Abstract

Supercooled fogs can have an important radiative impact at the surface of the Greenland Ice Sheet, but they are difficult to detect and our understanding of the factors that control their lifetime and radiative properties is limited by a lack of observations. This study demonstrates that spectrally resolved measurements of downwelling longwave radiation can be used to generate retrievals of fog microphysical properties (phase and particle effective radius) when the fog visible optical depth is greater than ~0.25. For twelve cases of fog under otherwise clear skies between June and September 2019 at Summit Station in central Greenland, nine cases were mixed-phase. The mean ice particle (optically-equivalent sphere) effective radius was $24.0\pm7.8 \mu m$, and the mean liquid droplet effective radius was $14.0\pm2.7 \mu m$. These results, combined with measurements of aerosol particle number concentrations, provide observational evidence supporting the hypotheses that (a) low surface aerosol particle number concentrations can limit fog liquid water path, (b) fog can act to increase near-surface aerosol particle number concentrations.

Observations of fog-aerosol interactions over central Greenland

20 Abstract

Supercooled fogs can have an important radiative impact at the surface of the Green-21 land Ice Sheet, but they are difficult to detect and our understanding of the factors that 22 control their lifetime and radiative properties is limited by a lack of observations. This 23 study demonstrates that spectrally resolved measurements of downwelling longwave ra-24 diation can be used to generate retrievals of fog microphysical properties (phase and par-25 ticle effective radius) when the fog visible optical depth is greater than ~ 0.25 . For twelve 26 cases of fog under otherwise clear skies between June and September 2019 at Summit 27 28 Station in central Greenland, nine cases were mixed-phase. The mean ice particle (opticallyequivalent sphere) effective radius was $24.0 \pm 7.8 \ \mu\text{m}$, and the mean liquid droplet ef-29 fective radius was $14.0 \pm 2.7 \,\mu m$. These results, combined with measurements of aerosol 30 particle number concentrations, provide observational evidence supporting the hypothe-31 ses that (a) low surface aerosol particle number concentrations can limit fog liquid wa-32 ter path, (b) fog can act to increase near-surface aerosol particle number concentrations 33 through enhanced mixing, and (c) multiple fog events in quiescent periods gradually de-34 plete near-surface aerosol particle number concentrations. 35

³⁶ Plain Language Summary

Fogs over the central Greenland Ice Sheet can modify the net radiation that reaches 37 the ice surface. How much a fog influences the net surface radiation is related to the fog 38 lifetime and optical depth. These properties are related to the phase and size distribu-39 tion of the particles that make up the fog, that in turn depend on the characteristics of 40 the atmospheric aerosol particles on which the fog forms. This study shows that the phase 41 and size distribution of fog particles can be determined from ground-based measurements 42 of downwelling longwave radiation, and explores how fogs interact with the number con-43 centration of atmospheric aerosols measured near the surface during twelve cases of summer-44 time fog in central Greenland. 45

46 1 Introduction

Central Greenland is a unique environment in the Northern Hemisphere: A uni-47 form surface of snow-covered ice extends for over 250 km in every direction from the ice 48 sheet's highest point at 3,250 m a.s.l (Howat et al., 2017). The structure of the atmo-49 spheric boundary layer over the ice sheet is driven by large-scale circulation, including 50 atmospheric rivers associated with extratropical storms (Mattingly et al., 2018; Gallagher 51 et al., 2018) and blocking anticyclones (Pettersen et al., 2022), and is modulated locally 52 by strong radiative cooling at the ice sheet surface (Hoch et al., 2007). Under quiescent 53 conditions (clear skies, light winds), surface radiative cooling frequently drives the for-54 mation of supercooled radiation fog through the condensation of water onto aerosol par-55 ticles that act as cloud condensation nuclei (CCN) (Bergin et al., 1994; Cox et al., 2019). 56

At Summit Station (Summit), a research base located at the highest point on the 57 Greenland Ice Sheet (72.57°N, -38.47°E), fogs comprised of supercooled droplets occur 58 vear-round even when the surface temperature falls below -30°C (Cox et al., 2019). These 59 fogs can have a strong effect on the ice sheet surface energy budget, contributing on av-60 erage an additional 27 W m⁻² of total net downwelling radiation relative to clear sky 61 conditions (Cox et al., 2019). In the summer months (May to September) solar heating 62 of the ice sheet surface during the day results in a diurnal cycle of net surface radiation. 63 Radiation fog forms during the period of the diurnal cycle when the sun elevation is low-64 est and the net radiative cooling at the surface is strongest, and the associated increase 65 in net downwelling longwave radiation acts to damp the diurnal temperature cycle, which 66 has been hypothesised to precondition the ice sheet surface for melt (Cox et al., 2019). 67 These fogs can also increase the rate of aerosol deposition to the surface (Bergin et al., 68

⁶⁹ 1994, 1995) and reduce ice sheet mass loss by recondensing sublimated water onto fog
 ⁷⁰ particles that then settle out under gravity (Berkelhammer et al., 2016).

Understanding the controls on the processes that modify the surface mass balance 71 of the Greenland Ice Sheet is becoming increasingly important as melt events become 72 more common and widespread (Tedesco & Fettweis, 2020; Hanna et al., 2021). The ra-73 diative impact of fog at the ice sheet surface depends on fog occurrence, duration, and 74 optical depth, which itself is determined by the fog liquid water path (LWP), and mi-75 crophysical properties such as fog particle phase and size distribution. The representa-76 77 tion of fog microphysical properties is one of the largest sources of uncertainty in fog forecast models and Large-eddy simulations (Boutle et al., 2022), and the representation of 78 cloud microphysical properties in general is one of the largest sources of uncertainty in 79 projections of future Greenland Ice Sheet melt (Hofer et al., 2019). One of the reasons 80 for these uncertainties is that there are very limited observations available to constrain 81 model parameterisations. This is particularly true for fog over Greenland, which often 82 occurs in shallow layers (< 100 m) below the lowest range gate of most ground-based 83 active remote sensing instruments (such as radar or lidar). These very shallow fog lay-84 ers are often subgrid-scale for most climate and weather models. 85

Important controls on fog (and cloud) lifetime, microphysical, and radiative prop-86 erties are the number concentration, size distribution, and composition of aerosol par-87 ticles on which droplets or ice crystals can form. Droplets form on CCN, so the num-88 ber concentration of CCN determines the number concentration of droplets at a given 89 supersaturation. When the CCN concentration is increased, a fog will contain a greater 90 number of smaller droplets than an equivalent fog (with the same liquid water content) 91 forming under a reduced CCN concentration, resulting in a relatively high fog optical 92 depth and solar reflectivity, and hence impacting the net downwelling radiation at the 93 surface (Twomey, 1977). Increased fog droplet number concentration also leads to en-94 hanced longwave radiative cooling at fog top (e.g. Garrett, Radke, & Hobbs, 2002), en-95 couraging further droplet activation, and smaller droplets that are not removed as quickly by sedimentation, with both processes working to extend fog lifetime (Maalick et al., 2016; 97 Boutle et al., 2018; Yan et al., 2021). Increased fog top cooling can also enhance mix-98 ing and entrainment that, depending on the humidity of the overlying air, can either re-99 duce or increase cloud/fog water content (Ackerman et al., 2004; Small et al., 2009; Williams 100 & Igel, 2021). 101

In very clean environments, low CCN concentrations can limit fog (and cloud) for-102 mation and lifetime, because the few activated CCN will grow to relatively large sizes 103 and precipitate out, removing CCN and preventing further droplet formation (Mauritsen 104 et al., 2011; Stevens et al., 2018). Evidence suggests that this situation can occur in the 105 Arctic, where naturally low concentrations of CCN (1 to 100 cm^{-3}) have the potential 106 to control cloud radiative properties (Mauritsen et al., 2011; Sterzinger et al., 2022). At 107 Summit, the annual mean aerosol particle concentration is low even compared to other 108 Arctic sites (Schmeisser et al., 2018); the mean annual total surface aerosol particle num-109 ber concentration (> 20 nm) at Summit in 2019-2020 was just 129 cm^{-3} , and fell to less 110 than 10 $\rm cm^{-3}$ on occasions in all seasons (Guy et al., 2021). Given that only some of these 111 aerosol particles act as CCN, these numbers are an upper limit on the number of CCN 112 available near the surface where fog forms. 113

When the temperature is below freezing, which is the case almost all the time in 114 central Greenland (Shupe et al., 2013), the phase partitioning of the fog is also impor-115 tant for fog lifetime and the radiative effect of the fog at the surface. Ice fogs usually form 116 117 through the direct deposition of vapour onto ice-nucleating particles (INPs, a subset of the aerosol population that can catalyse freezing) when the air is supersaturated with 118 respect to ice (Gultepe et al., 2015). Ice nucleation can also occur in supercooled liquid 119 fogs by either immersion freezing (INPs are activated within a droplet) or contact freez-120 ing (droplets freeze upon contact with an INP) (Kanji et al., 2017). Once primary ice 121

is present, further ice can form through several different multiplicative mechanisms, collectively known as secondary ice production (Field et al., 2017). If the air becomes supersaturated with respect to ice but subsaturated with respect to water, ice crystals will grow at the expense of liquid water droplets, causing the liquid droplets to evaporate and the ice crystals to grow to relatively large sizes and settle out, removing moisture from the surface layer and acting to reduce fog lifetime; this is known as the Wegener-Bergeron-Findeisen process (e.g. Korolev, 2007).

In addition to the aerosol population having the potential to control fog lifetime 129 130 and radiatively important microphysical properties, fog formation may also be an important control on the lifecycle of aerosol particles in the boundary layer over central Green-131 land. Fog can act as an aerosol sink, because the fog droplet deposition flux exceeds that 132 of aerosol dry deposition (Bergin et al., 1994, 1995). Through this mechanism, fog may 133 act to 'clean' the boundary layer of CCN and INP, which may in turn impact fog and/or 134 cloud formation later in time. Conversely, fog could act to increase aerosol particles in 135 the boundary layer by enhancing the transport of aerosol particles from above the fog 136 top into the surface layer, either by buoyancy or windshear driven turbulent entrainment 137 at fog top, or by aerosol activation at fog top followed by droplet evaporation closer to 138 the surface. Observational and model studies have demonstrated that the latter process 139 can be important in low-level Arctic stratocumulus (Solomon et al., 2014; Igel et al., 2017). 140

The relative importance of each of these fog-aerosol interactions over central Green-141 land is unknown, and our ability to model these processes is hindered by a lack of ob-142 servations of both fog microphysical properties and surface aerosol number concentra-143 tion and size distribution. Using in-situ measurements collected at Summit in 2013-2014, 144 Cox et al. (2019) completed a comprehensive assessment of the occurrence, microphys-145 ical characteristics, and radiative properties of fogs at Summit, but there were no aerosol 146 particle measurements available during this period. This study builds on the findings of 147 Cox et al. (2019), and has two main objectives: (1) to explore the possibility of using 148 spectral measurements of downwelling longwave radiation to generate retrievals of fog 149 microphysical properties, and (2) to use these results alongside measurements of surface 150 aerosol particle number concentration to look for observational evidence of fog-aerosol 151 interactions over central Greenland. 152

The spectral signature of downwelling longwave radiation is sensitive to the radia-153 tive properties of fog that are important for the ice sheet surface energy budget and can 154 be measured continuously by passive ground-based instrumentation that, unlike many 155 active remote sensing instruments, are not limited by the height of their lowest range gate 156 and so do not have a 'blind' spot close the surface. Such measurements have been used 157 to study the microphysical properties of mixed-phase polar clouds (Mahesh et al., 2001; 158 Rathke et al., 2002; Turner, 2005; Garrett & Zhao, 2013; Cox et al., 2014; Shupe et al., 159 2015; Lubin et al., 2020; Richter et al., 2022); however, these studies did not specifically 160 focus on fog. 161

Here, we use a case-study based approach to examine the advantages and limitations of retrieving the microphysical properties of fog from downwelling longwave radiation measurements. Such measurements have the greatest sensitivity to the microphysical properties of clouds when the atmosphere is dry and the clouds are low and optically thin. In addition, retrieval accuracy relies on a well-constrained cloud temperature.
Taken together, this makes such measurements ideal for studying fog over central Greenland.

For objective (2), we combine the results of the fog microphysical retrievals with measurements of surface aerosol particle number concentrations and supplementary observations of atmospheric state to look for observational evidence to support (or negate) the following hypotheses:

- (a) That low aerosol particle number concentration can be a critical control on fog liquid water path and lifetime.
- (b) That fogs can act to increase surface aerosol particle number concentration by enhancing mixing of air from above into near-surface stable layer.
 - (c) That multiple fog events during quiescent conditions act to deplete near surface aerosol particle number concentration, impacting fog development later in time.

The results of this analysis may be used as the basis of future modelling studies to systematically distinguish the importance of different fog-aerosol interaction processes, and to identify instrumentation requirements for future observational campaigns to study fogaerosol interactions over central Greenland or in similar environments.

¹⁸³ 2 Measurements and instrumentation

We make use of measurements from the ICECAPS project (the Integrated Char-184 acterisation of Energy, Clouds, Atmospheric state, and Precipitation at Summit; Shupe 185 et al., 2013) which consists of a suite of instrumentation for monitoring atmospheric pro-186 cesses at Summit. To generate the microphysical retrievals of fog properties we use data 187 from the Atmospheric Emitted Radiance Interferometer (AERI), which measures spec-188 trally resolved downwelling infrared radiance between 3 and 19 μ m at ~0.48 cm⁻¹ res-189 olution (Knuteson et al., 2004b, 2004a). At Summit, the AERI measures downwelling 190 radiation continuously, alternating between views of the sky at zenith and two calibra-191 tion sources, resulting in sky measurements every 15-20 s. The AERI data are quality 192 controlled as described in Guy et al. (2022) and subjected to noise filtering using the tech-193 nique described by Antonelli et al. (2004) and Turner et al. (2006). Section 3 describes 194 the retrieval algorithm. 195

To explore individual fog cases in more depth we examine data from the ceilome-196 ter (CT25K, Münkel, 2006), sodar (Neff et al., 2008), total sky imager, and near-surface 197 temperature profiles and sensible heat flux estimates from tower-mounted in-situ sen-198 sors (Guy et al., 2020). Data from the millimetre cloud radar and precipitation occur-199 rence sensor system were used to help identify fog cases during the summer of 2019, and 200 radiosonde data were used to help constrain retrievals of continuous thermodynamic pro-201 files from the AERI that are required as an input to the microphysical retrieval algorithm; 202 both steps are described in detail in Guy et al. (2022). See Shupe et al. (2013) for fur-203 ther information about the overall ICECAPS instrumentation suite. 204

2.1 Aerosol particle measurements

During the summer of 2019 there were two instruments at Summit measuring sur-206 face aerosol particle number concentration in different size ranges: a butanol-based con-207 densation particle counter (CPC, GRIMM 5.400) that measured the total concentration 208 of condensation nuclei every second, and an optical particle counter (SKYOPC, GRIMM 209 1.129) that measured size-resolved concentrations of 250 to 4500 nm diameter particles 210 every six seconds. Guy et al. (2021) describe the CPC data in more detail, including the 211 estimation of particle loss in the inlet line, which resulted in the CPC measuring the num-212 ber concentration of condensation nuclei with diameters between 20 and 230 nm with 213 greater than 50% efficiency. For this reason, measurements from the CPC are henceforth 214 referred to as N_{20} , indicating the number concentration of particles > 20 nm diameter. 215

The SKYOPC had an identical inlet to the CPC but a higher flow rate (1.2 L min⁻¹), and as a result larger particles could pass through the SKYOPC inlet. After accounting for particle losses in the inlet (using the Particle Loss Calculator, Von der Weiden, Drewnick, & Borrmann, 2009), the SKYOPC measured the number concentration of particles with diameters between 250 and 4500 nm with greater than 50% efficiency. For the SKYOPC, the measurements were corrected for particle loss in the inlet by multiplying the particle number concentration by a correction factor based on the modelled inlet efficiency as a function of particle size (which varied from 1.02 to 1.97 in the 250 to 4500 nm size range). The total particle number concentration between 250 and 4500 nm (henceforth N₂₅₀) was calculated by summing the corrected size resolved SKYOPC data.

Particles larger than 6 μ m in diameter, which is smaller than the typical size of fog 226 droplets (e.g. Mazoyer, Burnet, & Denjean, 2022), could not pass through either inlet, 227 and the instruments were located in a heated building that was always $>15^{\circ}C$ warmer 228 than the outside air. Thus, during fog events, we assume that N_{20} and N_{250} are mea-229 230 surements of the dried interstitial aerosol particle number concentration. Both N_{20} and N_{250} were resampled to five-minute medians for the purpose of this study, and quality 231 controlled to remove any instances of contamination from station pollution as in Guy 232 et al. (2021). Note that this quality control does not impact any of the data presented 233 here, because none of the fog cases coincide with local pollution events (which was part 234 of the original event selection criteria). 235

Figure 1 shows how the measurements from the SKYOPC (N_{250}) and CPC (N_{20}) 236 intersect with the 'typical' size range of CCN and INP from past literature, although the 237 proportion of aerosol particles that can act as a CCN depends on the aerosol type and 238 degree of supersaturation, and our knowledge of the typical size range of INP particles 239 is limited by sparse observations (particularly of small INP particles < 250 nm diam-240 eter). Supersaturations can reach higher values when the aerosol particle number con-241 centration is low, and particles as small as 20 nm have been observed to act as CCN in 242 clean Arctic environments (Leaitch et al., 2016; Baccarini et al., 2020). Several studies 243 indicate that the INP population is mostly made up of coarse-mode particles > 250 nm 244 diameter (Mason et al., 2016; Creamean et al., 2018; Si et al., 2018), however recent stud-245 ies of size-resolved INP concentration over the central Arctic suggest that particles as 246 small as 150 nm diameter can be an important source of INP (Creamean et al., 2022; 247 Porter et al., 2022). Figure 1 also shows how measurements during the summer of 2019 248 compare to those collected between 15 May and 16 June 2007 using a scanning mobil-249 ity particle sizer to detect particles with diameters from 5.5 to 195 nm diameter (Ziemba 250 et al., 2010), and how they compare to the 'typical' size distribution of near-surface aerosol 251 particles in the Arctic summer, which is mostly based on measurements from coastal and 252 low elevation Arctic sites (Carslaw, 2022). 253

254 2.2 Fog events

We focus on the twelve radiation fog events identified by Guy et al. (2022) that oc-255 curred during the summer of 2019 (Table 1). Each fog event occurred under otherwise 256 clear skies and had a detectable longwave radiative impact at the surface; the duration 257 of each fog event was defined as when the 962 $\rm cm^{-1}$ downwelling radiance measured by 258 the AERI is greater than a threshold of 1.7 RU (1 RU = 1 mW m⁻² sr⁻¹ cm⁻¹), which 259 is three standard deviations above the mean clear sky radiance between June and Septem-260 ber 2019. The 962 $\rm cm^{-1}$ microwindow is almost completely transparent under clear skies 261 for conditions at Summit, and is therefore particularly sensitive to the presence of clouds 262 (e.g. Cox, Walden, & Rowe, 2012). Note that this radiative definition of fog is distinct 263 from the traditional definition of fog (a reduction of horizontal visibility to < 1,000 m) 264 but is appropriate for this study because we are concerned with the radiative impact of 265 fog on the surface energy budget. See Guy et al. (2022) for further details about the se-266 lection criteria for each of these case studies. 267

Table 1 details each case study and indicates where aerosol particle number concentration measurements are available. The SKYOPC vacuum pump experienced intermittent faults resulting in missing N_{250} data for some of the fog cases, and an issue with the CPC power supply resulted in incomplete N_{20} data for case 3.

Figure 1. The portion of the aerosol particle size distribution measured in this study, N_{20} shaded in blue and N_{250} in red, overlaid on the typical size distribution of the near-surface Arctic atmosphere in summer (Carslaw, 2022, black dashed line), and the observed size distribution of surface aerosol particles at Summit between May and June 2007 from Ziemba et al. (2010) (green line). The blue and red lines indicate the mean values from the CPC (a single value in the range 20 to 230 nm) and the SKYOPC (size resolved measurements in 20 bins between 250 and 4500 nm) observed between June (or July for the SKYOPC) and September 2019.

3 Retrieval of fog microphysical properties

We use the mixed-phase cloud property retrieval algorithm (MIXCRA, Turner, 2005), 273 which uses optimal estimation to retrieve fog microphysical properties at 5-min inter-274 vals from the spectral longwave radiation measured by the AERI (note that we did not 275 apply temporal averaging to the AERI spectra). The longwave radiation is sensitive to 276 changes in cloud/fog phase, particle size, and optical depth when the optical depth is 277 between ~ 0.25 and 6, allowing the retrieval of these properties using optimal estimation 278 (Turner, 2005; Cox et al., 2014). As the optical depth approaches the upper end of this 279 range, the longwave spectral signature of the cloud/fog approaches that of a black body 280 and contains little information about microphysical properties. As the optical depth ap-281 proaches the lower end of this range, the signal to noise ratio of the AERI becomes too 282 low for meaningful retrievals. Figure 2 shows how the mean spectral signature from the 283 AERI during the fog events varied, spanning much of the dynamical range between clear 284 sky conditions and optically thick stratus in the atmospheric window region (where the 285 cloud-free atmosphere is mostly transparent to longwave gaseous absorption ~ 800 to 1200 286 cm^{-1}). 287

MIXCRA models each fog event as two collocated 'clouds', one consisting of ice crys-288 tals and the other of water droplets. Starting from user input a priori values of optical 289 depth (τ) and particle effective radius (R) for each cloud (τ_{liq} and R_{liq} for the liquid cloud 290 and τ_{ice} and R_{ice} for the ice cloud), as well as vertical profiles of atmospheric temper-291 ature and water vapor content, the algorithm uses a forward model to calculate the ex-292 pected spectral signature of the combined cloud and atmosphere, and then iterates us-293 ing optimal estimation to determine the values $[\tau_{liq}, R_{liq}, \tau_{ice}, R_{ice}]$ that optimally match 294 the spectral signature observed by the AERI, given the a priori and the measurement 295 uncertainty. 296

Figure 2. AERI radiance measurements averaged over each fog case (colored lines, see legend inset). The thick black line shows the median for all fog cases, which can be contrasted to the median over all confirmed clear sky hours (thick grey line), and an example of an optically thick stratus cloud (from 01 to 02 UTC on 08 June 2019, dashed black line). Spectral radiance is resampled to 4 cm⁻¹ for clarity (native resolution is 0.5 cm^{-1}). Vertical grey lines show the spectral bands used in the MIXCRA retrievals (between major gaseous absorption bands). Note the two spectral bands at wavenumbers below 570 cm⁻¹; these are critical for ascertaining the phase of the fog layers (?, ?; Turner, 2005).

²⁹⁷ Note that throughout this study τ refers to the visible optical depth (where extinc-²⁹⁸tion efficiency is 2), transformed from the optical depth at 11 μ m as described in Turner ²⁹⁹ (2005). See Turner (2005) for further information about the implementation of the op-³⁰⁰timal estimation. After the retrieval of [τ_{liq} , R_{liq} , τ_{ice} , R_{ice}], fog LWP is determined from ³⁰¹equation (1), where ρ is the bulk density of water.

302

 $LWP = \frac{2\rho R_{liq}\tau_{liq}}{3} \tag{1}$

MIXCRA uses the Line-by-Line Radiative Transfer Model (LBLRTM) version 12.1 303 (Clough et al., 1992; Clough & Iacono, 1995) as a forward model to calculate the gaseous 304 clear sky optical depth spectra as a function of height, and the DISORT algorithm (Stamnes 305 et al., 1988) to simulate radiance from the ice and liquid cloud (which accounts for both 306 scattering and absorption); the combined LBLRTM and DISORT code is referred to as 307 LBLDIS. The HITRAN 2008 database (Rothman et al., 2009) provides the molecular 308 absorption properties used by the LBLRTM. The single-scattering properties used by 309 DISORT are discussed in section 3.1.1. The radiative transfer calculation also requires 310 information about the thermodynamic structure of the atmosphere and profiles of at-311 mospheric gases. Trace gas concentrations are supplied by the U.S. standard atmosphere 312 (1976), and CO_2 concentrations are scaled to mimic the seasonal and yearly increase in 313 atmospheric CO_2 observed at the Mauna Loa observatory. Uncertainties related to the 314 distribution and concentration of these gases are mitigated in MIXCRA by only includ-315 ing narrow spectral bands (micro-windows) from the AERI in the optimal estimation pro-316 cess, and hence avoiding major gaseous absorption bands (the micro-windows used in 317 this study are highlighted on fig. 2). 318

Thermodynamic profiles (temperature and water vapor) used within MIXCRA were retrieved using the TROPoe algorithm, which also uses an optimal estimation approach

based on AERI observations, taking advantage of the fact that the AERI is also highly 321 sensitive to the thermodynamic structure of the atmosphere (Turner & Blumberg, 2019; 322 Turner & Löhnert, 2021). The accuracy of the TROPoe thermodynamic profile retrievals 323 during the 12 fog case studies is $\pm 1.0^{\circ}$ C for temperature and ± 0.39 g kg⁻¹ for water va-324 por in the lowest 1,000 m a.g.l (Guy et al., 2022). We assume that any impact of aerosols 325 on the radiative transfer calculation is negligible, because the absorption and scatter-326 ing coefficients of aerosol particles in the infrared at Summit are generally small (Schmeisser 327 et al., 2018) and there are no local sources of aerosol particles near Summit after instances 328 of local pollution from the station are excluded. 329

The a priori value of τ_{liq} used as starting point for the optimal estimation is based 330 on the LWP retrieved by the TROPoe algorithm (Guy et al., 2022) with a standard de-331 viation of 6. Note that TROPoe does not account for scattering processes and assumes 332 only liquid droplets are present; MIXCRA adjusts this first guess value to account for 333 the possible presence of ice particles and accounts for multiple scattering. The a priori 334 value for R_{liq} is set to $11\pm 6 \ \mu m$, based on in-situ measurements of the size distribution 335 of fog droplets at Summit in 2013 and 2014 (Cox et al., 2019). The a priori ice optical 336 depth is set to 0 with a standard deviation of 6, which gives the algorithm flexibility to 337 retrieve ice properties. The choice to initiate the retrieval with a liquid-only cloud is based 338 on the fact that liquid phase fogs are more commonly detected than ice fogs during the 339 summer at Summit (Cox et al., 2019). The a priori ice particle effective radius is set to 340 $18\pm15 \ \mu m$ based on the distribution of ice crystal effective radius retrieved from mixed-341 phase clouds over the Arctic Ocean in 1998 (Turner, 2005). 342

343

3.1 Uncertainty quantification and quality control

As an initial quality control, we omit any retrievals where the root mean squared 344 error (RMSE) between the final forward radiance calculation (that is, the calculation of 345 expected radiance using the retrieved cloud properties) and the measured AERI radi-346 ance is > 1.2 RU. The goal of this quality control is to omit any retrievals for which the 347 retrieval is unable to bring the calculated radiance into agreement with the measured 348 radiance to within the expected instrument uncertainty level (a threshold of 1.2 RU is 349 selected because in 90% of all retrievals the RMSE corresponding to a 3σ uncertainty 350 in the AERI measurements due to noise and calibration uncertainty falls below this value). 351 For rejected retrievals, we assume that additional unknown sources of error exist (e.g. 352 large errors in temperature), hindering accurate cloud property retrievals. Cox et al. (2019) 353 also used a threshold of 1.2 RU for the retrieval of cloud microphysical properties from 354 AERI measurements in northern Canada. 355

MIXCRA calculates the uncertainties in $[\tau_{liq}, R_{liq}, \tau_{ice}, R_{ice}]$ by propagating the 356 calibration uncertainty of the AERI (< 1% of ambient radiance, described in Knuteson 357 et al., 2004a) and the uncertainty associated with the sensitivity of the forward model 358 (i.e. how much the spectral cloud emissivity changes with small perturbations in τ_{lig} , 359 R_{liq} , τ_{ice} , R_{ice}]) through the optimal estimation algorithm (Turner, 2005). Figure 3 shows 360 how the 2σ percentage uncertainty (as output by the MIXCRA algorithm) varies as a 361 function of τ_{liq} (for τ_{liq} and R_{liq}) and τ_{ice} (for τ_{ice} and R_{ice}) for all the retrievals dur-362 ing the fog events. For all retrieved properties, the minimum percentage uncertainties 363 occur when the fog optical depth is ~ 1 , consistent with the findings of Turner (2005). 364

The percentage uncertainties in all properties increase when the fog is mixed phase (i.e. when both τ_{liq} and $\tau_{ice} > 0.02$, light blue and pink colours in fig. 3), which is related to the additional degrees of freedom when retrieving properties for a mixed-phase cloud compared to a single-phase cloud as well as the challenges of separating the two phases cleanly (because the liquid and ice signals are correlated). The higher percentage uncertainties in R_{ice} compared to R_{liq} are related to the fact that the retrieval is more sensitive to small particles, and ice particles are generally larger than liquid droplets.

Figure 3. Percentage uncertainty (2σ) in (a) τ_{liq} and (b) R_{liq} as a function of τ_{liq} , and in (c) τ_{ice} and (d) R_{ice} as a function of τ_{ice} , for every retrieval used in this study. The red line is the mean value (in nine logarithmically spaced bins). Points are coloured based on the magnitude of τ_{ice} (a and b) or τ_{liq} (c and d). The black vertical dashed line highlights an optical depth of 0.25 used as a minimum required optical depth for valid retrievals in this study.

As the fog optical depth approaches zero, the percentage uncertainties in all retrieved 372 properties become very large due to the decreasing signal-to-noise ratio, necessitating 373 the selection of a minimum optical depth above which fog microphysical properties can 374 be retrieved with an acceptable level of uncertainty. For this study we choose to use an 375 optical depth threshold of $\tau_{liq} > 0.25$ (for τ_{liq} , R_{liq} and LWP) and $\tau_{ice} > 0.25$ (for τ_{ice} , 376 R_{ice}), consistent with Cox et al. (2014), resulting in a mean 2σ percentage uncertainty 377 of < 40% for τ_{liq} and < 20% for R_{liq} (fig. 3). This corresponds to a minimum detectable 378 liquid water path of 2.0-3.0 g m $^{-2}$ (for R_{liq} 12 to 18 $\mu\mathrm{m})$ with a 2σ uncertainty of 0.9-379 1.5 g m⁻². For ice properties, $\tau_{ice} > 0.25$ corresponds to when the mean percentage un-380 certainties in τ_{ice} and R_{ice} are below ~60% (fig. 3). 381

We do not need to be concerned about a loss of sensitivity due to saturation in the 382 infrared, because none of the fog cases have a spectral signature approaching that of a 383 black body (fig. 2). Furthermore, because the maximum precipitable water vapor (PWV) 384 during the 12 fog events is only 0.78 cm (with a mean value of 0.35 cm across all events). 385 the ability of MIXCRA to determine fog phase is not impacted by excessive water va-386 por (> 1 cm PWV can lead to signal saturation in the 16 to 20 μ m region, Turner, 2005; 387 Cox et al., 2014). Figure 4 shows the percentage of retrievals during each case study that 388 meet the quality control criteria of RMSE < 1.2 RU and $\tau_{liq} > 0.25$ (for liquid phase re-389 trievals) or $\tau_{ice} > 0.25$ (for ice phase retrievals). Less than 8% of all retrievals are dis-390 carded due to poor RMSE, but the optical depth threshold severely limits the percent-391 age of valid retrievals in each fog case, and in case 7, the optical depth is too low for any 392 valid retrievals. 393

Figure 4. The percentage of all retrievals from each case study that meet the quality control criteria of RMSE < 1.2 and optical depth > 0.25 for liquid properties (blue) and ice properties (orange). The percentage of good retrievals used in the remainder of this study are shown by the dark blue and orange colours.

The MIXCRA algorithm does not account for uncertainties in the atmospheric state 394 (gas and temperature profiles) or for uncertainties related to the choice of single-scattering 395 properties (SSPs) for liquid droplets and ice crystals. As mentioned above, uncertain-396 ties related to the concentrations of atmospheric gases are minimised through the selec-397 tion of micro-windows used by MIXCRA. The atmospheric temperature profile has a mean 398 RMSE (compared to radiosonde profiles) of $\pm 1^{\circ}$ C in the lowest 1,000 m a.g.l during these 399 case studies (Guy et al., 2022), and the difference in the retrieved values of $[\tau_{lig}, R_{lig}]$ 400 τ_{ice}, R_{ice} if the temperature profile is uniformly increased or decreased by 1°C are small, 401 resulting in a mean difference in τ_{liq} of 0.2 and R_{liq} of 0.8 μ m based on sensitivity tests 402 with 38 retrievals. 403

3.1.1 Uncertainties related to the choice of SSPs

404

The choice of single-scattering properties (SSPs) to use in the retrievals is non-trivial. 405 There is emerging evidence that the SSPs of supercooled water droplets are tempera-406 ture dependent, and that the use of SSPs that assume a warmer temperature than re-407 ality can result in overestimations of ice fraction and underestimations of liquid droplet 408 effective radius (Rowe et al., 2013, 2022). Although the temperature profile during the 409 fog events is well characterised, the temperature during a single event can vary by up 410 to 13°C both temporally and vertically within the lowest 15 m a.g.l due to radiative cool-411 412 ing and changes in boundary layer mixing (fig. S1, supporting information). Furthermore, the SSPs of ice crystals depend on the ice crystal habit (e.g. Yang et al., 2005), 413 but there is very little information about ice crystal habit at Summit during fog events. 414 Isolated plates and bullets are often reported by observers, but whether any of these crys-415 tals are associated with fog events (as opposed to snow, blowing snow, or diamond dust) 416 is unclear. A multi-angled snowflake camera operational at Summit in 2019, which pho-417 tographed particles with a maximum dimension > 30 μ m (Garrett et al., 2012), did not 418 detect any identifiable ice crystals during the fog events. This suggests that any ice par-419 ticles that were present during the fog were unlikely to be bullets or columns, which are 420 typically > 30 μ m along their major axis (Walden et al., 2003). Schmitt et al. (2013) found 421 that ice fog particles in the interior of Alaska are generally droxtals or plates, although 422 these fogs are not necessarily comparable to Summit because they were heavily polluted. 423

To account for the additional uncertainty related to the choice of SSPs, we ran MIX-424 CRA in three configurations (P_w , P_c , and D_w ; Table 2). We choose from four databases 425 of liquid droplet SSPs corresponding to temperatures of 240, 253, 263, and 273 K (Rowe 426 et al., 2013, 2020). For P_w and D_w , we use the liquid SSPs that correspond to the warmest 427 temperature measured in the lowest 15 m a.g.l during each fog event, and for P_c we use 428 the liquid SSPs that correspond to the coldest temperature measured during the fog (fig. 429 S1). For the ice habit, we use SSPs associated with hexagonal plates (for P_w and P_c) 430 and droxtals (for D_w) (Yang et al., 2005). We choose these three configurations as a com-431 promise between reducing the computational time of running multiple configurations and 432 representing the uncertainty associated with the SSPs well. Results from individual test 433 cases indicated that changing the liquid SSPs between the warmest and coolest temper-434 atures had a larger impact on the results than changing the ice SSPs. 435

Table 2. The three configurations of single-scattering properties (SSPs) for ice and liquid particles used in the MIXCRA retrievals. Liquid SSPs at temperatures of either 240, 253, 263, or 273 K were used, corresponding to the warmest (or coldest, per table) measured temperature in the lowest 15 m a.g.l. during each fog event.

	Ice habit	Liquid SSP temperature
$\begin{array}{c} \mathbf{P}_w \\ \mathbf{P}_c \\ \mathbf{D}_w \end{array}$	Plates Plates Droxtals	warmest coldest warmest

For the rest of this study, the microphysical retrievals shown are the mean values of the three configurations in Table 2, and we account for the additional uncertainty introduced by the SSPs assumption using equation (2), where 2σ is the combined uncertainty of each retrieved parameter (i.e. τ_{liq} , R_{liq} , τ_{ice} , and R_{ice}), $2\sigma_a$ is the 2σ uncertainty output by the MIXCRA algorithm, ΔS_i is the maximum difference in the retrieved parameter resulting from varying the ice crystal SSPs, and ΔS_L is the maximum difference in the retrieved parameter resulting from varying the liquid SSPs. 443

444

472

$$2\sigma = \sqrt{2\sigma_a^2 + \Delta S_i^2 + \Delta S_L^2} \tag{2}$$

3.2 Validation against in-situ measurements

The ability of the MIXCRA algorithm to accurately determine simultaneous ice 445 and liquid optical depths of single-layer mixed-phase Arctic clouds is well established through 446 comparisons with depolarisation lidars (Turner et al., 2003; Turner & Eloranta, 2008), 447 but assessments of the accuracy of MIXCRA retrievals of cloud droplet effective radius 448 are limited to two comparisons with in-situ aircraft measurements of liquid-phase stra-449 tus clouds over the south-central US (Vogelmann et al., 2012) and off the west coast of 450 California (Turner, 2007). Vogelmann et al. (2012) found that MIXCRA captured the 451 primary mode of the cloud droplet distribution well; the mean and standard deviation 452 of the MIXCRA size distribution was 5.3 \pm 1.6 μ m compared to 4.9 \pm 0.7 μ m for the 453 aircraft probe. Turner (2007) found a mean bias of 0.1 μ m between the aircraft measure-454 ments and MIXCRA, with an interquartile spread of 1.9 μ m. In both cases, the aircraft 455 measurements represent just one level in the cloud whereas the MIXCRA retrievals are 456 representative of a column value (weighted by optical depth). To date, there have been 457 no assessments of the accuracy of MIXCRA in determining the microphysical proper-458 ties of fog. 459

Here, we assess the ability of MIXCRA to retrieve R_{liq} during fog at Summit by 460 comparing MIXCRA R_{lig} retrievals with droplet effective radius determined from FM100 461 single-particle light scattering spectrometers installed at 2 m and 10 m a.g.l during a su-462 percooled liquid fog event at Summit on 16 June 2013 (fig. 5). Note that the FM100 in-463 struments were installed on a tower approximately 480 m from the AERI instrument. 464 This case is described further in Cox et al. (2019) and is a near-idealised example of ra-465 diation fog formation at Summit, the development of which is particularly similar to case 466 4 in 2019. 467

The FM100 probes made size-resolved measurements of particles with radii (r) of 1-25 μ m based on individual particle scattering characteristics, under the assumption that the particles are liquid spheres. The effective radius (R) was calculated from the FM100 particle size distribution [n(r)] using equation (3).

$$R = \frac{\int_0^\infty \pi r^3 n(r) dr}{\int_0^\infty \pi r^2 n(r) dr}$$
(3)

To estimate the uncertainty in R determined from the FM100 measurements, we 473 recalculated the FM100 particle size distribution 100 times, each time randomly select-474 ing errors from uniform distributions of five possible sources of uncertainty: (1) probe 475 air speed (±5%), (2) wind speed (±0.5 m s⁻¹), (3) wind direction (±5°), (4) whether 476 or not overlapping bins were combined (as described in Cox et al., 2019) (binary), and 477 (5) the uncertainty in bin sizing (randomised shifts to neighbouring bins). For more de-478 tails on the uncertainties associated with the FM100 probe, see Cox et al. (2019) and 479 supplement. Bin sizing ambiguities were dominant over sampling errors for this case be-480 cause the latter were small due to the ambient wind direction and speed being optimally 481 aligned with the probe inlet geometry and the speed of the pumped air through the probe 482 (see also Spiegel et al., 2012). The 2σ uncertainty in R is then determined from the stan-483 dard deviation of R across all the perturbed calculations. 484

⁴⁸⁵ MIXCRA R_{liq} is not directly comparable to R determined from the FM100 probes, ⁴⁸⁶ because the downwelling radiance measured by the AERI is sensitive to the bulk infrared ⁴⁸⁷ signal from the entire population of particles in the scene view of the AERI instrument ⁴⁸⁸ (the height of which varies with accumulation but is typically around 3 m a.g.l), whereas ⁴⁸⁹ R determined from the FM100 is based on the forward scattering of light in the visible

Figure 5. Fog event on 16 June 2013. (a) Calculated effective radius (R) from FM100 measurements at 10 m a.g.l (red line) and 2 m a.g.l (white line) overlaid on the FM100 particle size distribution at 10 m a.g.l. (coloured shading). (b) Retrieved liquid optical depth (black line), raw ceilometer backscatter (grey shading), and ceilometer vertical visibility values (blue markers, and orange for 'obscured'). (c) Cross validation of fog droplet R_{liq} retrieved from the MIXCRA algorithm (black) and determined from in-situ measurements (FM100 probes at 2 m, cyan, and 10 m, red). Shading represents 2 σ uncertainties, and the light blue region shows where the retrieved optical depth was greater than 0.25.

range from individual particles passed across the detector at a set height above the sur-490 face (2 m or 10 m). Therefore, we would only expect these values to compare well if the 491 size distribution of the particle population at the height of the FM100 instrument was 492 representative of the vertical distribution of the particle population. Cox et al. (2019) 493 show that the fog droplet size distribution varies with height, with the 2 m probe gen-494 erally measuring larger particles than the 10 m probe, consistent with particles prefer-495 entially forming higher up before settling out. However, on 16 June 2013, after the ini-496 tial fog formation, the R at 2 m was consistently smaller than at 10 m (fig. 5), the par-497 ticle number concentration at 2 m was also consistently higher than at 10 m (Cox et al., 498 2019), possibly indicating partial evaporation of droplets and a reduction in settling ve-499 locity at 2 m. 500

Despite this caveat, the MIXCRA R_{liq} compares very well to the R calculated from 501 both FM100 probes when $\tau_{liq} > 0.25$ (fig. 5c) over a range of R from 12.5 to 20 μ m. The 502 RMSE between the MIXCRA R_{liq} and FM100 R is 2.0 μ m at both 2 m and 10 m, with 503 a Pearson's correlation coefficient of 0.57 and 0.69 respectively. However, the strength 504 of this correlation is not consistent over the fog lifetime. During the initial stage of the 505 fog (02:20 to 04:00) the MIXCRA R_{liq} was consistently smaller than R from both FM100 506 instruments (by an average of 1.5 μ m at 2 m and 2.7 μ m at 10m). Between 04:00 and 507 05:00 there was an initial reduction in R in the FM100 measurements (and a reduction 508 in particle number concentration, Cox et al., 2019) followed by a sharp increase in R at 509 04:15. This coincided with a sharp increase in optical depth (fig. 5b), erosion of the sur-510 face temperature inversion, and evidence of wind-shear driven mixing in sodar observa-511 tions (Cox et al., 2019). The increase in R was also apparent in the MIXCRA R_{lig} , but 512 started earlier (at 04:00), and the maximum R_{lig} between 04:30 and 05:00 (17 μ m) was 513 lower than the maximum R measured by the FM100 probes during this interval (21 μ m 514 at 2 m and 19 μ m at 10 m). This could be explained by an increase in altitude of the 515 main layer of droplet formation; when the optical depth increases and the surface-based 516 temperature inversion is eroded, new droplet formation would be initiated by radiative 517 cooling at the fog top (Haeffelin et al., 2013). If the droplet formation layer height in-518 creased to greater than 10 m a.g.l, these droplets would have then grown and settled, 519 resulting in larger particles at 10 m and even larger particles at 2 m (as observed between 520 04:30 and 05:15). After 05:15, the fog LWP decreased (Cox et al., 2019) suggesting no 521 further droplet growth, and the optical depth gradually decreased. Between 06:00 and 522 10:00, the boundary layer was well-mixed (Cox et al., 2019), R varied consistently at 2 523 m and 10 m, and the MIXCRA R_{liq} captured these variations well. Overall, the MIX-524 CRA R_{liq} is slightly better correlated with the measurements at 10 m, although this is 525 largely due to detection of large (> 20 μ m) particles detected at 2 m that are not reflected 526 in the MIXCRA retrieval. 527

In summary, this cross-validation demonstrates that the MIXCRA algorithm can accurately retrieve R_{liq} during fog events at Summit with the following caveats:

- Due to the threshold optical depth of 0.25, below which signal to noise ratio in the AERI measurements is insufficient to accurately retrieve fog microphysical properties, MIXCRA is not able to capture the initial growth period of the fog droplets (between 00:10 and 02:20 in fig. 5).
- 2. These results are based off a single case study and cover an effective radius range of 12.5 to 20 μ m. More observations of R at a variety of heights and over a larger range of fog conditions are necessary to fully characterise the ability of MIXCRA to accurately retrieve fog droplet effective radius.

539

4.1 Summary of microphysical retrievals during the 2019 fog cases

Figure 6 summarises the retrieved fog microphysical properties from the twelve case studies, and figures S2 and S3 in the supporting information show the temporal evolution of the microphysical properties during each case. Retrievals were calculated every five minutes during each fog event, so the number of valid retrievals indicated on fig. 6a is the number of five-minute intervals during which there was sufficient optical depth for the retrieval ($\tau_{liq} > 0.25$ for liquid, or $\tau_{ice} > 0.25$ for ice properties).

Figure 6. Relative probability distribution of fog microphysical properties retrieved during each individual case study listed in table 1 and for all cases (right hand side). The mean and interquartile range of each distribution is shown by the diamond shaped point and associated error bars when the number of valid retrievals is > 10, otherwise crosses show values from individual retrievals. (a) Liquid (τ_{liq} , green) and ice (τ_{ice} , purple) optical depth, (b) liquid (R_{liq} , green) and ice (R_{ice} , purple) particle effective radius, and (c) liquid water path (LWP). Only retrievals where the optical depth is sufficient are shown ($\tau_{ice} > 0.25$ for ice properties, or $\tau_{liq} > 0.25$ for liquid properties).

For the cases where there was sufficient ice optical depth for a retrieval, the mean R_{ice} was 24.0 μ m (fig. 6b) and the range was 18.5 to 31.4 μ m. This is in broad agreement with the mean effective radii of ice crystals measured in low-level Arctic clouds (~21-25 μ m, Lawson, Baker, Schmitt, & Jensen, 2001; Turner et al., 2003; McFarquhar et al.,

2007). The mean R_{liq} was 14.0 μ m and the mean during individual events varied from 550 10.0 to 15.1 μ m (fig. 6b). The overall mean R_{liq} is slightly larger than the mean R de-551 termined from the summertime FM100 measurements at 10 m in 2013/14 from Cox et 552 al. (2019), which was $11.4 \pm 3 \ \mu m$. However, it is important to note that the MIXCRA 553 retrievals are only valid when $\tau_{liq} > 0.25$, and hence they do not include the initial phase 554 of fog formation where there are a lot of very small droplets that can be detected by the 555 FM100 (for example, see fig. 5). The range in R_{liq} across all retrievals was 6.6 μ m (at 556 the beginning of case 3) to 34.8 μ m (just prior to fog dispersal in case 6). 557

Most of the fog cases have a mean LWP < 10 g m⁻² (fig. 6c), but for cases 2 and 558 4 the maximum LWP exceeds 30 g m⁻², which can result in an increase in downwelling longwave radiation of > 50 W m⁻² relative to clear sky conditions (Miller et al., 2015; 559 560 Cox et al., 2019). The minimum LWP retrieved by MIXCRA was 1.3 g m⁻² at the be-561 ginning of event 3, associated with the smallest retrieved droplet size (R_{liq} 6.6 μ m). In 562 cases 7, 8, and 10, the fog is so optically thin that the LWP is below the limit of detec-563 tion for most of the event despite a reduction in horizontal visibility at the surface (to 564 just 400 m in case 8) and observations of fog bows confirming the presence of liquid wa-565 ter on all three occasions. No optics were reported by onsite observers during the ice-566 phase fog (case 12), although the sun was below the horizon most of the time. 567

568

4.2 Aerosol particle measurements during fog events

The mean N_{250} across all fog events was 1.7 cm⁻³ (with the mean during individ-569 ual events ranging from 0.4 to 2.2 cm^{-3} , fig. 7a), and the mean N₂₀ across all fog events 570 was 187 cm^{-3} (ranging from 41.9 to 448 cm⁻³, fig. 7b), these values represent the in-571 terstitial aerosol particle number concentration during fog. The temporal evolution of 572 N_{20} and N_{250} during each event is shown in fig. S4 in the supporting information. The 573 mean N_{250} during fog events is slightly lower than the overall mean value (including clear 574 and foggy periods) from June to September 2019 (2.4 cm^{-3}), whereas the mean value 575 of N_{20} during fog is slightly higher than the seasonal mean (170 cm⁻³). However, the 576 mean N_{250} and N_{20} over the 2 hours prior to fog onset are 8.2 and 191 cm⁻³ respectively, 577 both of which are higher than the mean values over the entire period. In all but case 7, 578 N_{250} drops below 0.5 cm⁻³ during the fog event, suggesting that almost all particles in 579 the N_{250} size range are activated into (or scavenged by) fog particles. This is not the case 580 for N_{20} ; an order of magnitude decrease in N_{20} during fog is only apparent in case 10, 581 where N_{20} falls below 10 cm⁻³. 582

Figure 8 illustrates the temporal evolution of N_{250} and N_{20} during each fog event, 583 where fog onset is defined as when the downwelling radiance measured by the AERI in-584 creases above the clear sky threshold (see section 2.2), and the percentage change in N 585 is relative to the mean value during the two hours prior to fog onset. On average, both 586 N_{250} and N_{20} decrease during the first 300 minutes after fog onset, consistent with the 587 growth and activation of aerosol particles into fog particles that are too large for either 588 instrument to detect $(> 6 \ \mu m)$. Note that this does not necessarily mean that these par-589 ticles are removed from the atmosphere; they may sediment out or they may be released 590 back into the atmosphere after the fog evaporates, either in the same form or after pro-591 cessing within the fog particle. 592

For N_{250} there is a reduction in number concentration after fog onset in all events 593 (of $72 \pm 26\%$ after 300 minutes). For case 12, the magnitude of the percentage decrease 594 is small compared to the other events, which is related to the fact that the absolute val-595 ues of N_{250} during case 12 are exceptionally low, with an initial mean N_{250} in the two 596 hours prior to fog onset of only 0.2 cm^{-3} . The initial N₂₅₀ in the 2 hours prior to fog 597 onset is consistent in time for all cases apart from case 11, where it varies between 1.2 598 and 6.8 cm⁻³. In cases 8 and 10, a sharp reduction in N_{250} of 80% begins 30 minutes 599 prior to the radiative detection of fog onset, whereas in cases 3 and 7, there is a slight 600

Figure 7. Relative probability distribution of aerosol particle number concentrations [(a) N_{250} and (b) N_{20}] measured during each individual case study listed in table 1 (left) and for all cases (right). The mean and interquartile range of each distribution is shown by the diamond shaped point and associated error bars. Grey bars indicate missing data (< 80% complete during fog event).

Figure 8. Percent change in N_{250} (left) and N_{20} (right) during the first 300 minutes of each fog event (coloured lines, see legend inset), compared to the average value in the two hours prior to fog onset. Thick black line is the median across all events.

increase in N_{250} at fog onset followed by a reduction in N_{250} that starts 20-30 minutes later. The duration of case 7 is only 102 minutes in total, and 80 minutes into the event N_{250} begins to increase, returning to the concentration prior to fog formation 10 minutes after the fog is no longer detected, suggesting that on this occasion, 100% of the particles that were incorporated into the fog were re-released after the fog dissipated.

In contrast to N_{250} , the change in N_{20} is highly variable between different fog events 606 (fig. 8). In cases 2 and 11, there was more than a 100% increase in N_{20} during the event. 607 For case 2, this increase started two hours before the fog was detected, meaning that the 608 'initial' N_{20} concentration is not a good representation over average conditions prior to 609 the fog. In case 11 there was an initial decrease in N_{20} followed by a sharp increase 60 610 minutes into the fog event, during which N_{20} reached 1370 cm⁻³ (> 99th percentile of 611 N_{20} measured between June and September 2019), but 240 minutes later, after the fog 612 was no longer detected, N_{20} returned to values close to those prior to fog onset. This anoma-613 lous case is discussed further in section 5. In cases 8, 9, and 10, there was a reduction 614 in N_{20} that started 30-40 minutes prior to fog onset (of 20%, 30%, and 50% respectively). 615

Note that some of the variability in evolution of N_{20} during fog events could be re-616 lated to the size distribution of N_{20} particles; for example, if most of the N_{20} particles 617 are closer to 30 nm diameter (i.e. the first mode in the Ziemba et al., 2010 measurements, 618 fig. 1) these particles might be subject to different processes during a fog event than to 619 N_{20} particles closer to 150 nm (the second mode in the Ziemba et al., 2010 measurements, 620 fig. 1). Particles closer to 150 nm in size more readily act as CCN, whereas smaller par-621 ticles would require larger supersaturations before activation. Size resolved measurements 622 of particles < 250 nm diameter would be required to investigate these details further. 623

For five of the six cases where both N_{250} and N_{20} are available, the two measure-624 ments are positively correlated (fig. 9). The exception is case 11, during which N_{250} de-625 creases to $< 0.2 \text{ cm}^{-3}$, but there was an anomalous spike in N₂₀ in the middle of the fog 626 event (discussed further in section 5). In cases 4 and 8, N_{250} was almost completely de-627 pleted, but there is only a small reduction (< 35%) in N₂₀. This suggests that during 628 these two cases, the supersaturations were not high enough to activate many particles 629 with diameters < 250 nm. In cases 10 and 12, N₂₅₀ was almost completely depleted, and 630 N_{20} was also depleted by 73 and 41% respectively. During case 10, the reduction in N_{20} 631 occurred simultaneously with the reduction in N_{250} (fig. 9) even though the initial N_{250} 632 concentration was above average. The reduction in N_{20} and N_{250} started 30 minutes prior 633 to fog detection, and then both concentrations remained steady after fog onset, suggest-634 ing that supersaturations during this event were high enough to activate smaller parti-635 cles (or that the N_{20} concentration in this case was dominated by larger particles). In 636 case 12 the initial concentration of N_{250} was only 0.24 cm⁻³, and there was a gradual 637 decrease in N_{20} after fog onset. 638

⁶³⁹ 5 Discussion: Observational evidence of fog-aerosol interactions

The results described in section 4 hint that there are a variety of different ways in 640 which fog interacts with the surface aerosol particle population across the twelve case 641 studies. Of the seven cases for which N_{250} measurements are available, only cases 4 and 642 11 develop a LWP > 10 g m⁻². The longwave radiative forcing for a LWP of 5 to 30 g 643 m^{-2} compared to that of an equivalent clear sky day is very sensitive to small changes 644 in LWP, and the difference between a LWP of 5 g m^{-2} and a LWP of 10 g m^{-2} can equate 645 to $> 20 \text{ W m}^{-2}$ difference in longwave radiation at the surface (Miller et al., 2015). For 646 this reason, understanding why some fogs develop a LWP > 10 g m⁻² while others do 647 not is important for understanding the radiative impact of fog over the GrIS. One of the 648 factors that can influence LWP in liquid and mixed-phase fogs is the properties of the 649 aerosol population. In this section, we use the observations presented in section 4 to dis-650 cuss the role of fog-aerosol interactions over central Greenland. Throughout this discus-651

Figure 9. The relationship between N_{20} and N_{250} during the fog events for which both measurements are available. Boxplots show the aggregated distribution of N_{250} and N_{20} during all events. Coloured circles on the boxplots indicate the initial N_{20} and N_{250} concentration averaged over the 2 hours prior to each event. Pearson's-r correlation coefficients (r) in the legend inset are for the correlation between $\log(N_{20})$ and $\log(N_{250})$, all r values are significant at the 99% confidence level.

sion we make the assumption that changes in the fog and aerosol population were oc-652 curring in-situ (i.e. not related to advective processes). We justify this assumption based 653 on the fact that (a) most of the fog events are likely to be radiation fogs due to the fact 654 that they form in the evening on days with clear skies, and (b) that the wind speeds (2) 655 to 14 m a.g.l) during all events are relatively low $(3.5 \pm 0.3 \text{ m s}^{-1})$. Despite the low wind 656 speeds, for some of the longer events (> 8 hours) the horizontal length scale can be ~ 100 657 km, and we acknowledge that advective process may have played a role in some of the 658 observed changes in fog and aerosol properties. 659

660

5.1 Aerosol particle controls on fog microphysics

The goal of this section is to identify whether there is observational evidence that low aerosol particle number concentrations is a critical control on fog liquid water path and lifetime. To do this, we focus on the cases of liquid and mixed-phase fog where N_{250} measurements are available (cases 3, 4, 7, 8, 10, and 11).

In radiation fog, liquid droplets form when the surface cools radiatively until the 665 air becomes saturated with respect to water, after which water condenses on CCN par-666 ticles, growing them into fog droplets (e.g. Gultepe et al., 2007). Whether or not ice is 667 present, liquid droplets will continue to grow as long as supersaturation with respect to 668 water is maintained (either by continued radiative cooling or moisture influx) until they 669 are large enough to settle out, and new droplet formation will continue as long as there 670 are CCN particles present that may be activated for the given degree of supersaturation. 671 In the initial stages of radiation fog development, when the atmosphere is stable and close 672 to saturation, the degree of supersaturation is determined by the cooling rate, and by 673 the properties of the aerosol particle population, which determine the number concen-674 tration of CCN for a given supersaturation. The air mass specific humidity also plays 675 a role in determining the amount of cooling required to reach a given supersaturation, 676

but this effect is small because the saturation mixing ratio does not change much at cold temperatures (< 0.1 g kg⁻¹ °C⁻¹ for temperatures <-8 °C). Based on this, and assuming an absence of advective processes and limited turbulent mixing, the initial formation of liquid droplets in a supercooled radiation fog development might either be 'aerosollimited' or 'cooling-rate limited' (similar to how a convective cloud might be 'aerosollimited' or 'updraft limited', i.e. Reutter et al., 2009).

In a 'cooling-rate limited' scenario, the initial supersaturation would increase slowly. 683 Using the observations available in this study, this situation would be characterised by 684 relatively low activated fractions of N_{250} at fog onset, because particles that can act as 685 CCN at low supersaturations will be a subsample of N_{250} (McFiggans et al., 2006), fol-686 lowed by a gradual droplet growth and continual activation while cooling continues, and 687 higher supersaturations allow the activation of further particles. In contrast, an 'aerosol-688 limited' fog would be characterised by high initial activation ratios of N_{250} and N_{20} at 689 fog onset, as all particles that can act as CCN are activated. With continued cooling, 690 and in the absence of new droplet formation due to a lack of CCN, the existing fog droplets 691 would grow to relatively large sizes, ultimately settling out and preventing an increase 692 in fog LWP despite continued cooling (as described by Mauritsen et al., 2011). The pres-693 ence of 'aerosol-limited' fogs would support the hypothesis that the low aerosol parti-694 cle number concentrations can be a critical control on fog liquid water path and lifetime. 695

To identify whether there are any cases of 'aerosol-limited' fogs, we calculate cool-696 ing rates during each fog event from temperature measurements at 2 m, 4 m, 9 m and 697 14 m a.g.l. The development of the near surface temperature profile during each fog event 698 is shown in the supporting information (fig. S1). The cooling rate is calculated from the 699 60-minute rolling mean of the mean temperature across these four heights. Of the six 700 cases for which N_{250} measurements are available and liquid water is detected, case 7 has 701 an extremely low cooling rate ($< 0.5 \text{ K h}^{-1}$, fig. 10a) and a low activated fraction of N₂₅₀ 702 at fog onset (fig. 8), suggesting that this event is more likely to be limited by the low 703 cooling rate than by the aerosol population.

For the remaining five cases, the maximum cooling rate ranges from 2.4 K $\rm h^{-1}$ (case 705 11) to 4.0 K h⁻¹ (case 10) and occurs 30 to 50 minutes after fog onset, except in case 706 3, where the maximum cooling rate occurs 140 minutes after fog onset (fig. 10a). These 707 cooling rates are within the range of those observed in mid-latitude radiation fogs (~ 1 708 to 4 K h⁻¹, e.g. Price, 2011; Haeffelin et al., 2013). In cases 3 and 4, N₂₅₀ decreases grad-709 ually as the surface layer continues to cool, which suggests that neither of these two cases 710 were in the 'aerosol-limited' regime, and that aerosol number concentrations were not 711 the main reason why case 4 developed into an optically thick fog with LWP > 10 g m⁻² 712 but case 3 did not. The near-surface specific humidity and temperature profiles in both 713 cases were similar (see table 1), and so the difference in fog development was likely due 714 to differences in dynamics: In case 3, 110 minutes into the event, a burst of turbulent 715 kinetic energy $(0.3 \text{ m}^2 \text{ s}^{-2}, \text{ not shown})$ at 14 m is followed by warmer temperatures prop-716 agating downwards towards the surface (fig. S1), this mixing of warm air downwards could 717 have limited the fog development. 718

In cases 8 and 10, there is a high activated fraction of N_{250} at fog onset (68 and 719 62% respectively) as well as a relatively high activated fraction of N₂₀ (15 and 45\% re-720 spectively). Case 10 had the highest activated fraction of N_{20} out of all fog cases. In both 721 cases, there is little further change in N_{250} or N_{20} after fog onset despite continued cool-722 ing (figs. 8 and 10). This suggests that the aerosol particle number concentration could 723 have limited fog development (lifetime and LWP) in these cases. Unfortunately, the low 724 725 fog optical depths limit the ability of the MIXCRA retrieval algorithm to provide information about fog phase and particle sizes for both cases. Finally, in case 11, there is greater 726 variability in N_{250} both prior to and after fog onset compared to the other cases, and 727 in this case the fog develops much more rapidly than in case 4, with LWP increasing to 728 $>10~{\rm g~m^{-2}}$ 80 minutes after fog onset (as opposed to 180 minutes in case 4). The warm-729

Figure 10. Time series of (a) cooling rate (2 to 14 m a.g.l), (b) percentage change in N₂₅₀, (c) liquid water path (LWP), and (d) Liquid droplet effective radius (R_{liq}) during the case studies for which N₂₅₀ measurements are available. Note that cases 7 and 12, identified as 'cooling-rate limited' fogs are only included on panel (a). The error bars on panels (c) and (d) show the 2σ uncertainties in the MIXCRA retrievals.

ing of the surface layer that coincides with the sharp increase in LWP is indicative of a
 transition from near-surface radiative cooling to radiative cooling at fog top maintain ing the fog. This case is discussed further in section 5.2.

 $_{733}$ 5.2 Increase in N₂₀ associated with fog

We focus on case 11 to look for evidence to support the hypothesis that fog can 734 act to increase surface aerosol particle number concentrations by enhancing mixing of 735 air from above into the near-surface stable layer. Case 11 was anomalous out of the 12 736 cases because of the exceptionally high N_{20} that occurred during the fog event (1370 cm⁻³, 737 > 99th percentile of all N₂₀ measurements made between June and September 2019), 738 and because it consisted of two distinct phases; the LWP increased from 2.4 g m^{-2} to 739 17.0 g m⁻² between 05:05 and 06:00, then decreased to 2.6 g m⁻² at 07:05 before increas-740 ing again to 15.9 g m⁻² at a 07:45. 741

The fog formed initially as the near surface temperature cooled after the dissipation of a mixed-phase cloud (with a base height of approximately 1.3 km) at 04:30. But only 80 minutes after fog onset, near surface air temperatures started to increase, and the fog optical depth and LWP started to increase rapidly (fig. 11). Because the surface temperature was no longer decreasing, the increase in fog optical depth and LWP after 05:15 must have been due to a transition from surface radiative cooling to cooling higher in the atmosphere (i.e., radiative cooling at fog top).

If the increase in near-surface air temperature was radiatively driven, we would expect the temperature increase to start closest to the surface first (for example, as in case 2 and 4, fig. S1). The fact that the near-surface air temperature increased simultaneously at each of the four heights (fig. 11d) suggests that another mechanism was responsible. This could have been the advection of a warmer air mass, but the consistent wind direction (90% of all winds measured at 2, 4, 9, and 14 m come from 156° to 222°) and

Figure 11. Atmospheric conditions during Case 11 (05 September 2019). (a) Fog optical depth (τ_{liq} , green, and τ_{ice} , purple) and droplet effective radius (R_{liq} , orange) from MIX-CRA, shading indicates 2σ uncertainties. (b) Surface aerosol particle number concentrations (1-min mean), N_{250} (red) and N_{20} (blue). (c) Backscatter (grey shading), vertical visibility (cyan points), and obscured flag (orange) from the ceilometer. (d) Near surface temperature profile (reds) and fog liquid water path (LWP, blue, shading indicates 2σ uncertainties). (e) Upwards sensible heat fluxes at 2 m (solid) and 14 m (dashed). (f) Sodar backscatter, red dashed line indicates the height of strongest negative backscatter gradient (when $\Delta \log(backscatter) < -0.8 \text{ m}^{-1}$).

low winds speeds (90 % of which range from 1.65 to 3.86 m s⁻¹) throughout the event 755 indicates that advection at the surface is unlikely to be an important process on the timescale 756 of this event. Alternatively, this near-surface heating could result from the mixing of warm 757 air down from above. The sensible heat fluxes at 2 m and 14 m are small (mostly < 2.5758 $W m^{-2}$, fig. 11e) suggesting that this mixing was not driven by changes in thermody-759 namic stability at the surface. However, there is evidence both in the ceilometer backscat-760 ter (fig. 11c) and the sodar acoustic backscatter (fig. 11f) of features propagating down-761 wards towards the surface. These could be remnants of mesoscale dynamical features, 762 such as buoyancy waves, mixing warmer air down from higher in the atmosphere, or en-763 trainment driven by radiative cooling at fog top. In either case, propagation of these fea-764 tures down to the surface coincide with the sudden increase in N_{20} , suggesting this is re-765 lated to the mixing of more polluted air down to the surface from above into what was 766 previously an isolated stable surface layer. 767

The top of the strong surface echo in the sodar backscatter, identified by the max-768 imum negative gradient (fig. 11f), is associated with the top of the stable near-surface 769 layer which is isolated from above by a strong surface-based temperature inversion (fig. 770 11d). The top of this layer decreases intermittently with height between 05:00 and 07:00, 771 and these variations are strongly anti-correlated with N_{20} (Pearson's r = -0.69, p-value 772 < 0.001). For example, the top of the strong sodar echo falls to 5 m a.g.l at 05:20, co-773 inciding with the initial sharp increase in N_{20} and an increase in surface temperature. 774 Between 05:35 and 05:55, the height of the sodar echo increases again to 8 m a.g.l and 775 N_{20} decreases, before increasing again once the sodar echo height lowers at 05:55. This 776 pattern continues until 06:50 after which the surface temperature inversion is completely 777 eroded at 9 m a.g.l and the near-surface echo in the sodar disappears. The erosion of the 778 isolated surface layer from above indicated by the sodar echo, and the anti-correlation 779 between the surface layer height and N_{20} , is consistent with the hypothesis that the in-780 crease in N_{20} is related to the mixing of air down from above. 781

During the most optically thick part of the fog there was also detectable ice that 782 increased between 05:50 and 06:10. The increase in ice optical depth coincident with a 783 decrease in liquid optical depth could be indicative of ice growing at the expense of liq-784 uid water droplets (i.e. via the Wegener-Bergeron-Findeisen process). This would result 785 in the evaporation of liquid droplets and the release of any aerosol particles they con-786 tain within the surface layer. In this situation, liquid droplets could form due to radia-787 tive cooling at fog top in a layer of the atmosphere where aerosol particle concentrations 788 might be higher than at the surface, these droplets could then settle and mix towards 789 the surface, eventually reaching a lower level that is sub-saturated with respect to wa-790 ter but supersaturated with respect to ice. The droplets would then evaporate, releas-791 ing aerosol particles into the surface layer. This process has been observed in Arctic mixed-792 phase stratocumulus clouds (Igel et al., 2017), and could also contribute to an increase 793 in N₂₀, but it is unlikely to be the sole process driving the ($\sim 1000~{\rm cm}^{-3})$ increase in 794 N_{20} because the typical number concentration of fog droplets at Summit is only ~10 to 795 50 cm^{-3} (Cox et al., 2019). 796

When the surface temperature inversion was completely eroded above 9 m a.g.l at 797 06:50, the fog dissipated, and the surface began to cool again (fig. 11d). At this time, 798 N_{250} had decreased to near-zero, suggesting that there were no further particles > 250 799 nm diameter available to act as CCN or INP. The cooling of the near-surface air would 800 have increased saturation near the surface, potentially initiating the second phase of the 801 fog. The increase in LWP during the second phase of the fog coincided with a sharp de-802 pletion of N_{20} and given that there were no particles > 250 nm left to activate, the de-803 crease in N_{20} during the second phase of the fog was likely associated with the activa-804 tion of N_{20} particles into fog droplets and the scavenging of particles by fog droplets close 805 to the surface. 806

This case illustrates some of the complexities of the relationship between dynam-807 ics, thermodynamics, and aerosol properties during mixed-phase fog events, and it is not 808 possible to say definitively what processes were involved from looking at the available 809 observations alone. The observational evidence supports the hypothesis that the sharp 810 increase in N_{20} associated with this fog event resulted from the mixing of higher N_{20} con-811 centrations down to the surface, which was either driven by the fog itself (i.e. radiative 812 cooling at fog top), or both the fog and changes in N_{20} were forced by the same exter-813 nal mixing event (e.g. buoyancy waves). 814

815 816

5.3 The impact of multiple fog events on the surface aerosol particle number concentration.

In this section we look for evidence that multiple consecutive fog events in quies-817 cent conditions can act to deplete the near surface aerosol particle number concentra-818 tion with the potential to impact fog development later in time. Fog with an observable 819 radiative impact at the surface formed on four out of the five evenings between 01 and 820 06 August 2019 (fog case numbers 6 to 9, table 1), with skies otherwise clear through-821 out the day; associated with a persistent (weakening) high-pressure system over central 822 Greenland (fig. S5, supporting information). Although this persistent anticyclone con-823 tributed to the unprecedented GrIS surface melt in 2019 (Tedesco & Fettweis, 2020), sim-824 ilar events are common over Greenland in the summer (occurring 30% of the time in JJA 825 1981-2010; Tedesco & Fettweis, 2020). During this event, the near-surface winds were 826 consistently from the south-east, with 90% of measured 1-minute averaged wind speeds 827 ranging from 1.26 to 4.81 m s⁻¹. There was a strong diurnal cycle, with radiative cool-828 ing in the near-surface layer beginning in the evening when the sun dropped below $\sim 25^{\circ}$ 829 and lasting until the sun rose above $\sim 15^{\circ}$ the following morning (fig. 12b). 830

Figure 12. Surface aerosol particle number concentrations (a) and cooling rate (b) during a five day clear sky period in August 2019. Radiation fog events are highlighted in light blue, and the solar elevation angle is shown by the black dashed line on panel (b). The green highlighted region at the end of the period indicates the start of a cloudy period.

The initial N_{250} averaged over the two hours prior to case 6 was 27.7 cm⁻³, and N₂₀ was 262 cm⁻³. Both concentrations are higher than the seasonal average, associated

Figure 13. (a) Near surface wind shear (14 m minus 4 m wind speed, 5-minute mean) during the first week of August 2019. (b) Turbulent kinetic energy (TKE) at 2 m a.s.l (blue) and 14 m a.s.l (orange) over the same period. Radiation fog events are highlighted in blue shading as in fig. 12.

with the descent of free tropospheric air down to the surface during the high-pressure 833 event (Guy et al., 2021). Both concentrations decrease gradually throughout the period, 834 with daily minima generally occurring during fog events (fig. 12a). The minimum N_{250} 835 was 0.11 cm⁻³ towards the end of case 8 (5 Aug 2019), and the minimum N_{20} was 56.5 836 $\rm cm^{-3}$, at the end of case 9. After the end of case 9, the fog lifted from the surface, form-837 ing a low-level stratus cloud (base ~ 200 m) that persisted through 7 August. Both N₂₀ 838 and N_{250} increased after the fog lifted, N_{20} to 177 cm⁻³, and N_{250} to 7.63 cm⁻³, but even 839 after this recovery, both concentrations were 30% lower than the initial concentrations 840 at the beginning of the quiescent cloud-free period. 841

Despite similar maximum near-surface cooling rates on the evenings with fog (2.7)842 to 3.7 K h⁻¹), only the first case (case 6) develops a LWP > 10 g m⁻² (fig. 6), and there 843 is some evidence presented in section 5.1 that the development of case 8 might be lim-844 ited by low aerosol particle concentration. One explanation for the gradual decrease in 845 surface aerosol particle concentrations throughout this period (01 to 06 August) is that 846 the scavenging of particles by fog droplets exceeds the rate of particle influx (presum-847 ably due to descent via sedimentation and/or turbulent entrainment from the free tro-848 posphere). Without measurements of vertical aerosol profiles and subsidence rates we 849 cannot determine the relative importance of fog scavenging in this process compared to 850 changes in particle influx (i.e. particle influx may also be decreasing with time as the 851 anticyclonic circulation over Greenland weakens, fig. S5). However, the fact that the mean 852 deposition flux of particles to the surface during fog events (on average 0.62 ng cm⁻² for 853 SO_4^{2-} , Bergin et al., 1994) is twice that of the mean dry deposition flux during the summer at Summit (0.29 ng cm⁻² for SO_4^{2-} , Bergin et al., 1994), supports the hypothesis 854 855 that multiple fog events during quiescent conditions act to deplete near surface aerosol 856 particle concentrations, which in this case may have contributed to the latter fog cases 857 approaching the aerosol-limited regime. 858

Another interesting question is why the nocturnal fog did not form on 03 August. Both near-surface temperature and aerosol concentration were highly variable early on

03 August, the maximum near-surface cooling rate reached 5.70 K h⁻¹ and both N_{20} and 861 N_{250} remained higher than the seasonal average (fig. 12), suggesting that fog formation 862 was neither 'cooling-rate limited' nor 'aerosol limited'. Photographs from the total sky 863 imager and observer reports of unlimited visibility confirm that the sky remained clear throughout the day. One difference between the early morning period on 03 Aug and the 865 other mornings when fog did form is in the near-surface wind profile (fig. 13a), during 866 the morning of 03 Aug there was a wind speed maximum close to the surface (the 4 m 867 wind speed was consistently $1-2 \text{ m s}^{-1}$ faster than the 14 m wind speed). The shear gen-868 erated by this near-surface wind-speed jet modified the turbulent properties of the sur-869 face layer, increasing mixing (indicated by the coincident increase in turbulent kinetic 870 energy, fig. 13b), which may have been sufficient to prevent the formation of fog droplets 871 and likely contributed to the high variability in the near-surface aerosol concentrations 872 and temperature profile. 873

⁸⁷⁴ 6 Summary and conclusions

The first goal of this study was to highlight the advantages and limitations of us-875 ing spectral ground-based measurements of downwelling longwave radiation (measured 876 by the AERI) to examine fog microphysical properties. Unlike active remote sensing in-877 struments, which have a blind range close to the instrument, the AERI is most sensi-878 tive to the near-surface atmosphere, making it particularly suitable for the study of shal-879 low fogs. Measurements of shallow fog with an AERI at Summit Station, in central Green-880 land, also benefit from the extreme dryness of the atmosphere and the improved abil-881 ity to characterize temperature and humidity near the surface. The 8-19 μ m spectral range 882 of the AERI is most sensitive to fog (or cloud) microphysical properties when the fog 883 visible optical depth is close to 1. This is particularly advantageous for the study of op-884 tically thin clouds in polar regions (particularly fogs), which can be responsible for the 885 maximum cloud radiative forcing at the surface during summer months (e.g. Miller et al., 2015). At Summit, optically thin fogs are common (the maximum mixed-phase op-887 tical depth retrieved from the 12 fog cases in this study is 4.8, and the mean is 0.8) so 888 the sensitivity of the AERI instrument (which can detect LWP as low as 3 g m⁻²) is par-889 ticularly suited for the study of these fogs. However, the loss of sensitivity to fog micro-890 physical properties at optical depths > 6 means that this technique is not appropriate 891 for studying the microphysical properties of optically thick fogs/clouds. 892

The MIXCRA algorithm is designed to retrieve the optical depth of liquid droplets, the optical depth of ice crystals, and the effective radius of the liquid and ice particles from the measured spectral radiance. Although MIXCRA retrievals of cloud properties have been validated against independent measurements in multiple previous studies, this is the first validation of the MIXCRA algorithm for fog events. A cross-validation of droplet effective radius retrieved using the MIXCRA algorithm with in-situ measurements from an FM100 forward scattering probe demonstrates that MIXCRA can capture variations in R_{liq} with a RMSE of 2.0 μ m when the fog optical depth is sufficient (0.25 < τ < 6.0).

The loss of sensitivity of the spectral infrared signature to changes in fog micro-901 physical properties as the fog optical depth approaches zero means that MIXCRA is un-902 able to retrieve fog microphysical properties during the initial growth phase of fog. This 903 also means that MIXCRA is unable to retrieve microphysical properties associated with 904 tenuous fogs (or higher clouds) that are potentially limited by low aerosol particle num-905 ber concentration. We would expect such events to be characterised by large droplet ef-906 fective radius and low optical depths, but for the two potential examples shown in this 907 study, the optical depths are too low for MIXCRA to determine the fog phase or par-908 ticle effective radius. 909

For the 12 fog cases studied, 92% of retrievals passed the initial quality control (radiances calculated using retrieved cloud properties matched measured radiances to within

an RMSE of 1.2 RU). Where there was sufficient optical depth for the retrieval ($\tau > 0.25$), 912 the mean total (liquid plus ice) optical depth across all fog events was 0.78 ± 0.71 (one 913 standard deviation). Nine of the twelve cases were mixed-phase fogs, one consisted of 914 only ice particles, one of only liquid droplets, and one case was too optically thin for any 915 valid retrievals. The mean ice particle effective radius was $24.0 \pm 7.8 \ \mu m$, and the mean 916 liquid droplet effective radius was $14.0 \pm 2.8 \ \mu\text{m}$. The sensitivity of the AERI allows for the detection of LWP as small as 2.0-3.0 g m⁻² (for R_{liq} 12 to 18 μ m) with a 2σ uncertainty of 0.9-1.5 g m⁻². The mean LWP across all fog events was 7.9 \pm 6.6 g m⁻², and 917 918 919 in two cases the maximum LWP exceeded 30 g m^{-2} . 920

The second objective of this study was to use the MIXCRA microphysical retrievals 921 alongside measurements of surface aerosol number concentration to look for observational 922 evidence of fog-aerosol interactions at Summit. In all cases apart from one, the concen-923 tration of aerosol particles > 250 nm (N₂₅₀) decreased to < 0.5 cm⁻³ during the fog event 924 (with a median decrease of 82% after 300 minutes), suggesting that almost all particles 925 in this size range are activated into (or scavenged by) fog droplets, consistent with past 926 studies (Bergin et al., 1994, 1995). Changes in the concentration of 20 to 230 nm diam-927 eter particles (N_{20}) were more variable; in some cases, N_{20} was found to be well corre-928 lated with N_{250} and decreased by up to 50% during fog, whereas in others, the two pop-929 ulations were decoupled, and on two occasions there was a > 100% increase in N₂₀ dur-930 ing fog. 931

In two case studies, there is observational evidence that the near-surface aerosol 932 particle number concentration might be a critical control on fog LWP and lifetime, but 933 in other cases there is evidence that dynamical processes (i.e. turbulent mixing, subsi-934 dence, or the near-surface wind profile) are more important. Large-eddy simulations based 935 on these detailed case studies are necessary to determine why some cases developed into 936 well-mixed optically thick fogs and others did not, which is important for the resulting 937 net radiative forcing of the fog at the ice sheet surface. In one case study there is evi-038 dence that fog can act to increase the near-surface aerosol particle number concentra-939 tion by enhancing mixing of air from above into the near-surface stable layer. During 940 a separate period of clear skies and low winds, when nocturnal radiation fog formed on 941 four out of five consecutive nights, a gradual reduction in N_{20} and N_{250} supports the hy-942 pothesis that multiple fog events in quiescent periods act to clean the near-surface layer 943 of aerosol particles. 944

The examples presented in this study demonstrate that there are multiple path-945 ways through which the surface aerosol population may (or may not) impact fog devel-946 opment, and through which fog itself can modify the surface aerosol population. Cor-947 relations between aerosol properties and fog (or cloud) microphysics should not be con-948 sidered in isolation, because there are other completing processes that can impact fog 949 development, such as the thermodynamic and turbulent structure of the boundary layer. 950 A larger dataset of fog cases studies is necessary to investigate the competing effects of 951 the scavenging of surface aerosol particles by fog versus increases in aerosol particles dur-952 ing fog events, and the importance of both processes for fog and cloud formation later 953 in time. 954

955 Open Research Section

AERI data and the thermodynamic profiles used to drive the MIXCRA algorithm are in the process of being submitted to the Arctic Data Center at https://doi.org/ 10.5439/1880028. The temperature dependent single scattering property databases are available online at https://people.nwra.com/rowe/refractive_indices.shtml. The FM100 data from Cox et al. (2019) are archived at https://doi.org/10.18739/A28K74W5W (Noone & Cox, 2019). Aerosol particle number concentration measurements, near surface temperature and wind profiles from the 15 m tower, and sensible heat flux measurements are available from CEDA data archive (Guy et al., 2020). ICECAPS ceilometer
data (https://doi.org/10.18739/A27659G3R) and sodar data (https://doi.org/10
.18739/A2HM52K68) are archived at the Arctic Data Center (Shupe, 2020a, 2020b). The
MIXCRA retrievals used in this study are in the process of being submitted to the Arctic Data Center and are available upon request.

968 Acknowledgments

The efforts of technicians at Summit Station and science support provided by Polar Field 969 Services were crucial to maintaining data quality and continuity at Summit. ICECAPS 970 is a long-term research program with many collaborators, and we are grateful for all their 971 efforts in developing and maintaining the various instruments and data products used 972 in this study. Thank you also to Professor Ken S. Carslaw for proof-reading and provid-973 ing valuable feedback on this publication. Financial support for ICECAPS was provided 974 by NSFGEO-NERC grants 1801477 and 2137083. HG was funded by the NERC SPHERES 975 DTP grant number NE/L002574/1. MDS was supported by the National Science Foun-976 dation (OPP-1801477, OPP-2137091) and the NOAA cooperative agreement (NA22OAR4320151). 977 PMR was supported by the National Science Foundation OPP Grant 2127632. Ceilome-978 ter data were provided by the Atmospheric Radiation Measurement (ARM) User Facil-979 ity, a U. S. Department of Energy (DOE) Office of Science User Facility managed by the 980 Biological and Environmental Research Program. This work used JASMIN, the UK col-981

982 laborative data analysis facility.

20 Abstract

Supercooled fogs can have an important radiative impact at the surface of the Green-21 land Ice Sheet, but they are difficult to detect and our understanding of the factors that 22 control their lifetime and radiative properties is limited by a lack of observations. This 23 study demonstrates that spectrally resolved measurements of downwelling longwave ra-24 diation can be used to generate retrievals of fog microphysical properties (phase and par-25 ticle effective radius) when the fog visible optical depth is greater than ~ 0.25 . For twelve 26 cases of fog under otherwise clear skies between June and September 2019 at Summit 27 28 Station in central Greenland, nine cases were mixed-phase. The mean ice particle (opticallyequivalent sphere) effective radius was $24.0 \pm 7.8 \ \mu\text{m}$, and the mean liquid droplet ef-29 fective radius was $14.0 \pm 2.7 \,\mu m$. These results, combined with measurements of aerosol 30 particle number concentrations, provide observational evidence supporting the hypothe-31 ses that (a) low surface aerosol particle number concentrations can limit fog liquid wa-32 ter path, (b) fog can act to increase near-surface aerosol particle number concentrations 33 through enhanced mixing, and (c) multiple fog events in quiescent periods gradually de-34 plete near-surface aerosol particle number concentrations. 35

³⁶ Plain Language Summary

Fogs over the central Greenland Ice Sheet can modify the net radiation that reaches 37 the ice surface. How much a fog influences the net surface radiation is related to the fog 38 lifetime and optical depth. These properties are related to the phase and size distribu-39 tion of the particles that make up the fog, that in turn depend on the characteristics of 40 the atmospheric aerosol particles on which the fog forms. This study shows that the phase 41 and size distribution of fog particles can be determined from ground-based measurements 42 of downwelling longwave radiation, and explores how fogs interact with the number con-43 centration of atmospheric aerosols measured near the surface during twelve cases of summer-44 time fog in central Greenland. 45

46 1 Introduction

Central Greenland is a unique environment in the Northern Hemisphere: A uni-47 form surface of snow-covered ice extends for over 250 km in every direction from the ice 48 sheet's highest point at 3,250 m a.s.l (Howat et al., 2017). The structure of the atmo-49 spheric boundary layer over the ice sheet is driven by large-scale circulation, including 50 atmospheric rivers associated with extratropical storms (Mattingly et al., 2018; Gallagher 51 et al., 2018) and blocking anticyclones (Pettersen et al., 2022), and is modulated locally 52 by strong radiative cooling at the ice sheet surface (Hoch et al., 2007). Under quiescent 53 conditions (clear skies, light winds), surface radiative cooling frequently drives the for-54 mation of supercooled radiation fog through the condensation of water onto aerosol par-55 ticles that act as cloud condensation nuclei (CCN) (Bergin et al., 1994; Cox et al., 2019). 56

At Summit Station (Summit), a research base located at the highest point on the 57 Greenland Ice Sheet (72.57°N, -38.47°E), fogs comprised of supercooled droplets occur 58 vear-round even when the surface temperature falls below -30°C (Cox et al., 2019). These 59 fogs can have a strong effect on the ice sheet surface energy budget, contributing on av-60 erage an additional 27 W m⁻² of total net downwelling radiation relative to clear sky 61 conditions (Cox et al., 2019). In the summer months (May to September) solar heating 62 of the ice sheet surface during the day results in a diurnal cycle of net surface radiation. 63 Radiation fog forms during the period of the diurnal cycle when the sun elevation is low-64 est and the net radiative cooling at the surface is strongest, and the associated increase 65 in net downwelling longwave radiation acts to damp the diurnal temperature cycle, which 66 has been hypothesised to precondition the ice sheet surface for melt (Cox et al., 2019). 67 These fogs can also increase the rate of aerosol deposition to the surface (Bergin et al., 68

⁶⁹ 1994, 1995) and reduce ice sheet mass loss by recondensing sublimated water onto fog
 ⁷⁰ particles that then settle out under gravity (Berkelhammer et al., 2016).

Understanding the controls on the processes that modify the surface mass balance 71 of the Greenland Ice Sheet is becoming increasingly important as melt events become 72 more common and widespread (Tedesco & Fettweis, 2020; Hanna et al., 2021). The ra-73 diative impact of fog at the ice sheet surface depends on fog occurrence, duration, and 74 optical depth, which itself is determined by the fog liquid water path (LWP), and mi-75 crophysical properties such as fog particle phase and size distribution. The representa-76 77 tion of fog microphysical properties is one of the largest sources of uncertainty in fog forecast models and Large-eddy simulations (Boutle et al., 2022), and the representation of 78 cloud microphysical properties in general is one of the largest sources of uncertainty in 79 projections of future Greenland Ice Sheet melt (Hofer et al., 2019). One of the reasons 80 for these uncertainties is that there are very limited observations available to constrain 81 model parameterisations. This is particularly true for fog over Greenland, which often 82 occurs in shallow layers (< 100 m) below the lowest range gate of most ground-based 83 active remote sensing instruments (such as radar or lidar). These very shallow fog lay-84 ers are often subgrid-scale for most climate and weather models. 85

Important controls on fog (and cloud) lifetime, microphysical, and radiative prop-86 erties are the number concentration, size distribution, and composition of aerosol par-87 ticles on which droplets or ice crystals can form. Droplets form on CCN, so the num-88 ber concentration of CCN determines the number concentration of droplets at a given 89 supersaturation. When the CCN concentration is increased, a fog will contain a greater 90 number of smaller droplets than an equivalent fog (with the same liquid water content) 91 forming under a reduced CCN concentration, resulting in a relatively high fog optical 92 depth and solar reflectivity, and hence impacting the net downwelling radiation at the 93 surface (Twomey, 1977). Increased fog droplet number concentration also leads to en-94 hanced longwave radiative cooling at fog top (e.g. Garrett, Radke, & Hobbs, 2002), en-95 couraging further droplet activation, and smaller droplets that are not removed as quickly by sedimentation, with both processes working to extend fog lifetime (Maalick et al., 2016; 97 Boutle et al., 2018; Yan et al., 2021). Increased fog top cooling can also enhance mix-98 ing and entrainment that, depending on the humidity of the overlying air, can either re-99 duce or increase cloud/fog water content (Ackerman et al., 2004; Small et al., 2009; Williams 100 & Igel, 2021). 101

In very clean environments, low CCN concentrations can limit fog (and cloud) for-102 mation and lifetime, because the few activated CCN will grow to relatively large sizes 103 and precipitate out, removing CCN and preventing further droplet formation (Mauritsen 104 et al., 2011; Stevens et al., 2018). Evidence suggests that this situation can occur in the 105 Arctic, where naturally low concentrations of CCN (1 to 100 cm^{-3}) have the potential 106 to control cloud radiative properties (Mauritsen et al., 2011; Sterzinger et al., 2022). At 107 Summit, the annual mean aerosol particle concentration is low even compared to other 108 Arctic sites (Schmeisser et al., 2018); the mean annual total surface aerosol particle num-109 ber concentration (> 20 nm) at Summit in 2019-2020 was just 129 cm^{-3} , and fell to less 110 than 10 $\rm cm^{-3}$ on occasions in all seasons (Guy et al., 2021). Given that only some of these 111 aerosol particles act as CCN, these numbers are an upper limit on the number of CCN 112 available near the surface where fog forms. 113

When the temperature is below freezing, which is the case almost all the time in 114 central Greenland (Shupe et al., 2013), the phase partitioning of the fog is also impor-115 tant for fog lifetime and the radiative effect of the fog at the surface. Ice fogs usually form 116 117 through the direct deposition of vapour onto ice-nucleating particles (INPs, a subset of the aerosol population that can catalyse freezing) when the air is supersaturated with 118 respect to ice (Gultepe et al., 2015). Ice nucleation can also occur in supercooled liquid 119 fogs by either immersion freezing (INPs are activated within a droplet) or contact freez-120 ing (droplets freeze upon contact with an INP) (Kanji et al., 2017). Once primary ice 121

is present, further ice can form through several different multiplicative mechanisms, collectively known as secondary ice production (Field et al., 2017). If the air becomes supersaturated with respect to ice but subsaturated with respect to water, ice crystals will grow at the expense of liquid water droplets, causing the liquid droplets to evaporate and the ice crystals to grow to relatively large sizes and settle out, removing moisture from the surface layer and acting to reduce fog lifetime; this is known as the Wegener-Bergeron-Findeisen process (e.g. Korolev, 2007).

In addition to the aerosol population having the potential to control fog lifetime 129 130 and radiatively important microphysical properties, fog formation may also be an important control on the lifecycle of aerosol particles in the boundary layer over central Green-131 land. Fog can act as an aerosol sink, because the fog droplet deposition flux exceeds that 132 of aerosol dry deposition (Bergin et al., 1994, 1995). Through this mechanism, fog may 133 act to 'clean' the boundary layer of CCN and INP, which may in turn impact fog and/or 134 cloud formation later in time. Conversely, fog could act to increase aerosol particles in 135 the boundary layer by enhancing the transport of aerosol particles from above the fog 136 top into the surface layer, either by buoyancy or windshear driven turbulent entrainment 137 at fog top, or by aerosol activation at fog top followed by droplet evaporation closer to 138 the surface. Observational and model studies have demonstrated that the latter process 139 can be important in low-level Arctic stratocumulus (Solomon et al., 2014; Igel et al., 2017). 140

The relative importance of each of these fog-aerosol interactions over central Green-141 land is unknown, and our ability to model these processes is hindered by a lack of ob-142 servations of both fog microphysical properties and surface aerosol number concentra-143 tion and size distribution. Using in-situ measurements collected at Summit in 2013-2014, 144 Cox et al. (2019) completed a comprehensive assessment of the occurrence, microphys-145 ical characteristics, and radiative properties of fogs at Summit, but there were no aerosol 146 particle measurements available during this period. This study builds on the findings of 147 Cox et al. (2019), and has two main objectives: (1) to explore the possibility of using 148 spectral measurements of downwelling longwave radiation to generate retrievals of fog 149 microphysical properties, and (2) to use these results alongside measurements of surface 150 aerosol particle number concentration to look for observational evidence of fog-aerosol 151 interactions over central Greenland. 152

The spectral signature of downwelling longwave radiation is sensitive to the radia-153 tive properties of fog that are important for the ice sheet surface energy budget and can 154 be measured continuously by passive ground-based instrumentation that, unlike many 155 active remote sensing instruments, are not limited by the height of their lowest range gate 156 and so do not have a 'blind' spot close the surface. Such measurements have been used 157 to study the microphysical properties of mixed-phase polar clouds (Mahesh et al., 2001; 158 Rathke et al., 2002; Turner, 2005; Garrett & Zhao, 2013; Cox et al., 2014; Shupe et al., 159 2015; Lubin et al., 2020; Richter et al., 2022); however, these studies did not specifically 160 focus on fog. 161

Here, we use a case-study based approach to examine the advantages and limitations of retrieving the microphysical properties of fog from downwelling longwave radiation measurements. Such measurements have the greatest sensitivity to the microphysical properties of clouds when the atmosphere is dry and the clouds are low and optically thin. In addition, retrieval accuracy relies on a well-constrained cloud temperature.
Taken together, this makes such measurements ideal for studying fog over central Greenland.

For objective (2), we combine the results of the fog microphysical retrievals with measurements of surface aerosol particle number concentrations and supplementary observations of atmospheric state to look for observational evidence to support (or negate) the following hypotheses:

- (a) That low aerosol particle number concentration can be a critical control on fog liquid water path and lifetime.
- (b) That fogs can act to increase surface aerosol particle number concentration by enhancing mixing of air from above into near-surface stable layer.
 - (c) That multiple fog events during quiescent conditions act to deplete near surface aerosol particle number concentration, impacting fog development later in time.

The results of this analysis may be used as the basis of future modelling studies to systematically distinguish the importance of different fog-aerosol interaction processes, and to identify instrumentation requirements for future observational campaigns to study fogaerosol interactions over central Greenland or in similar environments.

¹⁸³ 2 Measurements and instrumentation

We make use of measurements from the ICECAPS project (the Integrated Char-184 acterisation of Energy, Clouds, Atmospheric state, and Precipitation at Summit; Shupe 185 et al., 2013) which consists of a suite of instrumentation for monitoring atmospheric pro-186 cesses at Summit. To generate the microphysical retrievals of fog properties we use data 187 from the Atmospheric Emitted Radiance Interferometer (AERI), which measures spec-188 trally resolved downwelling infrared radiance between 3 and 19 μ m at ~0.48 cm⁻¹ res-189 olution (Knuteson et al., 2004b, 2004a). At Summit, the AERI measures downwelling 190 radiation continuously, alternating between views of the sky at zenith and two calibra-191 tion sources, resulting in sky measurements every 15-20 s. The AERI data are quality 192 controlled as described in Guy et al. (2022) and subjected to noise filtering using the tech-193 nique described by Antonelli et al. (2004) and Turner et al. (2006). Section 3 describes 194 the retrieval algorithm. 195

To explore individual fog cases in more depth we examine data from the ceilome-196 ter (CT25K, Münkel, 2006), sodar (Neff et al., 2008), total sky imager, and near-surface 197 temperature profiles and sensible heat flux estimates from tower-mounted in-situ sen-198 sors (Guy et al., 2020). Data from the millimetre cloud radar and precipitation occur-199 rence sensor system were used to help identify fog cases during the summer of 2019, and 200 radiosonde data were used to help constrain retrievals of continuous thermodynamic pro-201 files from the AERI that are required as an input to the microphysical retrieval algorithm; 202 both steps are described in detail in Guy et al. (2022). See Shupe et al. (2013) for fur-203 ther information about the overall ICECAPS instrumentation suite. 204

2.1 Aerosol particle measurements

During the summer of 2019 there were two instruments at Summit measuring sur-206 face aerosol particle number concentration in different size ranges: a butanol-based con-207 densation particle counter (CPC, GRIMM 5.400) that measured the total concentration 208 of condensation nuclei every second, and an optical particle counter (SKYOPC, GRIMM 209 1.129) that measured size-resolved concentrations of 250 to 4500 nm diameter particles 210 every six seconds. Guy et al. (2021) describe the CPC data in more detail, including the 211 estimation of particle loss in the inlet line, which resulted in the CPC measuring the num-212 ber concentration of condensation nuclei with diameters between 20 and 230 nm with 213 greater than 50% efficiency. For this reason, measurements from the CPC are henceforth 214 referred to as N_{20} , indicating the number concentration of particles > 20 nm diameter. 215

The SKYOPC had an identical inlet to the CPC but a higher flow rate (1.2 L min⁻¹), and as a result larger particles could pass through the SKYOPC inlet. After accounting for particle losses in the inlet (using the Particle Loss Calculator, Von der Weiden, Drewnick, & Borrmann, 2009), the SKYOPC measured the number concentration of particles with diameters between 250 and 4500 nm with greater than 50% efficiency. For the SKYOPC, the measurements were corrected for particle loss in the inlet by multiplying the particle number concentration by a correction factor based on the modelled inlet efficiency as a function of particle size (which varied from 1.02 to 1.97 in the 250 to 4500 nm size range). The total particle number concentration between 250 and 4500 nm (henceforth N₂₅₀) was calculated by summing the corrected size resolved SKYOPC data.

Particles larger than 6 μ m in diameter, which is smaller than the typical size of fog 226 droplets (e.g. Mazoyer, Burnet, & Denjean, 2022), could not pass through either inlet, 227 and the instruments were located in a heated building that was always $>15^{\circ}C$ warmer 228 than the outside air. Thus, during fog events, we assume that N_{20} and N_{250} are mea-229 230 surements of the dried interstitial aerosol particle number concentration. Both N_{20} and N_{250} were resampled to five-minute medians for the purpose of this study, and quality 231 controlled to remove any instances of contamination from station pollution as in Guy 232 et al. (2021). Note that this quality control does not impact any of the data presented 233 here, because none of the fog cases coincide with local pollution events (which was part 234 of the original event selection criteria). 235

Figure 1 shows how the measurements from the SKYOPC (N_{250}) and CPC (N_{20}) 236 intersect with the 'typical' size range of CCN and INP from past literature, although the 237 proportion of aerosol particles that can act as a CCN depends on the aerosol type and 238 degree of supersaturation, and our knowledge of the typical size range of INP particles 239 is limited by sparse observations (particularly of small INP particles < 250 nm diam-240 eter). Supersaturations can reach higher values when the aerosol particle number con-241 centration is low, and particles as small as 20 nm have been observed to act as CCN in 242 clean Arctic environments (Leaitch et al., 2016; Baccarini et al., 2020). Several studies 243 indicate that the INP population is mostly made up of coarse-mode particles > 250 nm 244 diameter (Mason et al., 2016; Creamean et al., 2018; Si et al., 2018), however recent stud-245 ies of size-resolved INP concentration over the central Arctic suggest that particles as 246 small as 150 nm diameter can be an important source of INP (Creamean et al., 2022; 247 Porter et al., 2022). Figure 1 also shows how measurements during the summer of 2019 248 compare to those collected between 15 May and 16 June 2007 using a scanning mobil-249 ity particle sizer to detect particles with diameters from 5.5 to 195 nm diameter (Ziemba 250 et al., 2010), and how they compare to the 'typical' size distribution of near-surface aerosol 251 particles in the Arctic summer, which is mostly based on measurements from coastal and 252 low elevation Arctic sites (Carslaw, 2022). 253

254 2.2 Fog events

We focus on the twelve radiation fog events identified by Guy et al. (2022) that oc-255 curred during the summer of 2019 (Table 1). Each fog event occurred under otherwise 256 clear skies and had a detectable longwave radiative impact at the surface; the duration 257 of each fog event was defined as when the 962 $\rm cm^{-1}$ downwelling radiance measured by 258 the AERI is greater than a threshold of 1.7 RU (1 RU = 1 mW m⁻² sr⁻¹ cm⁻¹), which 259 is three standard deviations above the mean clear sky radiance between June and Septem-260 ber 2019. The 962 $\rm cm^{-1}$ microwindow is almost completely transparent under clear skies 261 for conditions at Summit, and is therefore particularly sensitive to the presence of clouds 262 (e.g. Cox, Walden, & Rowe, 2012). Note that this radiative definition of fog is distinct 263 from the traditional definition of fog (a reduction of horizontal visibility to < 1,000 m) 264 but is appropriate for this study because we are concerned with the radiative impact of 265 fog on the surface energy budget. See Guy et al. (2022) for further details about the se-266 lection criteria for each of these case studies. 267

Table 1 details each case study and indicates where aerosol particle number concentration measurements are available. The SKYOPC vacuum pump experienced intermittent faults resulting in missing N_{250} data for some of the fog cases, and an issue with the CPC power supply resulted in incomplete N_{20} data for case 3.

Figure 1. The portion of the aerosol particle size distribution measured in this study, N_{20} shaded in blue and N_{250} in red, overlaid on the typical size distribution of the near-surface Arctic atmosphere in summer (Carslaw, 2022, black dashed line), and the observed size distribution of surface aerosol particles at Summit between May and June 2007 from Ziemba et al. (2010) (green line). The blue and red lines indicate the mean values from the CPC (a single value in the range 20 to 230 nm) and the SKYOPC (size resolved measurements in 20 bins between 250 and 4500 nm) observed between June (or July for the SKYOPC) and September 2019.

3 Retrieval of fog microphysical properties

We use the mixed-phase cloud property retrieval algorithm (MIXCRA, Turner, 2005), 273 which uses optimal estimation to retrieve fog microphysical properties at 5-min inter-274 vals from the spectral longwave radiation measured by the AERI (note that we did not 275 apply temporal averaging to the AERI spectra). The longwave radiation is sensitive to 276 changes in cloud/fog phase, particle size, and optical depth when the optical depth is 277 between ~ 0.25 and 6, allowing the retrieval of these properties using optimal estimation 278 (Turner, 2005; Cox et al., 2014). As the optical depth approaches the upper end of this 279 range, the longwave spectral signature of the cloud/fog approaches that of a black body 280 and contains little information about microphysical properties. As the optical depth ap-281 proaches the lower end of this range, the signal to noise ratio of the AERI becomes too 282 low for meaningful retrievals. Figure 2 shows how the mean spectral signature from the 283 AERI during the fog events varied, spanning much of the dynamical range between clear 284 sky conditions and optically thick stratus in the atmospheric window region (where the 285 cloud-free atmosphere is mostly transparent to longwave gaseous absorption ~ 800 to 1200 286 cm^{-1}). 287

MIXCRA models each fog event as two collocated 'clouds', one consisting of ice crys-288 tals and the other of water droplets. Starting from user input a priori values of optical 289 depth (τ) and particle effective radius (R) for each cloud (τ_{liq} and R_{liq} for the liquid cloud 290 and τ_{ice} and R_{ice} for the ice cloud), as well as vertical profiles of atmospheric temper-291 ature and water vapor content, the algorithm uses a forward model to calculate the ex-292 pected spectral signature of the combined cloud and atmosphere, and then iterates us-293 ing optimal estimation to determine the values $[\tau_{liq}, R_{liq}, \tau_{ice}, R_{ice}]$ that optimally match 294 the spectral signature observed by the AERI, given the a priori and the measurement 295 uncertainty. 296

Figure 2. AERI radiance measurements averaged over each fog case (colored lines, see legend inset). The thick black line shows the median for all fog cases, which can be contrasted to the median over all confirmed clear sky hours (thick grey line), and an example of an optically thick stratus cloud (from 01 to 02 UTC on 08 June 2019, dashed black line). Spectral radiance is resampled to 4 cm⁻¹ for clarity (native resolution is 0.5 cm^{-1}). Vertical grey lines show the spectral bands used in the MIXCRA retrievals (between major gaseous absorption bands). Note the two spectral bands at wavenumbers below 570 cm⁻¹; these are critical for ascertaining the phase of the fog layers (?, ?; Turner, 2005).

²⁹⁷ Note that throughout this study τ refers to the visible optical depth (where extinc-²⁹⁸tion efficiency is 2), transformed from the optical depth at 11 μ m as described in Turner ²⁹⁹ (2005). See Turner (2005) for further information about the implementation of the op-³⁰⁰timal estimation. After the retrieval of [τ_{liq} , R_{liq} , τ_{ice} , R_{ice}], fog LWP is determined from ³⁰¹equation (1), where ρ is the bulk density of water.

302

 $LWP = \frac{2\rho R_{liq}\tau_{liq}}{3} \tag{1}$

MIXCRA uses the Line-by-Line Radiative Transfer Model (LBLRTM) version 12.1 303 (Clough et al., 1992; Clough & Iacono, 1995) as a forward model to calculate the gaseous 304 clear sky optical depth spectra as a function of height, and the DISORT algorithm (Stamnes 305 et al., 1988) to simulate radiance from the ice and liquid cloud (which accounts for both 306 scattering and absorption); the combined LBLRTM and DISORT code is referred to as 307 LBLDIS. The HITRAN 2008 database (Rothman et al., 2009) provides the molecular 308 absorption properties used by the LBLRTM. The single-scattering properties used by 309 DISORT are discussed in section 3.1.1. The radiative transfer calculation also requires 310 information about the thermodynamic structure of the atmosphere and profiles of at-311 mospheric gases. Trace gas concentrations are supplied by the U.S. standard atmosphere 312 (1976), and CO_2 concentrations are scaled to mimic the seasonal and yearly increase in 313 atmospheric CO_2 observed at the Mauna Loa observatory. Uncertainties related to the 314 distribution and concentration of these gases are mitigated in MIXCRA by only includ-315 ing narrow spectral bands (micro-windows) from the AERI in the optimal estimation pro-316 cess, and hence avoiding major gaseous absorption bands (the micro-windows used in 317 this study are highlighted on fig. 2). 318

Thermodynamic profiles (temperature and water vapor) used within MIXCRA were retrieved using the TROPoe algorithm, which also uses an optimal estimation approach

based on AERI observations, taking advantage of the fact that the AERI is also highly 321 sensitive to the thermodynamic structure of the atmosphere (Turner & Blumberg, 2019; 322 Turner & Löhnert, 2021). The accuracy of the TROPoe thermodynamic profile retrievals 323 during the 12 fog case studies is $\pm 1.0^{\circ}$ C for temperature and ± 0.39 g kg⁻¹ for water va-324 por in the lowest 1,000 m a.g.l (Guy et al., 2022). We assume that any impact of aerosols 325 on the radiative transfer calculation is negligible, because the absorption and scatter-326 ing coefficients of aerosol particles in the infrared at Summit are generally small (Schmeisser 327 et al., 2018) and there are no local sources of aerosol particles near Summit after instances 328 of local pollution from the station are excluded. 329

The a priori value of τ_{liq} used as starting point for the optimal estimation is based 330 on the LWP retrieved by the TROPoe algorithm (Guy et al., 2022) with a standard de-331 viation of 6. Note that TROPoe does not account for scattering processes and assumes 332 only liquid droplets are present; MIXCRA adjusts this first guess value to account for 333 the possible presence of ice particles and accounts for multiple scattering. The a priori 334 value for R_{liq} is set to $11\pm 6 \ \mu m$, based on in-situ measurements of the size distribution 335 of fog droplets at Summit in 2013 and 2014 (Cox et al., 2019). The a priori ice optical 336 depth is set to 0 with a standard deviation of 6, which gives the algorithm flexibility to 337 retrieve ice properties. The choice to initiate the retrieval with a liquid-only cloud is based 338 on the fact that liquid phase fogs are more commonly detected than ice fogs during the 339 summer at Summit (Cox et al., 2019). The a priori ice particle effective radius is set to 340 $18\pm15 \ \mu m$ based on the distribution of ice crystal effective radius retrieved from mixed-341 phase clouds over the Arctic Ocean in 1998 (Turner, 2005). 342

343

3.1 Uncertainty quantification and quality control

As an initial quality control, we omit any retrievals where the root mean squared 344 error (RMSE) between the final forward radiance calculation (that is, the calculation of 345 expected radiance using the retrieved cloud properties) and the measured AERI radi-346 ance is > 1.2 RU. The goal of this quality control is to omit any retrievals for which the 347 retrieval is unable to bring the calculated radiance into agreement with the measured 348 radiance to within the expected instrument uncertainty level (a threshold of 1.2 RU is 349 selected because in 90% of all retrievals the RMSE corresponding to a 3σ uncertainty 350 in the AERI measurements due to noise and calibration uncertainty falls below this value). 351 For rejected retrievals, we assume that additional unknown sources of error exist (e.g. 352 large errors in temperature), hindering accurate cloud property retrievals. Cox et al. (2019) 353 also used a threshold of 1.2 RU for the retrieval of cloud microphysical properties from 354 AERI measurements in northern Canada. 355

MIXCRA calculates the uncertainties in $[\tau_{liq}, R_{liq}, \tau_{ice}, R_{ice}]$ by propagating the 356 calibration uncertainty of the AERI (< 1% of ambient radiance, described in Knuteson 357 et al., 2004a) and the uncertainty associated with the sensitivity of the forward model 358 (i.e. how much the spectral cloud emissivity changes with small perturbations in τ_{lig} , 359 R_{liq} , τ_{ice} , R_{ice}]) through the optimal estimation algorithm (Turner, 2005). Figure 3 shows 360 how the 2σ percentage uncertainty (as output by the MIXCRA algorithm) varies as a 361 function of τ_{liq} (for τ_{liq} and R_{liq}) and τ_{ice} (for τ_{ice} and R_{ice}) for all the retrievals dur-362 ing the fog events. For all retrieved properties, the minimum percentage uncertainties 363 occur when the fog optical depth is ~ 1 , consistent with the findings of Turner (2005). 364

The percentage uncertainties in all properties increase when the fog is mixed phase (i.e. when both τ_{liq} and $\tau_{ice} > 0.02$, light blue and pink colours in fig. 3), which is related to the additional degrees of freedom when retrieving properties for a mixed-phase cloud compared to a single-phase cloud as well as the challenges of separating the two phases cleanly (because the liquid and ice signals are correlated). The higher percentage uncertainties in R_{ice} compared to R_{liq} are related to the fact that the retrieval is more sensitive to small particles, and ice particles are generally larger than liquid droplets.

Figure 3. Percentage uncertainty (2σ) in (a) τ_{liq} and (b) R_{liq} as a function of τ_{liq} , and in (c) τ_{ice} and (d) R_{ice} as a function of τ_{ice} , for every retrieval used in this study. The red line is the mean value (in nine logarithmically spaced bins). Points are coloured based on the magnitude of τ_{ice} (a and b) or τ_{liq} (c and d). The black vertical dashed line highlights an optical depth of 0.25 used as a minimum required optical depth for valid retrievals in this study.

As the fog optical depth approaches zero, the percentage uncertainties in all retrieved 372 properties become very large due to the decreasing signal-to-noise ratio, necessitating 373 the selection of a minimum optical depth above which fog microphysical properties can 374 be retrieved with an acceptable level of uncertainty. For this study we choose to use an 375 optical depth threshold of $\tau_{liq} > 0.25$ (for τ_{liq} , R_{liq} and LWP) and $\tau_{ice} > 0.25$ (for τ_{ice} , 376 R_{ice}), consistent with Cox et al. (2014), resulting in a mean 2σ percentage uncertainty 377 of < 40% for τ_{liq} and < 20% for R_{liq} (fig. 3). This corresponds to a minimum detectable 378 liquid water path of 2.0-3.0 g m $^{-2}$ (for R_{liq} 12 to 18 $\mu\mathrm{m})$ with a 2σ uncertainty of 0.9-379 1.5 g m⁻². For ice properties, $\tau_{ice} > 0.25$ corresponds to when the mean percentage un-380 certainties in τ_{ice} and R_{ice} are below ~60% (fig. 3). 381

We do not need to be concerned about a loss of sensitivity due to saturation in the 382 infrared, because none of the fog cases have a spectral signature approaching that of a 383 black body (fig. 2). Furthermore, because the maximum precipitable water vapor (PWV) 384 during the 12 fog events is only 0.78 cm (with a mean value of 0.35 cm across all events). 385 the ability of MIXCRA to determine fog phase is not impacted by excessive water va-386 por (> 1 cm PWV can lead to signal saturation in the 16 to 20 μ m region, Turner, 2005; 387 Cox et al., 2014). Figure 4 shows the percentage of retrievals during each case study that 388 meet the quality control criteria of RMSE < 1.2 RU and $\tau_{liq} > 0.25$ (for liquid phase re-389 trievals) or $\tau_{ice} > 0.25$ (for ice phase retrievals). Less than 8% of all retrievals are dis-390 carded due to poor RMSE, but the optical depth threshold severely limits the percent-391 age of valid retrievals in each fog case, and in case 7, the optical depth is too low for any 392 valid retrievals. 393

Figure 4. The percentage of all retrievals from each case study that meet the quality control criteria of RMSE < 1.2 and optical depth > 0.25 for liquid properties (blue) and ice properties (orange). The percentage of good retrievals used in the remainder of this study are shown by the dark blue and orange colours.

The MIXCRA algorithm does not account for uncertainties in the atmospheric state 394 (gas and temperature profiles) or for uncertainties related to the choice of single-scattering 395 properties (SSPs) for liquid droplets and ice crystals. As mentioned above, uncertain-396 ties related to the concentrations of atmospheric gases are minimised through the selec-397 tion of micro-windows used by MIXCRA. The atmospheric temperature profile has a mean 398 RMSE (compared to radiosonde profiles) of $\pm 1^{\circ}$ C in the lowest 1,000 m a.g.l during these 399 case studies (Guy et al., 2022), and the difference in the retrieved values of $[\tau_{lig}, R_{lig}]$ 400 τ_{ice}, R_{ice} if the temperature profile is uniformly increased or decreased by 1°C are small, 401 resulting in a mean difference in τ_{liq} of 0.2 and R_{liq} of 0.8 μ m based on sensitivity tests 402 with 38 retrievals. 403

3.1.1 Uncertainties related to the choice of SSPs

404

The choice of single-scattering properties (SSPs) to use in the retrievals is non-trivial. 405 There is emerging evidence that the SSPs of supercooled water droplets are tempera-406 ture dependent, and that the use of SSPs that assume a warmer temperature than re-407 ality can result in overestimations of ice fraction and underestimations of liquid droplet 408 effective radius (Rowe et al., 2013, 2022). Although the temperature profile during the 409 fog events is well characterised, the temperature during a single event can vary by up 410 to 13°C both temporally and vertically within the lowest 15 m a.g.l due to radiative cool-411 412 ing and changes in boundary layer mixing (fig. S1, supporting information). Furthermore, the SSPs of ice crystals depend on the ice crystal habit (e.g. Yang et al., 2005), 413 but there is very little information about ice crystal habit at Summit during fog events. 414 Isolated plates and bullets are often reported by observers, but whether any of these crys-415 tals are associated with fog events (as opposed to snow, blowing snow, or diamond dust) 416 is unclear. A multi-angled snowflake camera operational at Summit in 2019, which pho-417 tographed particles with a maximum dimension > 30 μ m (Garrett et al., 2012), did not 418 detect any identifiable ice crystals during the fog events. This suggests that any ice par-419 ticles that were present during the fog were unlikely to be bullets or columns, which are 420 typically > 30 μ m along their major axis (Walden et al., 2003). Schmitt et al. (2013) found 421 that ice fog particles in the interior of Alaska are generally droxtals or plates, although 422 these fogs are not necessarily comparable to Summit because they were heavily polluted. 423

To account for the additional uncertainty related to the choice of SSPs, we ran MIX-424 CRA in three configurations (P_w , P_c , and D_w ; Table 2). We choose from four databases 425 of liquid droplet SSPs corresponding to temperatures of 240, 253, 263, and 273 K (Rowe 426 et al., 2013, 2020). For P_w and D_w , we use the liquid SSPs that correspond to the warmest 427 temperature measured in the lowest 15 m a.g.l during each fog event, and for P_c we use 428 the liquid SSPs that correspond to the coldest temperature measured during the fog (fig. 429 S1). For the ice habit, we use SSPs associated with hexagonal plates (for P_w and P_c) 430 and droxtals (for D_w) (Yang et al., 2005). We choose these three configurations as a com-431 promise between reducing the computational time of running multiple configurations and 432 representing the uncertainty associated with the SSPs well. Results from individual test 433 cases indicated that changing the liquid SSPs between the warmest and coolest temper-434 atures had a larger impact on the results than changing the ice SSPs. 435

Table 2. The three configurations of single-scattering properties (SSPs) for ice and liquid particles used in the MIXCRA retrievals. Liquid SSPs at temperatures of either 240, 253, 263, or 273 K were used, corresponding to the warmest (or coldest, per table) measured temperature in the lowest 15 m a.g.l. during each fog event.

	Ice habit	Liquid SSP temperature
$\begin{array}{c} \mathbf{P}_w \\ \mathbf{P}_c \\ \mathbf{D}_w \end{array}$	Plates Plates Droxtals	warmest coldest warmest

For the rest of this study, the microphysical retrievals shown are the mean values of the three configurations in Table 2, and we account for the additional uncertainty introduced by the SSPs assumption using equation (2), where 2σ is the combined uncertainty of each retrieved parameter (i.e. τ_{liq} , R_{liq} , τ_{ice} , and R_{ice}), $2\sigma_a$ is the 2σ uncertainty output by the MIXCRA algorithm, ΔS_i is the maximum difference in the retrieved parameter resulting from varying the ice crystal SSPs, and ΔS_L is the maximum difference in the retrieved parameter resulting from varying the liquid SSPs. 443

444

472

$$2\sigma = \sqrt{2\sigma_a^2 + \Delta S_i^2 + \Delta S_L^2} \tag{2}$$

3.2 Validation against in-situ measurements

The ability of the MIXCRA algorithm to accurately determine simultaneous ice 445 and liquid optical depths of single-layer mixed-phase Arctic clouds is well established through 446 comparisons with depolarisation lidars (Turner et al., 2003; Turner & Eloranta, 2008), 447 but assessments of the accuracy of MIXCRA retrievals of cloud droplet effective radius 448 are limited to two comparisons with in-situ aircraft measurements of liquid-phase stra-449 tus clouds over the south-central US (Vogelmann et al., 2012) and off the west coast of 450 California (Turner, 2007). Vogelmann et al. (2012) found that MIXCRA captured the 451 primary mode of the cloud droplet distribution well; the mean and standard deviation 452 of the MIXCRA size distribution was 5.3 \pm 1.6 μ m compared to 4.9 \pm 0.7 μ m for the 453 aircraft probe. Turner (2007) found a mean bias of 0.1 μ m between the aircraft measure-454 ments and MIXCRA, with an interquartile spread of 1.9 μ m. In both cases, the aircraft 455 measurements represent just one level in the cloud whereas the MIXCRA retrievals are 456 representative of a column value (weighted by optical depth). To date, there have been 457 no assessments of the accuracy of MIXCRA in determining the microphysical proper-458 ties of fog. 459

Here, we assess the ability of MIXCRA to retrieve R_{liq} during fog at Summit by 460 comparing MIXCRA R_{lig} retrievals with droplet effective radius determined from FM100 461 single-particle light scattering spectrometers installed at 2 m and 10 m a.g.l during a su-462 percooled liquid fog event at Summit on 16 June 2013 (fig. 5). Note that the FM100 in-463 struments were installed on a tower approximately 480 m from the AERI instrument. 464 This case is described further in Cox et al. (2019) and is a near-idealised example of ra-465 diation fog formation at Summit, the development of which is particularly similar to case 466 4 in 2019. 467

The FM100 probes made size-resolved measurements of particles with radii (r) of 1-25 μ m based on individual particle scattering characteristics, under the assumption that the particles are liquid spheres. The effective radius (R) was calculated from the FM100 particle size distribution [n(r)] using equation (3).

$$R = \frac{\int_0^\infty \pi r^3 n(r) dr}{\int_0^\infty \pi r^2 n(r) dr}$$
(3)

To estimate the uncertainty in R determined from the FM100 measurements, we 473 recalculated the FM100 particle size distribution 100 times, each time randomly select-474 ing errors from uniform distributions of five possible sources of uncertainty: (1) probe 475 air speed (±5%), (2) wind speed (±0.5 m s⁻¹), (3) wind direction (±5°), (4) whether 476 or not overlapping bins were combined (as described in Cox et al., 2019) (binary), and 477 (5) the uncertainty in bin sizing (randomised shifts to neighbouring bins). For more de-478 tails on the uncertainties associated with the FM100 probe, see Cox et al. (2019) and 479 supplement. Bin sizing ambiguities were dominant over sampling errors for this case be-480 cause the latter were small due to the ambient wind direction and speed being optimally 481 aligned with the probe inlet geometry and the speed of the pumped air through the probe 482 (see also Spiegel et al., 2012). The 2σ uncertainty in R is then determined from the stan-483 dard deviation of R across all the perturbed calculations. 484

⁴⁸⁵ MIXCRA R_{liq} is not directly comparable to R determined from the FM100 probes, ⁴⁸⁶ because the downwelling radiance measured by the AERI is sensitive to the bulk infrared ⁴⁸⁷ signal from the entire population of particles in the scene view of the AERI instrument ⁴⁸⁸ (the height of which varies with accumulation but is typically around 3 m a.g.l), whereas ⁴⁸⁹ R determined from the FM100 is based on the forward scattering of light in the visible

Figure 5. Fog event on 16 June 2013. (a) Calculated effective radius (R) from FM100 measurements at 10 m a.g.l (red line) and 2 m a.g.l (white line) overlaid on the FM100 particle size distribution at 10 m a.g.l. (coloured shading). (b) Retrieved liquid optical depth (black line), raw ceilometer backscatter (grey shading), and ceilometer vertical visibility values (blue markers, and orange for 'obscured'). (c) Cross validation of fog droplet R_{liq} retrieved from the MIXCRA algorithm (black) and determined from in-situ measurements (FM100 probes at 2 m, cyan, and 10 m, red). Shading represents 2 σ uncertainties, and the light blue region shows where the retrieved optical depth was greater than 0.25.

range from individual particles passed across the detector at a set height above the sur-490 face (2 m or 10 m). Therefore, we would only expect these values to compare well if the 491 size distribution of the particle population at the height of the FM100 instrument was 492 representative of the vertical distribution of the particle population. Cox et al. (2019) 493 show that the fog droplet size distribution varies with height, with the 2 m probe gen-494 erally measuring larger particles than the 10 m probe, consistent with particles prefer-495 entially forming higher up before settling out. However, on 16 June 2013, after the ini-496 tial fog formation, the R at 2 m was consistently smaller than at 10 m (fig. 5), the par-497 ticle number concentration at 2 m was also consistently higher than at 10 m (Cox et al., 498 2019), possibly indicating partial evaporation of droplets and a reduction in settling ve-499 locity at 2 m. 500

Despite this caveat, the MIXCRA R_{liq} compares very well to the R calculated from 501 both FM100 probes when $\tau_{liq} > 0.25$ (fig. 5c) over a range of R from 12.5 to 20 μ m. The 502 RMSE between the MIXCRA R_{liq} and FM100 R is 2.0 μ m at both 2 m and 10 m, with 503 a Pearson's correlation coefficient of 0.57 and 0.69 respectively. However, the strength 504 of this correlation is not consistent over the fog lifetime. During the initial stage of the 505 fog (02:20 to 04:00) the MIXCRA R_{liq} was consistently smaller than R from both FM100 506 instruments (by an average of 1.5 μ m at 2 m and 2.7 μ m at 10m). Between 04:00 and 507 05:00 there was an initial reduction in R in the FM100 measurements (and a reduction 508 in particle number concentration, Cox et al., 2019) followed by a sharp increase in R at 509 04:15. This coincided with a sharp increase in optical depth (fig. 5b), erosion of the sur-510 face temperature inversion, and evidence of wind-shear driven mixing in sodar observa-511 tions (Cox et al., 2019). The increase in R was also apparent in the MIXCRA R_{lig} , but 512 started earlier (at 04:00), and the maximum R_{lig} between 04:30 and 05:00 (17 μ m) was 513 lower than the maximum R measured by the FM100 probes during this interval (21 μ m 514 at 2 m and 19 μ m at 10 m). This could be explained by an increase in altitude of the 515 main layer of droplet formation; when the optical depth increases and the surface-based 516 temperature inversion is eroded, new droplet formation would be initiated by radiative 517 cooling at the fog top (Haeffelin et al., 2013). If the droplet formation layer height in-518 creased to greater than 10 m a.g.l, these droplets would have then grown and settled, 519 resulting in larger particles at 10 m and even larger particles at 2 m (as observed between 520 04:30 and 05:15). After 05:15, the fog LWP decreased (Cox et al., 2019) suggesting no 521 further droplet growth, and the optical depth gradually decreased. Between 06:00 and 522 10:00, the boundary layer was well-mixed (Cox et al., 2019), R varied consistently at 2 523 m and 10 m, and the MIXCRA R_{liq} captured these variations well. Overall, the MIX-524 CRA R_{liq} is slightly better correlated with the measurements at 10 m, although this is 525 largely due to detection of large (> 20 μ m) particles detected at 2 m that are not reflected 526 in the MIXCRA retrieval. 527

In summary, this cross-validation demonstrates that the MIXCRA algorithm can accurately retrieve R_{liq} during fog events at Summit with the following caveats:

- Due to the threshold optical depth of 0.25, below which signal to noise ratio in the AERI measurements is insufficient to accurately retrieve fog microphysical properties, MIXCRA is not able to capture the initial growth period of the fog droplets (between 00:10 and 02:20 in fig. 5).
- 2. These results are based off a single case study and cover an effective radius range of 12.5 to 20 μ m. More observations of R at a variety of heights and over a larger range of fog conditions are necessary to fully characterise the ability of MIXCRA to accurately retrieve fog droplet effective radius.

539

4.1 Summary of microphysical retrievals during the 2019 fog cases

Figure 6 summarises the retrieved fog microphysical properties from the twelve case studies, and figures S2 and S3 in the supporting information show the temporal evolution of the microphysical properties during each case. Retrievals were calculated every five minutes during each fog event, so the number of valid retrievals indicated on fig. 6a is the number of five-minute intervals during which there was sufficient optical depth for the retrieval ($\tau_{liq} > 0.25$ for liquid, or $\tau_{ice} > 0.25$ for ice properties).

Figure 6. Relative probability distribution of fog microphysical properties retrieved during each individual case study listed in table 1 and for all cases (right hand side). The mean and interquartile range of each distribution is shown by the diamond shaped point and associated error bars when the number of valid retrievals is > 10, otherwise crosses show values from individual retrievals. (a) Liquid (τ_{liq} , green) and ice (τ_{ice} , purple) optical depth, (b) liquid (R_{liq} , green) and ice (R_{ice} , purple) particle effective radius, and (c) liquid water path (LWP). Only retrievals where the optical depth is sufficient are shown ($\tau_{ice} > 0.25$ for ice properties, or $\tau_{liq} > 0.25$ for liquid properties).

For the cases where there was sufficient ice optical depth for a retrieval, the mean R_{ice} was 24.0 μ m (fig. 6b) and the range was 18.5 to 31.4 μ m. This is in broad agreement with the mean effective radii of ice crystals measured in low-level Arctic clouds (~21-25 μ m, Lawson, Baker, Schmitt, & Jensen, 2001; Turner et al., 2003; McFarquhar et al.,

2007). The mean R_{liq} was 14.0 μ m and the mean during individual events varied from 550 10.0 to 15.1 μ m (fig. 6b). The overall mean R_{liq} is slightly larger than the mean R de-551 termined from the summertime FM100 measurements at 10 m in 2013/14 from Cox et 552 al. (2019), which was $11.4 \pm 3 \ \mu m$. However, it is important to note that the MIXCRA 553 retrievals are only valid when $\tau_{liq} > 0.25$, and hence they do not include the initial phase 554 of fog formation where there are a lot of very small droplets that can be detected by the 555 FM100 (for example, see fig. 5). The range in R_{liq} across all retrievals was 6.6 μ m (at 556 the beginning of case 3) to 34.8 μ m (just prior to fog dispersal in case 6). 557

Most of the fog cases have a mean LWP < 10 g m⁻² (fig. 6c), but for cases 2 and 558 4 the maximum LWP exceeds 30 g m⁻², which can result in an increase in downwelling longwave radiation of > 50 W m⁻² relative to clear sky conditions (Miller et al., 2015; 559 560 Cox et al., 2019). The minimum LWP retrieved by MIXCRA was 1.3 g m⁻² at the be-561 ginning of event 3, associated with the smallest retrieved droplet size (R_{liq} 6.6 μ m). In 562 cases 7, 8, and 10, the fog is so optically thin that the LWP is below the limit of detec-563 tion for most of the event despite a reduction in horizontal visibility at the surface (to 564 just 400 m in case 8) and observations of fog bows confirming the presence of liquid wa-565 ter on all three occasions. No optics were reported by onsite observers during the ice-566 phase fog (case 12), although the sun was below the horizon most of the time. 567

568

4.2 Aerosol particle measurements during fog events

The mean N_{250} across all fog events was 1.7 cm⁻³ (with the mean during individ-569 ual events ranging from 0.4 to 2.2 cm^{-3} , fig. 7a), and the mean N₂₀ across all fog events 570 was 187 cm^{-3} (ranging from 41.9 to 448 cm⁻³, fig. 7b), these values represent the in-571 terstitial aerosol particle number concentration during fog. The temporal evolution of 572 N_{20} and N_{250} during each event is shown in fig. S4 in the supporting information. The 573 mean N_{250} during fog events is slightly lower than the overall mean value (including clear 574 and foggy periods) from June to September 2019 (2.4 cm^{-3}), whereas the mean value 575 of N_{20} during fog is slightly higher than the seasonal mean (170 cm⁻³). However, the 576 mean N_{250} and N_{20} over the 2 hours prior to fog onset are 8.2 and 191 cm⁻³ respectively, 577 both of which are higher than the mean values over the entire period. In all but case 7, 578 N_{250} drops below 0.5 cm⁻³ during the fog event, suggesting that almost all particles in 579 the N_{250} size range are activated into (or scavenged by) fog particles. This is not the case 580 for N_{20} ; an order of magnitude decrease in N_{20} during fog is only apparent in case 10, 581 where N_{20} falls below 10 cm⁻³. 582

Figure 8 illustrates the temporal evolution of N_{250} and N_{20} during each fog event, 583 where fog onset is defined as when the downwelling radiance measured by the AERI in-584 creases above the clear sky threshold (see section 2.2), and the percentage change in N 585 is relative to the mean value during the two hours prior to fog onset. On average, both 586 N_{250} and N_{20} decrease during the first 300 minutes after fog onset, consistent with the 587 growth and activation of aerosol particles into fog particles that are too large for either 588 instrument to detect $(> 6 \ \mu m)$. Note that this does not necessarily mean that these par-589 ticles are removed from the atmosphere; they may sediment out or they may be released 590 back into the atmosphere after the fog evaporates, either in the same form or after pro-591 cessing within the fog particle. 592

For N_{250} there is a reduction in number concentration after fog onset in all events 593 (of $72 \pm 26\%$ after 300 minutes). For case 12, the magnitude of the percentage decrease 594 is small compared to the other events, which is related to the fact that the absolute val-595 ues of N_{250} during case 12 are exceptionally low, with an initial mean N_{250} in the two 596 hours prior to fog onset of only 0.2 cm^{-3} . The initial N₂₅₀ in the 2 hours prior to fog 597 onset is consistent in time for all cases apart from case 11, where it varies between 1.2 598 and 6.8 cm⁻³. In cases 8 and 10, a sharp reduction in N_{250} of 80% begins 30 minutes 599 prior to the radiative detection of fog onset, whereas in cases 3 and 7, there is a slight 600

Figure 7. Relative probability distribution of aerosol particle number concentrations [(a) N_{250} and (b) N_{20}] measured during each individual case study listed in table 1 (left) and for all cases (right). The mean and interquartile range of each distribution is shown by the diamond shaped point and associated error bars. Grey bars indicate missing data (< 80% complete during fog event).

Figure 8. Percent change in N_{250} (left) and N_{20} (right) during the first 300 minutes of each fog event (coloured lines, see legend inset), compared to the average value in the two hours prior to fog onset. Thick black line is the median across all events.

increase in N_{250} at fog onset followed by a reduction in N_{250} that starts 20-30 minutes later. The duration of case 7 is only 102 minutes in total, and 80 minutes into the event N_{250} begins to increase, returning to the concentration prior to fog formation 10 minutes after the fog is no longer detected, suggesting that on this occasion, 100% of the particles that were incorporated into the fog were re-released after the fog dissipated.

In contrast to N_{250} , the change in N_{20} is highly variable between different fog events 606 (fig. 8). In cases 2 and 11, there was more than a 100% increase in N_{20} during the event. 607 For case 2, this increase started two hours before the fog was detected, meaning that the 608 'initial' N_{20} concentration is not a good representation over average conditions prior to 609 the fog. In case 11 there was an initial decrease in N_{20} followed by a sharp increase 60 610 minutes into the fog event, during which N_{20} reached 1370 cm⁻³ (> 99th percentile of 611 N_{20} measured between June and September 2019), but 240 minutes later, after the fog 612 was no longer detected, N_{20} returned to values close to those prior to fog onset. This anoma-613 lous case is discussed further in section 5. In cases 8, 9, and 10, there was a reduction 614 in N_{20} that started 30-40 minutes prior to fog onset (of 20%, 30%, and 50% respectively). 615

Note that some of the variability in evolution of N_{20} during fog events could be re-616 lated to the size distribution of N_{20} particles; for example, if most of the N_{20} particles 617 are closer to 30 nm diameter (i.e. the first mode in the Ziemba et al., 2010 measurements, 618 fig. 1) these particles might be subject to different processes during a fog event than to 619 N_{20} particles closer to 150 nm (the second mode in the Ziemba et al., 2010 measurements, 620 fig. 1). Particles closer to 150 nm in size more readily act as CCN, whereas smaller par-621 ticles would require larger supersaturations before activation. Size resolved measurements 622 of particles < 250 nm diameter would be required to investigate these details further. 623

For five of the six cases where both N_{250} and N_{20} are available, the two measure-624 ments are positively correlated (fig. 9). The exception is case 11, during which N_{250} de-625 creases to $< 0.2 \text{ cm}^{-3}$, but there was an anomalous spike in N₂₀ in the middle of the fog 626 event (discussed further in section 5). In cases 4 and 8, N_{250} was almost completely de-627 pleted, but there is only a small reduction (< 35%) in N₂₀. This suggests that during 628 these two cases, the supersaturations were not high enough to activate many particles 629 with diameters < 250 nm. In cases 10 and 12, N₂₅₀ was almost completely depleted, and 630 N_{20} was also depleted by 73 and 41% respectively. During case 10, the reduction in N_{20} 631 occurred simultaneously with the reduction in N_{250} (fig. 9) even though the initial N_{250} 632 concentration was above average. The reduction in N_{20} and N_{250} started 30 minutes prior 633 to fog detection, and then both concentrations remained steady after fog onset, suggest-634 ing that supersaturations during this event were high enough to activate smaller parti-635 cles (or that the N_{20} concentration in this case was dominated by larger particles). In 636 case 12 the initial concentration of N_{250} was only 0.24 cm⁻³, and there was a gradual 637 decrease in N_{20} after fog onset. 638

5 Discussion: Observational evidence of fog-aerosol interactions

The results described in section 4 hint that there are a variety of different ways in 640 which fog interacts with the surface aerosol particle population across the twelve case 641 studies. Of the seven cases for which N_{250} measurements are available, only cases 4 and 642 11 develop a LWP > 10 g m⁻². The longwave radiative forcing for a LWP of 5 to 30 g 643 m^{-2} compared to that of an equivalent clear sky day is very sensitive to small changes 644 in LWP, and the difference between a LWP of 5 g m^{-2} and a LWP of 10 g m^{-2} can equate 645 to $> 20 \text{ W m}^{-2}$ difference in longwave radiation at the surface (Miller et al., 2015). For 646 this reason, understanding why some fogs develop a LWP > 10 g m⁻² while others do 647 not is important for understanding the radiative impact of fog over the GrIS. One of the 648 factors that can influence LWP in liquid and mixed-phase fogs is the properties of the 649 aerosol population. In this section, we use the observations presented in section 4 to dis-650 cuss the role of fog-aerosol interactions over central Greenland. Throughout this discus-651

Figure 9. The relationship between N_{20} and N_{250} during the fog events for which both measurements are available. Boxplots show the aggregated distribution of N_{250} and N_{20} during all events. Coloured circles on the boxplots indicate the initial N_{20} and N_{250} concentration averaged over the 2 hours prior to each event. Pearson's-r correlation coefficients (r) in the legend inset are for the correlation between $\log(N_{20})$ and $\log(N_{250})$, all r values are significant at the 99% confidence level.

sion we make the assumption that changes in the fog and aerosol population were oc-652 curring in-situ (i.e. not related to advective processes). We justify this assumption based 653 on the fact that (a) most of the fog events are likely to be radiation fogs due to the fact 654 that they form in the evening on days with clear skies, and (b) that the wind speeds (2) 655 to 14 m a.g.l) during all events are relatively low $(3.5 \pm 0.3 \text{ m s}^{-1})$. Despite the low wind 656 speeds, for some of the longer events (> 8 hours) the horizontal length scale can be ~ 100 657 km, and we acknowledge that advective process may have played a role in some of the 658 observed changes in fog and aerosol properties. 659

660

5.1 Aerosol particle controls on fog microphysics

The goal of this section is to identify whether there is observational evidence that low aerosol particle number concentrations is a critical control on fog liquid water path and lifetime. To do this, we focus on the cases of liquid and mixed-phase fog where N_{250} measurements are available (cases 3, 4, 7, 8, 10, and 11).

In radiation fog, liquid droplets form when the surface cools radiatively until the 665 air becomes saturated with respect to water, after which water condenses on CCN par-666 ticles, growing them into fog droplets (e.g. Gultepe et al., 2007). Whether or not ice is 667 present, liquid droplets will continue to grow as long as supersaturation with respect to 668 water is maintained (either by continued radiative cooling or moisture influx) until they 669 are large enough to settle out, and new droplet formation will continue as long as there 670 are CCN particles present that may be activated for the given degree of supersaturation. 671 In the initial stages of radiation fog development, when the atmosphere is stable and close 672 to saturation, the degree of supersaturation is determined by the cooling rate, and by 673 the properties of the aerosol particle population, which determine the number concen-674 tration of CCN for a given supersaturation. The air mass specific humidity also plays 675 a role in determining the amount of cooling required to reach a given supersaturation, 676

but this effect is small because the saturation mixing ratio does not change much at cold temperatures (< 0.1 g kg⁻¹ °C⁻¹ for temperatures <-8 °C). Based on this, and assuming an absence of advective processes and limited turbulent mixing, the initial formation of liquid droplets in a supercooled radiation fog development might either be 'aerosollimited' or 'cooling-rate limited' (similar to how a convective cloud might be 'aerosollimited' or 'updraft limited', i.e. Reutter et al., 2009).

In a 'cooling-rate limited' scenario, the initial supersaturation would increase slowly. 683 Using the observations available in this study, this situation would be characterised by 684 relatively low activated fractions of N_{250} at fog onset, because particles that can act as 685 CCN at low supersaturations will be a subsample of N_{250} (McFiggans et al., 2006), fol-686 lowed by a gradual droplet growth and continual activation while cooling continues, and 687 higher supersaturations allow the activation of further particles. In contrast, an 'aerosol-688 limited' fog would be characterised by high initial activation ratios of N_{250} and N_{20} at 689 fog onset, as all particles that can act as CCN are activated. With continued cooling, 690 and in the absence of new droplet formation due to a lack of CCN, the existing fog droplets 691 would grow to relatively large sizes, ultimately settling out and preventing an increase 692 in fog LWP despite continued cooling (as described by Mauritsen et al., 2011). The pres-693 ence of 'aerosol-limited' fogs would support the hypothesis that the low aerosol parti-694 cle number concentrations can be a critical control on fog liquid water path and lifetime. 695

To identify whether there are any cases of 'aerosol-limited' fogs, we calculate cool-696 ing rates during each fog event from temperature measurements at 2 m, 4 m, 9 m and 697 14 m a.g.l. The development of the near surface temperature profile during each fog event 698 is shown in the supporting information (fig. S1). The cooling rate is calculated from the 699 60-minute rolling mean of the mean temperature across these four heights. Of the six 700 cases for which N_{250} measurements are available and liquid water is detected, case 7 has 701 an extremely low cooling rate ($< 0.5 \text{ K h}^{-1}$, fig. 10a) and a low activated fraction of N₂₅₀ 702 at fog onset (fig. 8), suggesting that this event is more likely to be limited by the low 703 cooling rate than by the aerosol population.

For the remaining five cases, the maximum cooling rate ranges from 2.4 K $\rm h^{-1}$ (case 705 11) to 4.0 K h⁻¹ (case 10) and occurs 30 to 50 minutes after fog onset, except in case 706 3, where the maximum cooling rate occurs 140 minutes after fog onset (fig. 10a). These 707 cooling rates are within the range of those observed in mid-latitude radiation fogs (~ 1 708 to 4 K h⁻¹, e.g. Price, 2011; Haeffelin et al., 2013). In cases 3 and 4, N₂₅₀ decreases grad-709 ually as the surface layer continues to cool, which suggests that neither of these two cases 710 were in the 'aerosol-limited' regime, and that aerosol number concentrations were not 711 the main reason why case 4 developed into an optically thick fog with LWP > 10 g m⁻² 712 but case 3 did not. The near-surface specific humidity and temperature profiles in both 713 cases were similar (see table 1), and so the difference in fog development was likely due 714 to differences in dynamics: In case 3, 110 minutes into the event, a burst of turbulent 715 kinetic energy $(0.3 \text{ m}^2 \text{ s}^{-2}, \text{ not shown})$ at 14 m is followed by warmer temperatures prop-716 agating downwards towards the surface (fig. S1), this mixing of warm air downwards could 717 have limited the fog development. 718

In cases 8 and 10, there is a high activated fraction of N_{250} at fog onset (68 and 719 62% respectively) as well as a relatively high activated fraction of N₂₀ (15 and 45\% re-720 spectively). Case 10 had the highest activated fraction of N_{20} out of all fog cases. In both 721 cases, there is little further change in N_{250} or N_{20} after fog onset despite continued cool-722 ing (figs. 8 and 10). This suggests that the aerosol particle number concentration could 723 have limited fog development (lifetime and LWP) in these cases. Unfortunately, the low 724 725 fog optical depths limit the ability of the MIXCRA retrieval algorithm to provide information about fog phase and particle sizes for both cases. Finally, in case 11, there is greater 726 variability in N_{250} both prior to and after fog onset compared to the other cases, and 727 in this case the fog develops much more rapidly than in case 4, with LWP increasing to 728 $>10~{\rm g~m^{-2}}$ 80 minutes after fog onset (as opposed to 180 minutes in case 4). The warm-729

Figure 10. Time series of (a) cooling rate (2 to 14 m a.g.l), (b) percentage change in N₂₅₀, (c) liquid water path (LWP), and (d) Liquid droplet effective radius (R_{liq}) during the case studies for which N₂₅₀ measurements are available. Note that cases 7 and 12, identified as 'cooling-rate limited' fogs are only included on panel (a). The error bars on panels (c) and (d) show the 2σ uncertainties in the MIXCRA retrievals.

ing of the surface layer that coincides with the sharp increase in LWP is indicative of a
 transition from near-surface radiative cooling to radiative cooling at fog top maintain ing the fog. This case is discussed further in section 5.2.

 $_{733}$ 5.2 Increase in N₂₀ associated with fog

We focus on case 11 to look for evidence to support the hypothesis that fog can 734 act to increase surface aerosol particle number concentrations by enhancing mixing of 735 air from above into the near-surface stable layer. Case 11 was anomalous out of the 12 736 cases because of the exceptionally high N_{20} that occurred during the fog event (1370 cm⁻³, 737 > 99th percentile of all N₂₀ measurements made between June and September 2019), 738 and because it consisted of two distinct phases; the LWP increased from 2.4 g m^{-2} to 739 17.0 g m⁻² between 05:05 and 06:00, then decreased to 2.6 g m⁻² at 07:05 before increas-740 ing again to 15.9 g m⁻² at a 07:45. 741

The fog formed initially as the near surface temperature cooled after the dissipation of a mixed-phase cloud (with a base height of approximately 1.3 km) at 04:30. But only 80 minutes after fog onset, near surface air temperatures started to increase, and the fog optical depth and LWP started to increase rapidly (fig. 11). Because the surface temperature was no longer decreasing, the increase in fog optical depth and LWP after 05:15 must have been due to a transition from surface radiative cooling to cooling higher in the atmosphere (i.e., radiative cooling at fog top).

If the increase in near-surface air temperature was radiatively driven, we would expect the temperature increase to start closest to the surface first (for example, as in case 2 and 4, fig. S1). The fact that the near-surface air temperature increased simultaneously at each of the four heights (fig. 11d) suggests that another mechanism was responsible. This could have been the advection of a warmer air mass, but the consistent wind direction (90% of all winds measured at 2, 4, 9, and 14 m come from 156° to 222°) and

Figure 11. Atmospheric conditions during Case 11 (05 September 2019). (a) Fog optical depth (τ_{liq} , green, and τ_{ice} , purple) and droplet effective radius (R_{liq} , orange) from MIX-CRA, shading indicates 2σ uncertainties. (b) Surface aerosol particle number concentrations (1-min mean), N_{250} (red) and N_{20} (blue). (c) Backscatter (grey shading), vertical visibility (cyan points), and obscured flag (orange) from the ceilometer. (d) Near surface temperature profile (reds) and fog liquid water path (LWP, blue, shading indicates 2σ uncertainties). (e) Upwards sensible heat fluxes at 2 m (solid) and 14 m (dashed). (f) Sodar backscatter, red dashed line indicates the height of strongest negative backscatter gradient (when $\Delta \log(backscatter) < -0.8 \text{ m}^{-1}$).

low winds speeds (90 % of which range from 1.65 to 3.86 m s⁻¹) throughout the event 755 indicates that advection at the surface is unlikely to be an important process on the timescale 756 of this event. Alternatively, this near-surface heating could result from the mixing of warm 757 air down from above. The sensible heat fluxes at 2 m and 14 m are small (mostly < 2.5758 $W m^{-2}$, fig. 11e) suggesting that this mixing was not driven by changes in thermody-759 namic stability at the surface. However, there is evidence both in the ceilometer backscat-760 ter (fig. 11c) and the sodar acoustic backscatter (fig. 11f) of features propagating down-761 wards towards the surface. These could be remnants of mesoscale dynamical features, 762 such as buoyancy waves, mixing warmer air down from higher in the atmosphere, or en-763 trainment driven by radiative cooling at fog top. In either case, propagation of these fea-764 tures down to the surface coincide with the sudden increase in N_{20} , suggesting this is re-765 lated to the mixing of more polluted air down to the surface from above into what was 766 previously an isolated stable surface layer. 767

The top of the strong surface echo in the sodar backscatter, identified by the max-768 imum negative gradient (fig. 11f), is associated with the top of the stable near-surface 769 layer which is isolated from above by a strong surface-based temperature inversion (fig. 770 11d). The top of this layer decreases intermittently with height between 05:00 and 07:00, 771 and these variations are strongly anti-correlated with N_{20} (Pearson's r = -0.69, p-value 772 < 0.001). For example, the top of the strong sodar echo falls to 5 m a.g.l at 05:20, co-773 inciding with the initial sharp increase in N_{20} and an increase in surface temperature. 774 Between 05:35 and 05:55, the height of the sodar echo increases again to 8 m a.g.l and 775 N_{20} decreases, before increasing again once the sodar echo height lowers at 05:55. This 776 pattern continues until 06:50 after which the surface temperature inversion is completely 777 eroded at 9 m a.g.l and the near-surface echo in the sodar disappears. The erosion of the 778 isolated surface layer from above indicated by the sodar echo, and the anti-correlation 779 between the surface layer height and N_{20} , is consistent with the hypothesis that the in-780 crease in N_{20} is related to the mixing of air down from above. 781

During the most optically thick part of the fog there was also detectable ice that 782 increased between 05:50 and 06:10. The increase in ice optical depth coincident with a 783 decrease in liquid optical depth could be indicative of ice growing at the expense of liq-784 uid water droplets (i.e. via the Wegener-Bergeron-Findeisen process). This would result 785 in the evaporation of liquid droplets and the release of any aerosol particles they con-786 tain within the surface layer. In this situation, liquid droplets could form due to radia-787 tive cooling at fog top in a layer of the atmosphere where aerosol particle concentrations 788 might be higher than at the surface, these droplets could then settle and mix towards 789 the surface, eventually reaching a lower level that is sub-saturated with respect to wa-790 ter but supersaturated with respect to ice. The droplets would then evaporate, releas-791 ing aerosol particles into the surface layer. This process has been observed in Arctic mixed-792 phase stratocumulus clouds (Igel et al., 2017), and could also contribute to an increase 793 in N₂₀, but it is unlikely to be the sole process driving the ($\sim 1000 \text{ cm}^{-3}$) increase in 794 N_{20} because the typical number concentration of fog droplets at Summit is only ~10 to 795 50 cm^{-3} (Cox et al., 2019). 796

When the surface temperature inversion was completely eroded above 9 m a.g.l at 797 06:50, the fog dissipated, and the surface began to cool again (fig. 11d). At this time, 798 N_{250} had decreased to near-zero, suggesting that there were no further particles > 250 799 nm diameter available to act as CCN or INP. The cooling of the near-surface air would 800 have increased saturation near the surface, potentially initiating the second phase of the 801 fog. The increase in LWP during the second phase of the fog coincided with a sharp de-802 pletion of N_{20} and given that there were no particles > 250 nm left to activate, the de-803 crease in N_{20} during the second phase of the fog was likely associated with the activa-804 tion of N_{20} particles into fog droplets and the scavenging of particles by fog droplets close 805 to the surface. 806

This case illustrates some of the complexities of the relationship between dynam-807 ics, thermodynamics, and aerosol properties during mixed-phase fog events, and it is not 808 possible to say definitively what processes were involved from looking at the available 809 observations alone. The observational evidence supports the hypothesis that the sharp 810 increase in N_{20} associated with this fog event resulted from the mixing of higher N_{20} con-811 centrations down to the surface, which was either driven by the fog itself (i.e. radiative 812 cooling at fog top), or both the fog and changes in N_{20} were forced by the same exter-813 nal mixing event (e.g. buoyancy waves). 814

815 816

5.3 The impact of multiple fog events on the surface aerosol particle number concentration.

In this section we look for evidence that multiple consecutive fog events in quies-817 cent conditions can act to deplete the near surface aerosol particle number concentra-818 tion with the potential to impact fog development later in time. Fog with an observable 819 radiative impact at the surface formed on four out of the five evenings between 01 and 820 06 August 2019 (fog case numbers 6 to 9, table 1), with skies otherwise clear through-821 out the day; associated with a persistent (weakening) high-pressure system over central 822 Greenland (fig. S5, supporting information). Although this persistent anticyclone con-823 tributed to the unprecedented GrIS surface melt in 2019 (Tedesco & Fettweis, 2020), sim-824 ilar events are common over Greenland in the summer (occurring 30% of the time in JJA 825 1981-2010; Tedesco & Fettweis, 2020). During this event, the near-surface winds were 826 consistently from the south-east, with 90% of measured 1-minute averaged wind speeds 827 ranging from 1.26 to 4.81 m s^{-1} . There was a strong diurnal cycle, with radiative cool-828 ing in the near-surface layer beginning in the evening when the sun dropped below $\sim 25^{\circ}$ 829 and lasting until the sun rose above $\sim 15^{\circ}$ the following morning (fig. 12b). 830

Figure 12. Surface aerosol particle number concentrations (a) and cooling rate (b) during a five day clear sky period in August 2019. Radiation fog events are highlighted in light blue, and the solar elevation angle is shown by the black dashed line on panel (b). The green highlighted region at the end of the period indicates the start of a cloudy period.

The initial N_{250} averaged over the two hours prior to case 6 was 27.7 cm⁻³, and N₂₀ was 262 cm⁻³. Both concentrations are higher than the seasonal average, associated

Figure 13. (a) Near surface wind shear (14 m minus 4 m wind speed, 5-minute mean) during the first week of August 2019. (b) Turbulent kinetic energy (TKE) at 2 m a.s.l (blue) and 14 m a.s.l (orange) over the same period. Radiation fog events are highlighted in blue shading as in fig. 12.

with the descent of free tropospheric air down to the surface during the high-pressure 833 event (Guy et al., 2021). Both concentrations decrease gradually throughout the period, 834 with daily minima generally occurring during fog events (fig. 12a). The minimum N_{250} 835 was 0.11 cm⁻³ towards the end of case 8 (5 Aug 2019), and the minimum N_{20} was 56.5 836 $\rm cm^{-3}$, at the end of case 9. After the end of case 9, the fog lifted from the surface, form-837 ing a low-level stratus cloud (base ~ 200 m) that persisted through 7 August. Both N₂₀ 838 and N_{250} increased after the fog lifted, N_{20} to 177 cm⁻³, and N_{250} to 7.63 cm⁻³, but even 839 after this recovery, both concentrations were 30% lower than the initial concentrations 840 at the beginning of the quiescent cloud-free period. 841

Despite similar maximum near-surface cooling rates on the evenings with fog (2.7)842 to 3.7 K h⁻¹), only the first case (case 6) develops a LWP > 10 g m⁻² (fig. 6), and there 843 is some evidence presented in section 5.1 that the development of case 8 might be lim-844 ited by low aerosol particle concentration. One explanation for the gradual decrease in 845 surface aerosol particle concentrations throughout this period (01 to 06 August) is that 846 the scavenging of particles by fog droplets exceeds the rate of particle influx (presum-847 ably due to descent via sedimentation and/or turbulent entrainment from the free tro-848 posphere). Without measurements of vertical aerosol profiles and subsidence rates we 849 cannot determine the relative importance of fog scavenging in this process compared to 850 changes in particle influx (i.e. particle influx may also be decreasing with time as the 851 anticyclonic circulation over Greenland weakens, fig. S5). However, the fact that the mean 852 deposition flux of particles to the surface during fog events (on average 0.62 ng cm⁻² for 853 SO_4^{2-} , Bergin et al., 1994) is twice that of the mean dry deposition flux during the summer at Summit (0.29 ng cm⁻² for SO_4^{2-} , Bergin et al., 1994), supports the hypothesis 854 855 that multiple fog events during quiescent conditions act to deplete near surface aerosol 856 particle concentrations, which in this case may have contributed to the latter fog cases 857 approaching the aerosol-limited regime. 858

Another interesting question is why the nocturnal fog did not form on 03 August. Both near-surface temperature and aerosol concentration were highly variable early on

03 August, the maximum near-surface cooling rate reached 5.70 K h⁻¹ and both N_{20} and 861 N_{250} remained higher than the seasonal average (fig. 12), suggesting that fog formation 862 was neither 'cooling-rate limited' nor 'aerosol limited'. Photographs from the total sky 863 imager and observer reports of unlimited visibility confirm that the sky remained clear throughout the day. One difference between the early morning period on 03 Aug and the 865 other mornings when fog did form is in the near-surface wind profile (fig. 13a), during 866 the morning of 03 Aug there was a wind speed maximum close to the surface (the 4 m 867 wind speed was consistently $1-2 \text{ m s}^{-1}$ faster than the 14 m wind speed). The shear gen-868 erated by this near-surface wind-speed jet modified the turbulent properties of the sur-869 face layer, increasing mixing (indicated by the coincident increase in turbulent kinetic 870 energy, fig. 13b), which may have been sufficient to prevent the formation of fog droplets 871 and likely contributed to the high variability in the near-surface aerosol concentrations 872 and temperature profile. 873

⁸⁷⁴ 6 Summary and conclusions

The first goal of this study was to highlight the advantages and limitations of us-875 ing spectral ground-based measurements of downwelling longwave radiation (measured 876 by the AERI) to examine fog microphysical properties. Unlike active remote sensing in-877 struments, which have a blind range close to the instrument, the AERI is most sensi-878 tive to the near-surface atmosphere, making it particularly suitable for the study of shal-879 low fogs. Measurements of shallow fog with an AERI at Summit Station, in central Green-880 land, also benefit from the extreme dryness of the atmosphere and the improved abil-881 ity to characterize temperature and humidity near the surface. The 8-19 μ m spectral range 882 of the AERI is most sensitive to fog (or cloud) microphysical properties when the fog 883 visible optical depth is close to 1. This is particularly advantageous for the study of op-884 tically thin clouds in polar regions (particularly fogs), which can be responsible for the 885 maximum cloud radiative forcing at the surface during summer months (e.g. Miller et al., 2015). At Summit, optically thin fogs are common (the maximum mixed-phase op-887 tical depth retrieved from the 12 fog cases in this study is 4.8, and the mean is 0.8) so 888 the sensitivity of the AERI instrument (which can detect LWP as low as 3 g m⁻²) is par-889 ticularly suited for the study of these fogs. However, the loss of sensitivity to fog micro-890 physical properties at optical depths > 6 means that this technique is not appropriate 891 for studying the microphysical properties of optically thick fogs/clouds. 892

The MIXCRA algorithm is designed to retrieve the optical depth of liquid droplets, the optical depth of ice crystals, and the effective radius of the liquid and ice particles from the measured spectral radiance. Although MIXCRA retrievals of cloud properties have been validated against independent measurements in multiple previous studies, this is the first validation of the MIXCRA algorithm for fog events. A cross-validation of droplet effective radius retrieved using the MIXCRA algorithm with in-situ measurements from an FM100 forward scattering probe demonstrates that MIXCRA can capture variations in R_{liq} with a RMSE of 2.0 μ m when the fog optical depth is sufficient (0.25 < τ < 6.0).

The loss of sensitivity of the spectral infrared signature to changes in fog micro-901 physical properties as the fog optical depth approaches zero means that MIXCRA is un-902 able to retrieve fog microphysical properties during the initial growth phase of fog. This 903 also means that MIXCRA is unable to retrieve microphysical properties associated with 904 tenuous fogs (or higher clouds) that are potentially limited by low aerosol particle num-905 ber concentration. We would expect such events to be characterised by large droplet ef-906 fective radius and low optical depths, but for the two potential examples shown in this 907 study, the optical depths are too low for MIXCRA to determine the fog phase or par-908 ticle effective radius. 909

For the 12 fog cases studied, 92% of retrievals passed the initial quality control (radiances calculated using retrieved cloud properties matched measured radiances to within

an RMSE of 1.2 RU). Where there was sufficient optical depth for the retrieval ($\tau > 0.25$), 912 the mean total (liquid plus ice) optical depth across all fog events was 0.78 ± 0.71 (one 913 standard deviation). Nine of the twelve cases were mixed-phase fogs, one consisted of 914 only ice particles, one of only liquid droplets, and one case was too optically thin for any 915 valid retrievals. The mean ice particle effective radius was $24.0 \pm 7.8 \ \mu m$, and the mean 916 liquid droplet effective radius was $14.0 \pm 2.8 \ \mu\text{m}$. The sensitivity of the AERI allows for the detection of LWP as small as 2.0-3.0 g m⁻² (for R_{liq} 12 to 18 μ m) with a 2σ uncertainty of 0.9-1.5 g m⁻². The mean LWP across all fog events was 7.9 \pm 6.6 g m⁻², and 917 918 919 in two cases the maximum LWP exceeded 30 g m^{-2} . 920

The second objective of this study was to use the MIXCRA microphysical retrievals 921 alongside measurements of surface aerosol number concentration to look for observational 922 evidence of fog-aerosol interactions at Summit. In all cases apart from one, the concen-923 tration of aerosol particles > 250 nm (N₂₅₀) decreased to < 0.5 cm⁻³ during the fog event 924 (with a median decrease of 82% after 300 minutes), suggesting that almost all particles 925 in this size range are activated into (or scavenged by) fog droplets, consistent with past 926 studies (Bergin et al., 1994, 1995). Changes in the concentration of 20 to 230 nm diam-927 eter particles (N_{20}) were more variable; in some cases, N_{20} was found to be well corre-928 lated with N_{250} and decreased by up to 50% during fog, whereas in others, the two pop-929 ulations were decoupled, and on two occasions there was a > 100% increase in N₂₀ dur-930 ing fog. 931

In two case studies, there is observational evidence that the near-surface aerosol 932 particle number concentration might be a critical control on fog LWP and lifetime, but 933 in other cases there is evidence that dynamical processes (i.e. turbulent mixing, subsi-934 dence, or the near-surface wind profile) are more important. Large-eddy simulations based 935 on these detailed case studies are necessary to determine why some cases developed into 936 well-mixed optically thick fogs and others did not, which is important for the resulting 937 net radiative forcing of the fog at the ice sheet surface. In one case study there is evi-038 dence that fog can act to increase the near-surface aerosol particle number concentra-939 tion by enhancing mixing of air from above into the near-surface stable layer. During 940 a separate period of clear skies and low winds, when nocturnal radiation fog formed on 941 four out of five consecutive nights, a gradual reduction in N_{20} and N_{250} supports the hy-942 pothesis that multiple fog events in quiescent periods act to clean the near-surface layer 943 of aerosol particles. 944

The examples presented in this study demonstrate that there are multiple path-945 ways through which the surface aerosol population may (or may not) impact fog devel-946 opment, and through which fog itself can modify the surface aerosol population. Cor-947 relations between aerosol properties and fog (or cloud) microphysics should not be con-948 sidered in isolation, because there are other completing processes that can impact fog 949 development, such as the thermodynamic and turbulent structure of the boundary layer. 950 A larger dataset of fog cases studies is necessary to investigate the competing effects of 951 the scavenging of surface aerosol particles by fog versus increases in aerosol particles dur-952 ing fog events, and the importance of both processes for fog and cloud formation later 953 in time. 954

955 Open Research Section

AERI data and the thermodynamic profiles used to drive the MIXCRA algorithm are in the process of being submitted to the Arctic Data Center at https://doi.org/ 10.5439/1880028. The temperature dependent single scattering property databases are available online at https://people.nwra.com/rowe/refractive_indices.shtml. The FM100 data from Cox et al. (2019) are archived at https://doi.org/10.18739/A28K74W5W (Noone & Cox, 2019). Aerosol particle number concentration measurements, near surface temperature and wind profiles from the 15 m tower, and sensible heat flux measurements are available from CEDA data archive (Guy et al., 2020). ICECAPS ceilometer
data (https://doi.org/10.18739/A27659G3R) and sodar data (https://doi.org/10
.18739/A2HM52K68) are archived at the Arctic Data Center (Shupe, 2020a, 2020b). The
MIXCRA retrievals used in this study are in the process of being submitted to the Arctic Data Center and are available upon request.

968 Acknowledgments

The efforts of technicians at Summit Station and science support provided by Polar Field 969 Services were crucial to maintaining data quality and continuity at Summit. ICECAPS 970 is a long-term research program with many collaborators, and we are grateful for all their 971 efforts in developing and maintaining the various instruments and data products used 972 in this study. Thank you also to Professor Ken S. Carslaw for proof-reading and provid-973 ing valuable feedback on this publication. Financial support for ICECAPS was provided 974 by NSFGEO-NERC grants 1801477 and 2137083. HG was funded by the NERC SPHERES 975 DTP grant number NE/L002574/1. MDS was supported by the National Science Foun-976 dation (OPP-1801477, OPP-2137091) and the NOAA cooperative agreement (NA22OAR4320151). 977 PMR was supported by the National Science Foundation OPP Grant 2127632. Ceilome-978 ter data were provided by the Atmospheric Radiation Measurement (ARM) User Facil-979 ity, a U. S. Department of Energy (DOE) Office of Science User Facility managed by the 980 Biological and Environmental Research Program. This work used JASMIN, the UK col-981

982 laborative data analysis facility.

Introduction

This supporting information contains additional figures that expand on and support the figures and ideas presented in the main text, but that are not used to generate the main conclusions.

Corresponding author: H. Guy, (heather.guy@ncas.ac.uk)

February 16, 2023, 4:26pm

Figure S1. The temperature at four heights (2 m, 4 m, 9 m, and 14 m, see legend inset) measured by tower-mounted in-situ probes during each fog case. Plots include the two hours prior the event, the duration of each event (when there was a detectable radiative impact at the surface) is shaded in blue. Note the different y-scales on each plot.

Figure S2. Temporal evolution of optical depth retrievals for the liquid (τ_{liq} , green) and ice (τ_{ice} , purple) phase of each fog event. Error bars show 2σ uncertainties. Retrievals for which the optical depth is insufficient ($\tau < 0.25$) are included on the plot but are faded out.

Figure S3. Temporal evolution of fog particle effective radius retrievals for the liquid (R_{liq} , orange) and ice (R_{ice} , brown) phase of each fog event. Error bars show 2σ uncertainties. Retrievals for which the optical depth is insufficient ($\tau < 0.25$) are included on the plot but are faded out.

February 16, 2023, 4:26pm

Figure S4. Aerosol particle number concentration measurements (N_{20} , blue, and N_{250} , red) during each fog case. Plots include the two hours prior to and after each event, the duration of each fog event (when there was a detectable radiative impact at the surface) is shaded in blue. Note the different y-scales on each plot.

Figure S5. 500 hPa geopotential heights (shaded) and winds (barbed) from ERA5 reanalysis during the first week of August 2019. Plots show the mean value averaged over the 12 hours centered on the time labelled in the upper left. The location of Summit Station is indicated by a black triangle.
