hydrological impacts analysis is a rather natural outgrowth of intensification

447   scenarios (Rosa et al., 2018), while it tends to be neglected in expansion plans. In the case of coffee in Kenya,

448   there is a wide scope of action for closing the yield gap through intensification, such that different

449   irrigation/fertigation systems could be proposed, depending on external and context specific factors as the

450   energy availability for withdrawing water, the availability of pre-existent infrastructures or the financial

451   capability to install new ones, the skills of the farmers and the possible cultural barriers to the adoption of

452   new agricultural technologies (Piemontese et al., 2021). Indeed, the identified sustainable areas target

453   precise regions within the country, and this could furtherly be refined when considering other factors, such

454   as proximity to markets, to workforce or to infrastructure, as well as more local knowledge-based insights on

455   the ecosystem and heritage values of the pre-existing landscape. In the case of commercial agriculture

456   expansion in developing countries, as here, giving policy relevance to this type of biophysical assessments,

457   especially when combined with bottom-up co-creation approaches, can serve as a significant dissuasion also

458   against LSLA, which otherwise often take advantage of less specific agricultural expansion policies (Lanz et

459   al., 2018). In any case, the proposed methodology for the assessment of hydrological impacts of agricultural

460   expansion and subsequent sizing of expansion scenarios can be adapted to agricultural intensification in a

461   relatively straightforward way. As already stated in the results section, the procedure is water-based,

462   meaning that areas identified as sustainable for coffee expansion are areas where water is sufficient to

463   ensure a hydrologically sustainable implementation of that scenario. But if we decouple the scenario from

464   the water availability, it means that in these areas there is water available to support, to different extents,

465   different development scenarios, without impacting on pre-existing water uses. Simple instances of this

466   include the aforementioned possibility of mixing intensification of existing plantations and the creation of

467   new ones, or the use of deficit or emergency irrigation. More in general, the advantages of the proposed

468   methodology, related to the low amount of necessary input data and the high flexibility, make it viable for

469   replication for different crops in different contexts. In fact, the procedure can be adopted for other situations

470   similar to the one analysed here, identifying areas for hydrologically sustainable agricultural production. It

471   may potentially be a prominent and useful tool for country-level planning of agricultural development. This

472   analysis clearly shows how referring only to partial information with respect to the complexity of the issue of

473   agricultural development may lead to partial, when not misleading, results with respect to a correct framing

474   of sustainability in agriculture. Thus, it can be seen as a research contribution towards the integration of the

475   blue water scarcity indicator into quantitative analyses aimed at the design and/or impact assessment of

476   nexus solutions employing irrigated agriculture within the water planetary boundary.

Data availability statement
480   Suitability maps are retrieved from the GAEZ project (FAO, 2021; IIASA & FAO, 2012) available from
