#### Abstract

The multi-scale roughness of a fault interface is responsible for multiple asperities that establish a complex and discrete set of real contacts. Since asperities control the initiation and evolution of the fault slip, it is important to explore the intrinsic relationships between the collective behavior of local asperities and the frictional stability of the global fault. Here we propose a novel analog experimental approach, which allows us to capture the temporal evolution of the slip of each asperity on a faulting interface. We find that many destabilizing events at the local asperity scale occurred in the frictional strengthening stage which is conventionally considered as the stable regime of a fault. We compute the interseismic coupling to evaluate the slipping behaviors of asperities during the fault-strengthening stage. We evidence that the interseismic coupling can be affected by the elastic interactions between asperities through the embedding soft matrix. Scaling laws of natural slow slip events are reproduced by our setup in particular the moment-duration scaling. We also evidence an unexpected persistency of a disordering of the asperities through the seismic cycles despite the relaxation effects of the large slip events.

#### 12 Abstract

The multi-scale roughness of a fault interface is responsible for multiple asperities that 13 establish a complex and discrete set of real contacts. Since asperities control the initi-14 ation and evolution of the fault slip, it is important to explore the intrinsic relationships 15 between the collective behavior of local asperities and the frictional stability of the global 16 fault. Here we propose a novel analog experimental approach, which allows us to cap-17 ture the temporal evolution of the slip of each asperity on a faulting interface. We find 18 that many destabilizing events at the local asperity scale occurred in the frictional strength-19 ening stage which is conventionally considered as the stable regime of a fault. We com-20 pute the interseismic coupling to evaluate the slipping behaviors of asperities during the 21 fault-strengthening stage. We evidence that the interseismic coupling can be affected by 22 the elastic interactions between asperities through the embedding soft matrix. Scaling 23 laws of natural slow slip events are reproduced by our setup in particular the moment-24 duration scaling. We also evidence an unexpected persistency of a disordering of the as-25 perities through the seismic cycles despite the relaxation effects of the large slip events. 26

#### 27 Plain Language Summary

Earthquakes are the results of a slip along a rough fault on which a complex and 28 discrete set of asperities establish the interfacial contacts and control the frictional sta-29 bility of the fault. We propose a novel experimental setup capable of measuring directly 30 the subtle motion of individual asperities on an analog faulting interface. By capturing 31 the temporal evolution of the slip of each asperity, we link the mechanical behavior of 32 the global fault with the collective behavior of local asperities. Many destabilizing events 33 at the local asperity scale are found during the globally stable stage of the fault. We prove 34 that the interseismic coupling of asperities is affected by the normal load, the peak height 35 of asperities, and the interactions between asperities. The spatiotemporal interactions 36 of asperities are quantified as slip episodes to mimic the ruptures including both stable 37 and unstable slips. With the catalog of slip episodes, we reproduce the significant char-38 acteristics and scaling laws observed in natural faults, such as the magnitude-frequency 39 distribution and the moment-duration scaling. Such upscaling suggests that our results 40 can be extrapolated to natural faults and provide insights into fault physics and mechan-41 ics. 42

# 43 1 Introduction

Crustal fault interfaces display geological heterogeneities at various scales (Faulkner 44 et al., 2003; Chester et al., 1993; Ben-Zion & Sammis, 2003). In particular, exhumed fault 45 surfaces exhibit a complex topography characterized by height variations at all scales (Candela 46 et al., 2009, 2012; Power et al., 1987; Schmittbuhl et al., 1993, 1995; Scholz, 2019). Sup-47 posing that the roughness of these interfaces is similar to those of active faults at depth, 48 it implies that the frictional interface is formed by a complex set of junctions across the 49 two opposite surfaces in contact (Schmittbuhl et al., 2006; Pohrt & Popov, 2012). These 50 junctions are commonly known as asperities (Bhushan, 1998). They have been charac-51 terized at the laboratory scale as microcontacts (Dieterich & Kilgore, 1994) where the 52 resistance to an imposed shear stress is shown to be governed by the initiation and evo-53 lution of the fault slip (Scholz, 2019). 54

The presence of these asperities on the fault is supported by the observation of small 55 repeating earthquakes, supposedly representing cohesive zones that fail periodically un-56 der constant loading (Nadeau & Johnson, 1998). The role of such asperities in the be-57 havior of earthquakes has long been recognized. For example, it is suggested that small 58 and scattered asperities on a subduction interface may lead only to a minor release of 59 the seismic moment (Ruff & Kanamori, 1983). On the other hand, a great earthquake 60 may involve the simultaneous rupture of multiple asperities, such as the 1960  $M_W$  9.5 61 Chile earthquake (Moreno et al., 2009) or the 2004  $M_W$  9.2 Sumatra-Andaman earth-62 quake (Subarya et al., 2006). Such examples have been interpreted in a framework draw-63 ing a strong link between the rupture synchronization of asperities and the magnitude 64 of the impending earthquake (Lay & Kanamori, 1981; Lay et al., 1982). This synchro-65 nization of asperities actually emphasizes a strong time-and-space dependent mechanism 66 for the underlying physics and corresponding mechanical response of fault slip. The role 67 of asperities on the behavior of the faulting interface is not limited to dynamic rupture 68 events. Indeed, the interseismic phase is also strongly impacted by the presence of such 69 strong contact areas. This notably arises as locked patches can create stress shadows which 70 lead to reduced interseismic slip rates on the surroundings of the asperity (Bürgmann 71 et al., 2005) and thus a spatial modulation of the interseismic coupling (Perfettini et al., 72 2010). 73

-3-

Numerical models have addressed the behavior of a fault interface comprising mul-74 tiple asperities. A number of simulations represent the interface notably in the context 75 of the rate-and-state friction framework (Dieterich, 1979; Ruina, 1983; Marone, 1998) 76 and asperities are presented as distinct patches spatially distributed over the fault plane 77 with distinct frictional parameters (Barbot et al., 2012; Dublanchet et al., 2013; Luo & 78 Ampuero, 2018; Li & Rubin, 2017). In these numerical models, the asperities are usu-79 ally considered as velocity weakening patches and are therefore defined to be potentially 80 unstable. These models indicate that the mechanical response of a fault is evidently af-81 fected by the interactions of discrete asperities surrounded by aseismic creep areas. For 82 instance, a variable density of asperities (Dublanchet et al., 2013), which is the ratio be-83 tween the total area covered by asperities and the total area of the fault plane is pro-84 posed and utilized to explain at which condition the fault will be ruptured entirely or 85 locally. Incorporating roughness on the fault plane (as fluctuations of the normal stress), 86 Cattania and Segall (2021) show that this heterogeneity modulates the slip stability across 87 the fault. Finally, Romanet et al. (2018) demonstrate that the sliding diversity of a fault 88 can be obtained from geometrical complexities alone, without the need for the complex-89 ity of the friction law. All these numerical approaches, therefore, point to the importance 90 of these asperities and their interactions in controlling fault mechanics. However, these 91 models are severely limited by the computational cost of simulating heterogeneities with 92 a variable size over a large time and space domain and inherently only describe a lim-93 ited aspect of the ongoing physics. 94

At the laboratory scale, numerous experiments on rock samples have also shown 95 that fault roughness plays a crucial role in fault slip behavior (Goebel et al., 2017; Har-96 bord et al., 2017; Morad et al., 2022; Zhou et al., 2021) as it controls actual stress con-97 ditions at contacting asperities (Aubry et al., 2020). These results imply that the stress 98 heterogeneity at local asperities is significant for influencing fault slip behavior. How-99 ever, these experiments usually analyze the effects of asperities by comparing the initial 100 and final roughness of the fault interface as the nontransparent rock slabs cannot pro-101 vide the possibility to capture what is happening on the interface during the fault slip 102 process. On the contrary, some other experiments take advantage of the transparency 103 of analog materials (e.g., Poly-methyl-methacrylate, PMMA) to optically observe the as-104 perities distributed on the interface (Lengliné et al., 2012; Jestin et al., 2019; Selvadu-105 rai & Glaser, 2015, 2017), which provides a possibility for the direct monitoring of the 106

-4-

faulting interface. Although the contacts were captured during these experiments, it was
 not possible to track the slip at each point during shearing.

Here we present a novel experimental setup that aims at capturing the slip as a func-109 tion of time for each asperity on a sheared interface. Our experimental setup is much 110 simpler than a complex fault zone system, which has no mineralogy, no fluid, and no chem-111 ical transformation, but the fundamental process of interest, the relationship between 112 the collective behavior of local asperities and the stability regime of the global fault sys-113 tem, remains similar. Specifically, this novel experimental approach allows a thick trans-114 parent PMMA plate to slide slowly on a customized surface with height variations, on 115 which asperities are modeled by numerous identical spherical PMMA beads embedded 116 in a softer polymer base. Thanks to a high-resolution camera, our setup is capable of 117 measuring directly the subtle motion of local asperities on the interface during the whole 118 slipping process, which helps to understand the time-and-space dependent behavior of 119 each single asperity. The mechanical response of the global fault system is well recorded 120 and explained through the collective behavior of local asperities. The link between the 121 fault topography and the interseismic coupling is also investigated. In addition, the spatio-122 temporal interactions of asperities are quantified as collective slip episodes mimicking 123 fault ruptures including both stable and unstable slips. To give some geophysical impli-124 cations, the effective upscaling from the analog interface to natural faults is demonstrated 125 by reproducing significant characteristics and scaling-laws observed in natural fault sys-126 tems. 127

128

# 2 Experimental Setup

We build an analog model of a shear interface that aims at reproducing the typ-129 ical mechanical structure of a natural fault core. We consider that a fault zone consists 130 of several key elements. At the interface, the roughness of the fault topography creates 131 contacts on a number of discrete sites, i.e. asperities, that are here modeled as PMMA 132 beads. The core of the fault, which consists generally in a heavily fractured medium (Chester 133 & Chester, 1998; Schulz & Evans, 2000) is represented in our setup with a soft material 134 surrounding the PMMA beads. At a greater distance from the fault, the number of dam-135 age decreases (Ben-Zion & Sammis, 2003; Mitchell & Faulkner, 2009; Stierman, 1984), 136 and the fault becomes stiffer which translates in our setup in a rigid base attached to 137 the soft material (Figure 1). The asperities are in contact with a top rigid block and es-138

The rigid asperities embedded in the soft thick block establish a rough slip plane beneath the top rigid block.

tablish a rough slip plane, while the soft embedding block fixed within the bottom rigid
frame is easily deformed. This thick, rough, and deformable interface allows us to study
the interactions of asperities and their collective behavior with respect to the frictional
stability of the fault interface.

#### 143

## 2.1 Sample Preparation and Characterization

To prepare such a model of multi-asperity contact, numerous identical spherical 144 PMMA beads (a total number of 175) with a radius R of 3 mm are embedded in a soft 145 block. The soft block is composed of silicone (BLUESIL RTV 3428 A&B product from 146 the Elkem company), with dimensions  $10 \times 10 \times 3.0$  cm. The preparation of the sam-147 ple consists in first pouring a thin layer (of the thickness of a bead radius) of edible gelatin 148 mixed with water at the bottom of a mold. Then PMMA beads are dropped randomly 149 in this layer all over the interface. After the gelatin layer solidifies, we then pour the liq-150 uid silicon into the mold to cover the beads and wait for at least 24 hours at room tem-151 perature for its solidification. Finally, we take out the upside-down sample and remove 152 the mixture of gelatin and water. Following the procedures above, we customize an ex-153 perimental sample and its picture is displayed in Figure 2. The resulting sample is made 154 such that all beads have nearly the same height while being scattered randomly over the 155 sample. Physical characteristics of the silicone are derived from the technical datasheet, 156

-6-

the relation of Gent (1958) for converting durometer values to Young's modulus, and laboratory measurements of the P-wave velocity of the material. We obtain a P-wave velocity for this material of 1000 m/s, an S-wave velocity of 19 m/s, a Young's modulus of 1.1 MPa, and a density of 1100 kg/m<sup>3</sup>.

In order to precisely describe the so-formed interface and get the summit heights 161 of all the beads, we measure a high-resolution topographical map for the interface. The 162 data are acquired by a digital microscope profiler (RH-2000, HIROX) and a non-contact 163 Nano Point Scanner (NPS, HIROX). The system uses a white light confocal LED beam 164 with grids of 28  $\mu$ m and 100  $\mu$ m in the x- and y-directions, respectively. The topograph-165 ical map of the interface is shown in Figure 3a, where the blueish part indicates the em-166 bedding silicone block while the discrete circles represent the asperities with different heights. 167 We determine the peak heights of all the asperities (Figure 3b) and statistically analyze 168 their distribution (Figure 3c). The peak heights of asperities (relative to the average sil-169 icone upper face level) range from 1.31 mm to 3.15 mm, with most of them within the 170 peak height interval [1.4, 2.6]. The average peak height is 2.02 mm and the standard de-171 viation of the peak heights is 0.39 mm, which indicates a small variance in the peak heights 172 of asperities. We notice that there is a large-scale trend across the entire sample of this 173 peak bead height. This is most likely due to the non-perfect planarity of the gelatin layer. 174 Removing this large-scale trend, we observe that the height difference between neigh-175 boring asperities is low. In addition, we compute the average peak height difference be-176 tween two asperities as a function of the distance in x and y direction (Figure 3d). We 177 find a pattern highlighting the large scale variation of the peak height but no other cor-178 relation of the peak heights emerges. 179

180

#### 2.2 Mechanical Loading

To simulate a large-scale, far-field, loading imposed on a fault, the shear of the whole 181 analog interface system is induced by imposing a small displacement rate to the PMMA 182 plate under well-controlled normal loads (Figure 2). PMMA has been widely used, as 183 an analog material, to simulate numerous mechanical processes taking place within the 184 Earth. In particular, frictional processes taking place on natural faults have been inves-185 tigated using this material, such as fault creep and nucleation phases (e.g., McLaskey 186 & Glaser, 2011; McLaskey et al., 2012; Selvadurai & Glaser, 2015) but also ruptures (e.g., 187 Ben-David et al., 2010; Gvirtzman & Fineberg, 2021; Schmittbuhl & Måløy, 1997). Due 188

-7-

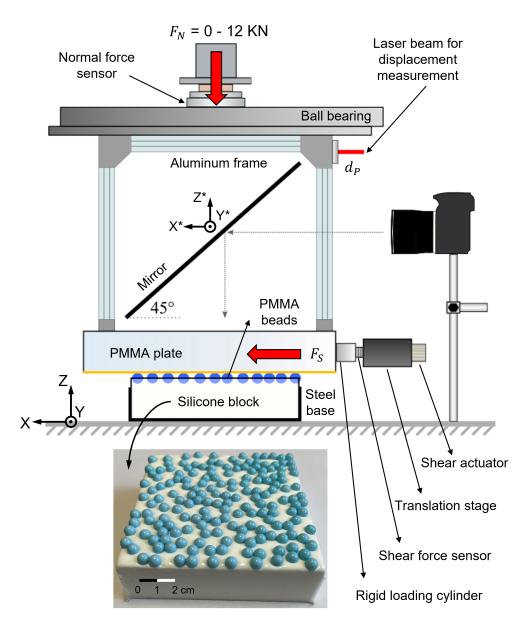

Figure 2. Schematic diagram of the technical experimental setup (side view). The normal force,  $F_N$ , and shear force,  $F_S$ , are measured by their corresponding sensors. A laser is employed to measure the displacement of the PMMA plate,  $d_P$ . A high-resolution camera is utilized with a mirror to monitor the positions of the PMMA beads during the whole shear process. Two axis systems, one attached to the ground and another one attached to the mirror, are represented. The yellow line indicates a rough slip plane established between the PMMA plate and the PMMA beads. The inset shows an image of the PMMA beads embedded in the soft silicone block.

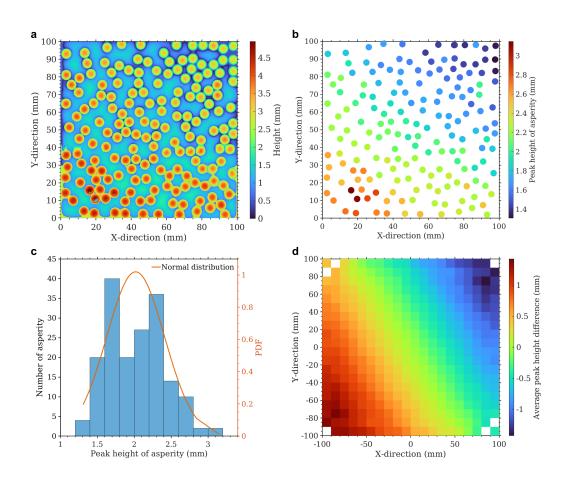

Figure 3. a: Topographical map of the analog fault interface. The blueish part is the embedding silicone block while the colored circles are the asperities created by the PMMA beads. There are a few non-measured points in the bottom-left corner that have little effect on characterizing the interface. b: Peak height of each asperity. The minimum and the maximum are 1.31 mm and 3.15 mm, respectively. c: Distribution of the peak heights of all the asperities. The asperities with peak heights ranging from 1.4 to 2.6 mm account for the majority. A standard deviation of 0.39 mm indicates a small variance in the peak heights. d: Average peak height difference as a function of the x and y direction. This highlights the large scale variation of the peak heights.

to its transparency, the PMMA enables a clear direct observation of the deforming medium
(Lengliné et al., 2012; Jestin et al., 2019). The shear modulus of the PMMA is estimated
as 2277.1 MPa (Selvadurai & Glaser, 2015).

The normal force  $F_N$  is applied by the vertical movement of the rigid load platen 192 driven by a high-precision micro stepper motor (LoadTrac II), and uniformly transferred 193 to the PMMA plate through the ball bearing and the rigid aluminum frame. A sensor 194 of resolution 0.01 N is utilized to record the normal force and maintain a constant nor-195 mal load throughout the whole duration of an experiment. We run the shear actuator, 196 a combination of servo and stepper motor, with a constant displacement rate  $V_S$  to drive 197 the translation stage and the rigid loading cylinder to impose the shear force  $F_S$  while 198 maintaining a normal force  $F_N$  on the PMMA plate. The loading cylinder is composed 199 of the aluminium alloy 2017A, with a stiffness of 78 N/ $\mu$ m. The shear force  $F_S$  is mea-200 sured using a sensor placed between the cylinder and the translation stage, with a res-201 olution of 0.01 N. The stiffness of this sensor is  $1 \text{ N}/\mu\text{m}$ , thus most of the loading stage 202 deformation is actually taking place within the force sensor. We employ a laser (Keyence 203 IL-S025), range 10 mm and resolution 0.1  $\mu$ m, to measure the displacement of the PMMA 204 plate,  $d_P$  (Figure 2). For all the experiments, we keep the initial value of  $d_P$  the same 205 to ensure each fault slip starts from the same position. 206

Prior to performing the experiments, we fix the PMMA plate to the aluminum frame 207 and attach the silicone block to the rigid steel base and clamp it. We use a digital level 208 to make sure that the whole experimental system, especially the slip plane, is flat hor-209 izontal. Each experiment begins at the moment when the shear force starts to increase 210 on the PMMA plate, given the analog fault has been previously loaded by a stable nor-211 mal load. The duration of each experiment is set to 600 s. We performed 28 experiments 212 by applying various normal loads ranging from 10 N to 1000 N and displacement rates 213 ranging from 5.0  $\mu$ m/s to 15.0  $\mu$ m/s (Table S1). We define the x-direction as the slid-214 ing direction of the PMMA plate while the direction y is set perpendicular to the x-direction. 215

To demonstrate the transition from steady slip to stick-slip in our analog fault system, the evolution of the shear force,  $F_S$ , under multiple normal loads,  $F_N$ , maintaining the same loading rate  $V_S$  of 5.0  $\mu$ m/s is presented in Figure 4. We clearly observe the steady sliding of the interface when the normal load is quite small (e.g.,  $F_N = 10$  N). On the other hand, multiple stick-slips are observed when the normal load becomes greater

-10-

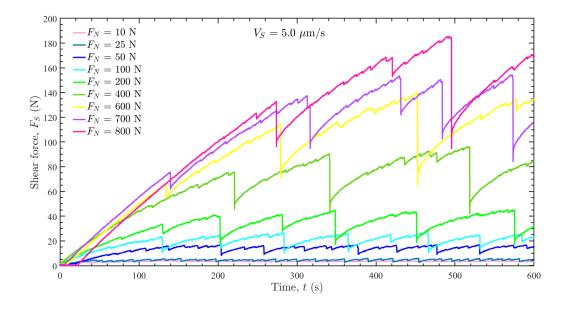

Figure 4. Temporal evolution of the shear force under multiple normal loads. The interface slips steadily when the normal load is quite small while evident stick-slips occur when the normal load becomes greater than 50 N. With the increase of the normal load, the shear force drop also increases.

than 50 N (Figure 4). In addition, the shear force drop of each stick-slip increases with the increase of the normal load.

223

#### 2.3 Optical Monitoring

To capture the positions of asperities and compute their slips during the experi-224 ments, we use a high-resolution camera (Nikon D800) with a lens (Nikon 105 mm f/2.8 D225 AF Micro-Nikkor) in automatic focus mode to record videos. A mirror fixed inside the 226 aluminum frame, which is inclined at 45 degrees, reflects the interface and moves with 227 the sliding of the PMMA plate during the experiments (Figure 2). The main settings 228 of the optical system are as follows: aperture size f/14, exposure time 1/30 s, and pho-229 tosensitivity (ISO) 100. Two LED lights are placed behind the camera to supplement 230 sufficient light for the clear observation of the interface. We record videos of dimensions 231 in  $1920 \times 1080$  pixels with a sampling rate of 29.97 frames per second. In addition, to 232 synchronize the force measurement and the optical monitoring, we send an electrical syn-233 chronization signal and correct the time base of each record. 234

For each experiment, we extract all pictures taken by the camera between the times  $t_0$  and  $t_f$  which are respectively the times at the beginning and the end of an experiment. From this set of pictures, we extract the slip of each individual asperity as a function of time. Denoting  $x_i(t)$  and  $y_i(t)$  the positions of the center of asperity *i* in a fixed reference frame (attached to the ground) we can define the displacement,  $d_i(t)$ , of an asperity along the loading direction in this fixed frame,

 $d_i(t) = x_i(t) - x_i(t_0).$ 

241

245

248

Similarly, we define  $x_P(t)$  as the position of the center of the mirror in the same fixed frame and then its displacement (which corresponds to the displacement of the PMMA plate as well), is computed as:

$$d_P(t) = x_P(t) - x_P(t_0).$$
 (2)

(1)

The cumulative slip of asperity i at time t is defined as the difference of the displacement between the two sides of the interface (i.e., the asperity and the PMMA plate):

$$u_i(t) = d_i(t) - d_P(t).$$
 (3)

As the camera and the silicone block are both fixed to the ground while the mirror moves 249 with the sliding PMMA plate, the position of each asperity, i, on pictures taken by the 250 camera is relative to the moving frame of the mirror and is noted  $(x_i^*(t), y_i^*(t))$ . It fol-251 lows that the displacement of an asperity in this moving frame is simply  $d_i^*(t) = x_i^*(t) - x_i^*(t)$ 252  $x_i^*(t_0)$ . From the definition of the cumulative slip introduced before, this displacement, 253  $d_i^*(t)$ , corresponds exactly to the cumulative slip,  $u_i(t)$  of asperity i. Consequently, the 254 cumulative slip of each asperity is obtained by tracking the evolution of its position,  $x_i^*(t)$ , 255 between time  $t_0$  and time  $t_f$ . 256

We developed a two steps procedure for tracking the evolution of the position  $x_i^*(t)$ of each asperity *i* in the moving frame of the mirror. In the first step, we applied the circular Hough transform algorithm implemented within MATLAB for automatically detecting circular objects (Yuen et al., 1990; Davies, 2005). From the first and last pictures at times  $t_0$  and  $t_f$  respectively, we extract the initial position  $x_i^*(t_0)$  and final position  $x_i^*(t_f)$  of asperity *i*. We also estimate the initial position of the beads,  $y_i^*(t_0)$  in the direction perpendicular to the slip direction.

The initial positions of asperities detected at time  $t_0$  are shown in Figure 5. The asperities marked by red circles, with a total number of N = 144, are retained in our

analysis while the asperities with blue markers are excluded from the subsequent image 266 analysis because they are located too close to one of the image edges. We note the value 267 of N may change with different experiments mainly due to the field view of the camera, 268 but it fluctuates around 140. In addition, we obtain the radius R, which is 36 pixels, and 269 compute the scaling of the image from the known radius of the PMMA beads (R = 3270 mm), 12 pixels/mm. Based on the initial and final positions of asperities, we are able 271 to estimate the total slip  $u_i^*(t_f) = x_i^*(t_f) - x_i^*(t_0)$  of each asperity. Due to the con-272 stant loading rate, a simple linear trend between these two positions gives an approx-273 imate position,  $x_i^*(t)$  of asperity i at each time step. This provides a first order estimate 274 of each asperity location during the experiment. In the second step, in order to obtain 275 the most accurate locations, we applied an image correlation technique (Sutton et al., 276 2009) to refine these first measurements. 277

To quantify the slip of each asperity, a square window for image correlation with 278 a size of  $\sqrt{2R}$  is defined at the center of each asperity based on our previous estimates 279 of  $x_i^*(t)$  and  $y_i^*(t_0)$ . We extract the image defined by the square correlation window of 280 each asperity at all frames. For each asperity, we compute the FFT (fast Fourier transform)-281 based two-dimensional cross-correlation between the extracted window defined at time 282  $t_k$  and the window defined at time  $t_{k-1}$ . From the correlation map, we isolate the po-283 sition of the maximum value which gives the displacement of the bead. We then shift 284 the correlation window of the second frame based on this displacement and repeat the 285 procedure until the computed displacement is null. At this last stage, we then extract 286 a sub-sample displacement by interpolating the correlation map around its maximum. 287 The final displacement of the bead between the two time frames is then obtained by sum-288 ming all displacements computed during this iterative process. Repeating this procedure 289 for all time frames and for each bead we are able to obtain the cumulative slip of each 290 asperity during the whole duration of an experiment. The typical resolution of the re-291 solved displacement in each direction is of the order of 0.01 mm. 292

Due to the geometry of our experimental setup, the non-parallelism which may result from the non-perfect 45 degree inclination of the mirror and/or the non-parallel view between the camera lens and the slip plane (Figure 2), can create a non-linear scaling along the x axis. In order to eliminate this effect, we correct the cumulative slip of asperity *i* based on its total slip  $u_i(t_f)$ , which is supposed to be no greater than the displacement  $d_P(t_f)$  of the PMMA plate at time  $t_f$ . Given the corrected cumulative slip

-13-

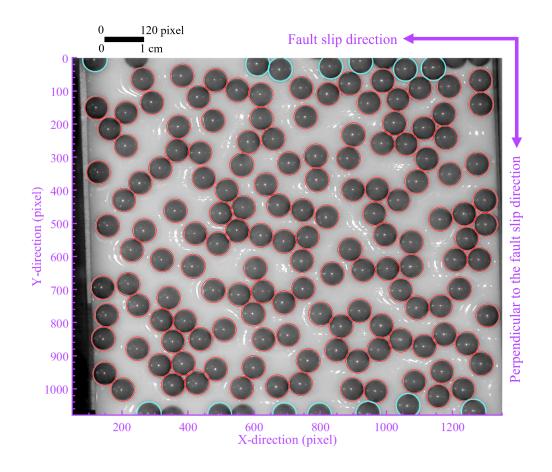

Figure 5. Typical automatic detection results indicating the initial positions of asperities at time  $t_0$ , on the interface within a region of interest of dimensions  $1300 \times 1080$  pixels (i.e.,  $108.33 \times 90$  mm). The asperities without markers represent the undetected ones while the asperities with blue circles correspond to the excluded ones as their correlation windows exceed the image boundary. A total of N = 144 asperities marked by red circles are kept and their positions  $x_i^*(t_0)$  are taken as the initial positions for computing the slip through the image correlation.

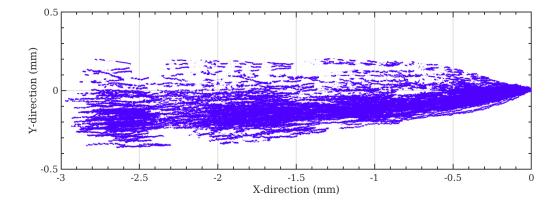

Figure 6. Trajectories of all the asperities during the whole duration of an experiment under a normal load of 400 N and a loading rate of 5  $\mu$ m/s. The onset of each trajectory is superimposed to be at the origin (0,0). The prominent gaps correspond to the large stick-slip events.

 $u_i(t)$  of asperities, we then update the displacement  $d_i(t)$  of asperities following the equation (3).

Finally, we also note that the asperities also exhibit slips perpendicular to the load-301 ing direction. These cumulative slips are near-evenly distributed around zero and the 302 maximum cumulative slip is quite small compared to the cumulative slip along the fault-303 ing direction. We present the trajectories of all the asperities during the whole exper-304 imental duration in Figure 6, where the onset of the trajectory of each asperity is set to 305 be at the origin (0,0). The total slip during this experiment is of the order of the asper-306 ity size, R = 3 mm, and the slip in the x direction is about 10 times larger than that 307 in the y direction. There is a fan shape of the trajectories with a mean y-direction that 308 is close to zero. We observe several prominent gaps that correspond to the large stick-309 slip events during the faulting. For the other experiments under different loading char-310 acteristics, the total slip of asperities in the x direction is dependent on the loading rate 311 and the experimental duration while that in the y direction is generally of the same or-312 der of  $\sim 0.3$  mm. 313

314

# 3 Collective Behavior of Asperities

315

#### 3.1 Temporal Evolution of the Cumulative Slips of Asperities

To understand the individual behaviors of asperities as well as the relationship be-316 tween each local asperity and the whole interface, we present the temporal evolution of 317 the cumulative slips of individual asperities. For a better visibility, only 20 asperities, 318 randomly selected out of 144 asperities, are presented in Figure 7. The cumulative slips 319 of the 20 asperities are color-coded by their initial positions  $y_i(t_0)$ . We also indicate in 320 Figure 7 the loading rate of the interface which is 15.0  $\mu$ m/s here. Any asperity follow-321 ing this trend could be considered then as fully sliding. On the contrary, a fully stick-322 ing asperity would accumulate no relative slip with respect to the loading plate. Its be-323 havior would appear as a horizontal line in Figure 7. 324

The stepping feature of cumulative slip evolution of the asperities in Figure 7 il-325 lustrates the repetitive stick-slip events of the interface (20 events in Figure 7a and a zoom 326 on one of them in Figure 7b). These events involve all the asperities of the interface. In 327 the time interval between these whole stick-slip episodes, during the sticking phase, the 328 asperities show distinct behaviors. We observe that all the slipping rates are smaller than 329 that of imposed loading rate (see the slopes of the cumulative slip of the asperities and 330 the PMMA plate) but with a non-horizontal trend, which indicates that, actually, the 331 asperities are slipping at a low rate during the sticking phase, instead of being fully locked. 332

It is noteworthy that the slips accumulated during each sticking period are not the 333 same for different asperities. This proves that different asperities can slip at different rates, 334 though they are all in the quasi-static regime (i.e. the sticking phase of the interface stick-335 slip behavior). Another interesting finding is that there are also some small visible slips 336 that occurred at different single asperities during the overall sticking phase and corre-337 spond to small stick-slip events at the scale of several asperities. These small episodes 338 contrast with global slip episodes, when all the local asperities slip rapidly in a synchronous 339 way and that we define as a large stick-slip event (LSE). Moreover, the observation that 340 the slips on all asperities after a LSE do not reach the imposed loading slip, indicates 341 that accumulated stress is only partly released during such a whole scale event. 342

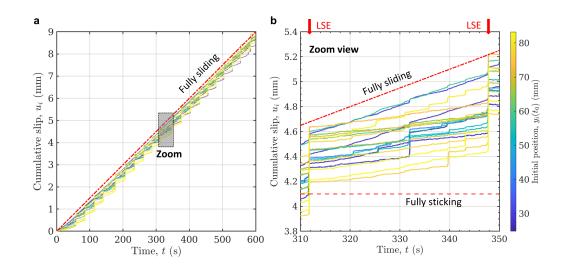

Figure 7. a: Temporal evolution of the cumulative slip in the x direction for 20 asperities during an experiment under a normal load of 200 N and a loading rate of 15.0  $\mu$ m/s. The cumulative slips of the 20 asperities are colored-coded by their initial y positions at time  $t_0$ . b: Zoom view of Figure 7a showing the detailed behaviors of asperities during one time interval between two large stick-slip events (LSE) and ranging from 310 s to 350 s. Fully sticking indicates a locked state while fully sliding gives the slope of the imposed displacement rate to the system.

#### 343

# 3.2 Slip Velocity of Asperities

344 345

346

347

Slip velocity reflects the slipping rate of asperities, which is estimated using a given discretization of the time (i.e., time step) during the whole experiment. The slip velocity  $v_i(t_k)$  of each asperity *i* is computed as

$$v_i(t_k) = \frac{s_i(t_k)}{\Delta t} = \frac{u_i(t_k) - u_i(t_{k-1})}{\Delta t},$$
(4)

where  $s_i(t_k)$  is the slip of the asperity *i* at time  $t_k$  and  $\Delta t$  is the fixed time step of 1/29.97 348 s determined by the sampling rate of the camera, i.e.,  $t_k - t_{k-1}$ . Following the same ex-349 perimental data used in Figure 7, for illustration, the slip velocity of all the 144 asper-350 ities ranging from time 330 s to time 350 s is shown in Figure 8, where the asperities are 351 sorted in ascending order by their initial positions  $x_i(t_0)$ . A LSE involving the synchronous 352 slipping of all the asperities is observed at the time 348 s. We also observe several small 353 stick-slip events that share the same characteristic, which is the synchronized sliding of 354 only a part of the asperities. 355

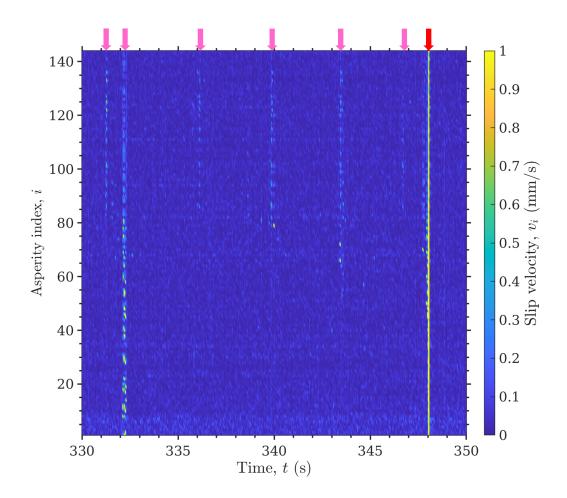

Figure 8. Slip velocity of all the asperities during the time period ranging from 330 s to 350 s of the same experiment shown in Figure 7. The asperities are sorted in ascending order by their initial x positions at time  $t_0$ ,  $x_i(t_0)$ . A large stick-slip event (LSE) indicated by the red arrow occurred at time 348 s observed, where all the asperities are synchronously slipping. During the sticking phase, there are also several small stick-slip events (SEs) which are indicated by the pink arrows involving the slipping of a part of asperities.

#### 3.3 Mechanical Response of the Interface

356

360

In order to document the mechanical response of the frictional interface, we analyze how the friction coefficient,  $\mu = F_S/F_N$ , evolves as a function of slip. We compute the spatial average of the cumulative slip,  $\langle u(t) \rangle$ , over all asperities, N, following

$$\langle u(t) \rangle = \frac{1}{N} \sum_{i=1}^{N} u_i(t), \tag{5}$$

which is a global indicator of the collective behavior of all the asperities. As multiple seis-361 mic cycles (i.e., large stick-slip events) are produced during a single experiment, we re-362 port in Figure 9a the evolution of  $\mu$  as a function of  $\langle u(t) \rangle$ , for all the cycles of a single 363 experiment. Each cycle is separated based on the onset of a large scale slip event LSE 364 (observed when  $\mu$  reaches a local maximum before an abrupt decrease). The value of the 365 friction coefficient mainly ranges between 0.10 and 0.23, which is a low friction coeffi-366 cient but comparable to the values in other PMMA-PMMA interfaces (Baumberger & 367 Caroli, 2006; Selvadurai & Glaser, 2015). We observe, in each cycle, an overall frictional 368 strengthening stage during the sticking phase and a weakening stage during the slipping 369 phase. 370

To focus on the sticking phase of the whole faulting process, the variations of fric-371 tion coefficient,  $\Delta \mu$ , and of the average cumulative slip,  $\Delta \langle u(t) \rangle$ , are both computed rel-372 ative to their respective values at the onset of these large scale slips. We plot the fric-373 tion coefficient variation,  $\Delta \mu$ , as a function of the variation of the average cumulative 374 slip of all the asperities,  $\Delta \langle u(t) \rangle$ , by superimposing all the sticking phases and the slip-375 ping phases, where each onset of the slipping phase is set to be  $\Delta \mu = 0$  and  $\Delta \langle u(t) \rangle =$ 376 0 (Figure 9b). The curves represent the sticking phase while the circles represent only 377 a few time steps after the onset of the LSE. We observe a good similarity between all 378 seismic cycles, proving the repeatability of our observations. We observe that the fric-379 tion coefficient during the period preceding the large scale event (LSE) is increasing. This 380 strengthening of the interface is occurring while the interface is slipping. We observe that 381 during this overall increase of the friction coefficient, there exist multiple instances where 382  $\mu$  actually drops significantly compared to the error of the friction coefficient measure-383 ment. The strengthening of the interface (an overall increase of  $\mu$ ) is thus not a homo-384 geneous process and is slip-controlled in a non-linear manner. This shows as well that 385 this strengthening stage, conventionally considered as the stable regime of a fault, ac-386 tually consists of many small-scale destabilizing events. The rapid slip that occurs dur-387

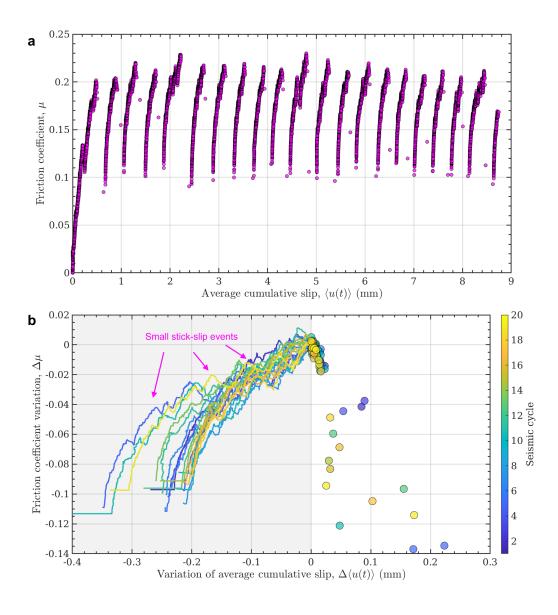

Figure 9. a: Evolution of the friction coefficient,  $\mu$ , as a function of the average cumulative slip,  $\langle u(t) \rangle$ , during the same experiment shown in Figure 7 with multiple seismic cycles. b: Friction coefficient variation,  $\Delta \mu$ , as a function of the variation of the average cumulative slip of all the asperities,  $\Delta \langle u(t) \rangle$ , for the same experiment shown in Figure 9a. All the seismic cycles represented by different colors are superimposed together by setting the onset of each slipping phase as the origin. The colored curves in the shadow indicate different sticking phases while the circles denote the corresponding slipping phases.

ing a LSE is not well captured by our experiments mainly because of the limited time
resolution of the camera that does not allow a sufficient time sampling during this stage.
It is also possible that the weakening part is velocity dependent which is not well captured here since Figure 9b represents the friction coefficient as a function of slip with no
information on the velocity.

393

403

# 3.4 Topographical Effect on Interseismic Slipping Behaviors

Our results show that many small stick-slip events accompanied by friction coef-394 ficient drops are found during every fault strengthening stage (Figure 9). These inter-395 seismic, small stick-slip events result from the slip of a limited number of asperities on 396 the interface. In order to identify what controls the number and the amount of these par-397 tial slips, we document the interseismic slipping behaviors of the asperity using the in-398 terseismic coupling coefficient (Hyndman et al., 1997). We denote the onset times of the 399 j and the j+1 large stick-slip events as t(LSE(j)) and t(LSE(j+1)), respectively. To 400 describe the extent of the slipping of the asperity i during the interseismic phase between 401 t(LSE(j)) and t(LSE(j+1)), the interseismic coupling,  $\lambda_{i,j+1}$ , is computed as 402

$$\lambda_{i,j+1} = 1 - \frac{u_i(t(\text{LSE}(j+1))) - u_i(t(\text{LSE}(j)))}{d_P(t(\text{LSE}(j+1))) - d_P(t(\text{LSE}(j)))}.$$
(6)

We note that  $\lambda$  is in the range [0, 1], where  $\lambda = 0$  indicates no coupling or fully sliding while  $\lambda = 1$  denotes a fully coupled interface or sticking. For experiments with multiple seismic cycles, we compute the final interseismic coupling for each asperity *i* by averaging  $\lambda_i$  over all of the interseismic phases.

With the experimental data used in Figure 9, we present the interseismic coupling 408 of these asperities along the interface (Figure 10). We observe a large scale trend of this 409 interseismic coupling that we can link with the same trend observed from the peak height 410 of asperity derived from the topographical map (Figure 3b). A higher peak height of as-411 perity corresponds to a higher interseismic coupling while a smaller peak height is cor-412 responding to a lower interseismic coupling. This can be interpreted in terms of normal 413 stress on the asperity where a higher peak height causes a greater normal stress, and there-414 fore creates the locking of the asperity which increases the interseismic coupling. On the 415 contrary, the asperities with smaller peak heights have a low normal stress and thus can-416 not accumulate large shear stress (and consequently large slip deficit) and will fail more 417 often during the interseismic phase and have a low coupling, i.e., low values of  $\lambda$ . 418

-21-

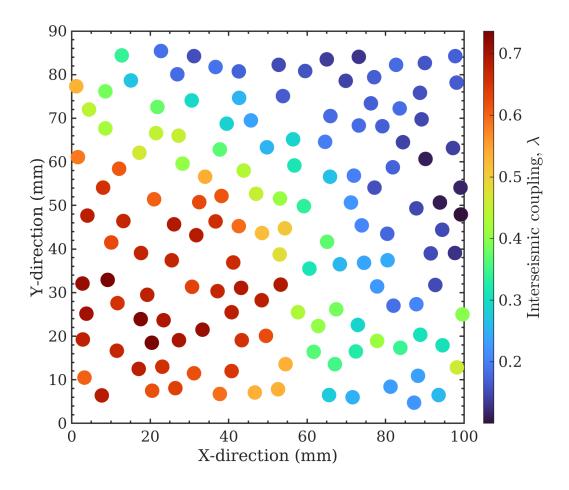

Figure 10. Map of the interseismic coupling of asperities along the interface using the same experimental data shown in Figure 9. A similar pattern between the peak heights of asperity (Figure 3b) and the interseismic coupling is observed, which shows that a larger peak height corresponds to a larger interseismic coupling whereas a smaller peak height corresponds to a lower interseismic coupling.

We also investigate the direct effect of the macroscopic normal load on the inter-419 seismic coupling, as shown in Figure 11. For all experiments with the same normal load, 420 we compute the interseismic coupling of each asperity, which is indicated by the color 421 circles. The average evolution of the interseismic coupling with peak heights conceals some 422 scattering. Indeed, we can observe from Figure 11 that for the same normal load and 423 the same asperity height, different values of  $\lambda$  are computed. To present the evolution 424 of the interseismic coupling as a function of the peak height of asperity, we average the 425 interseismic coupling values over peak heights within a bin width of 0.10 mm. It evidences 426 that, when the normal load is low: 10 N and 25 N, all the asperities have a quite small 427 interseismic coupling, a value that is not distinguishable from zero. The interseismic cou-428 pling shows no dependency on the peak height. This is consistent with the mechanical 429 response of the fault system shown in Figure 4, where the global fault slips almost steadily 430 under the normal loads of 10 N and 25 N. 431

As the normal load increases and becomes large enough such that large stick-slips 432 of the whole fault system are observed, we evidence that interseismic coupling is then 433 dependent on the peak height of asperities. The asperities with low peak heights cor-434 respond to low normal stresses, thus inducing the small stick-slip events observed in be-435 tween the large stick-slip events due to a small interseismic coupling. For the same peak 436 height of asperity, the interseismic coupling increases with the increase of normal stress, 437 which strengthens the locking of the asperities. The maximum value of the interseismic 438 coupling is about 0.55 which is significantly lower than 1. This is consistent with the par-439 tial slipping of asperities shown in Figure 7b and Figure 8. It is interesting to note a tran-440 sition of the interseismic coupling, for a given normal load, at a specific peak height thresh-441 old. This peak height threshold is decreasing as a function of the increased normal stress 442 (from about 2.67 mm at 50 N to about 1.85 mm at 700 N). The interseismic coupling 443 above this peak height threshold converges for all loading conditions to a constant value 444 of around 0.6. Below the threshold,  $\lambda$  decreases towards 0. 445

446

# 4 Interactions between Asperities during the Strengthening Phase

447

# 4.1 Collective Slip Episodes

To investigate the spatiotemporal interactions of asperities, we use a two-step procedure in order to define and characterize slip episodes (SEs). In the first step, we an-

-23-

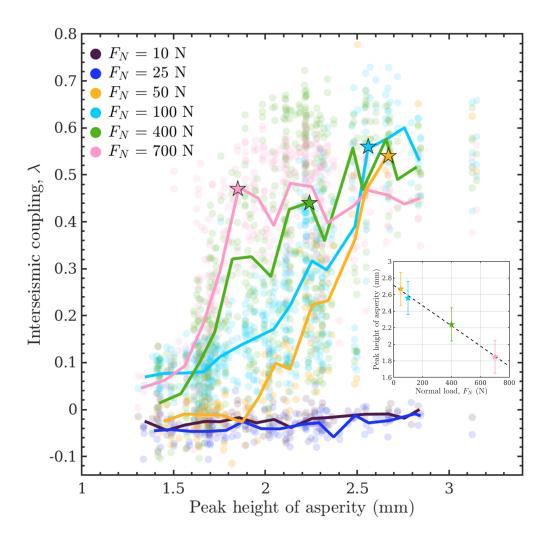

Figure 11. Evolution of the interseismic coupling at different peak heights of asperity under multiple normal loads. The circles with one filled color are the dataset computed for all the experiments under the corresponding normal load. Each curve is obtained by averaging the interseismic coupling over the peak height of asperity with a bin width of 0.10 mm. The inset displays the peak height of asperity at transitions from high to low coupling (stars) as a function of the normal load, where the peak height of asperity decreases with the increase of the normal load.

alyze individually each asperity to isolate individual asperity slips (IASs) from their slip history. In the second step, we identify collective behavior by clustering IASs based on their time and space connection to build slip episodes. The first step is realized by thresholding the velocity  $v_i(t)$  for each asperity *i*. We use a threshold  $\Gamma_i$  specifically for each asperity *i*, which is determined by considering the median  $\tilde{v}_i$  and the median absolute deviation  $D_i^{med}$  of the slip velocity  $v_i(t)$ ,

$$\Gamma_i = \tilde{v}_i + c \cdot D_i^{med},\tag{7}$$

We test several values of the coefficient c in front of  $D_i^{med}$  (see Figure S1) and found 457 that the value retained here (c = 6) is best able to separate noise from slip event. Fol-458 lowing equation (7), we define the IASs as periods with  $v_i(t) > \Gamma_i$  while the others with 459  $v_i(t) \leq \Gamma_i$  are taken as minor slip events and possible noise, and are not included in the 460 catalog of IASs. Figure 12 presents the slip events (blue stars) of one single asperity (i461 = 98) for the same experiment displayed in Figure 7 and its corresponding threshold  $\Gamma_{98}$ 462 (thick magenta line). We find a diversity of slip velocities of IASs. To display the IASs 463 with low slip velocities during the interseismic phase, we zoom in on Figure 12 during 464 a time interval between two large stick-slip events, ranging from 310 s to 350 s (the same 465 time period exhibited in Figure 7b). The observation that several IASs with moderate 466 maximum slip velocity are observed for this asperity is actually consistent with the small 467 stick-slip events found during the fault strengthening stage shown in Figure 9. For each 468 experiment, we establish a complete catalog of IASs by computing the slip velocity  $v_i(t)$ 469 of all the asperities and the corresponding threshold  $\Gamma_i$ . 470

To cluster in space and time all the IASs defined at different asperities into collec-471 tive SEs covering multiple asperities and time steps, we analyze the time and space con-472 nections of these IASs. We define a link between a pair of IASs if the two events are sep-473 arated in time by one or less time step and if they have a spatial connection (i.e., they 474 are nearest neighbor), introducing a two-dimensional Delaunay triangulation, and con-475 sidering the location of each asperity as a vertex (Lee & Schachter, 1980). The edges of 476 the resulting triangulation give the spatial connection between asperities used to make 477 clusters. Additionally, we assume that an asperity is always spatially linked with itself. 478 The IASs simultaneously connected in time and space scales are clustered as a new SE 479 using a single linkage clustering algorithm (Gan et al., 2020). IASs that are not linked 480 to other neighboring IASs are considered as individual SEs. Figure 13 shows one SE last-481

-25-

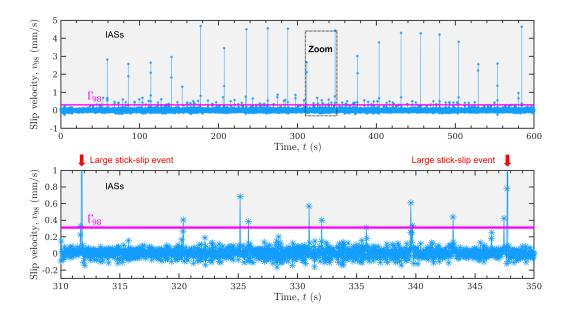

Figure 12. Time-localized slip events produced by a single asperity (i = 98) in the same experiment shown in Figure 7. The blue stars and the thick magenta line represent slip events and the corresponding threshold  $\Gamma_{98}$  specifically computed for this asperity. The slip events localized in the shadow region with slip velocity greater than the threshold are defined as IASs while the others indicating minor slip events and noise are removed. A zoom view showing the low amplitude IASs during an interseismic phase ranging from 310 s to 350 s is presented below. Several IASs with low slip velocities are observed.

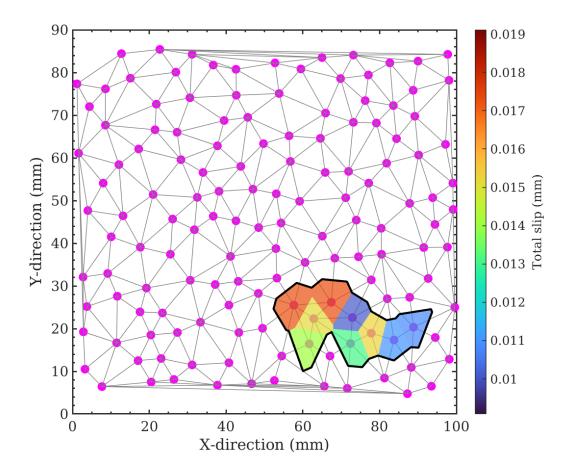

Figure 13. Example of one SE lasting one time step which is composed of nine IASs (polygons with different colors) colored by their total slips. The magenta dots and gray lines indicate the bead locations and the spatial connections all over the interface determined by the Delaunay triangulation, respectively.

ing only one time step, and composed of nine IASs. The polygons with different colors
represent the slip area allocated to each IAS and are determined by the Voronoi diagram
corresponding to the performed triangulation (Fortune, 1995). We, therefore, are able
to build the catalog of spatiotemporal SEs for each experiment.

486

# 4.2 Magnitude-Frequency Distribution

In order to characterize the so-formed slip events, we first investigate their magnitude distribution. The magnitude of the slip event is estimated based on the computation of their moment,  $M_0$ . For one SE containing *n* IASs, its seismic moment is com<sup>490</sup> puted as:

495

$$M_0 = \sum_{i=1}^n G \cdot A_i \cdot s_i,\tag{8}$$

where G is the shear modulus of the PMMA,  $A_i$  and  $s_i$  are respectively the slip area and the slip of each IAS *i* that compose this SE. Then, we can calculate the magnitude Mof each SE following (Hanks & Kanamori, 1979) as:

$$M = (\log_{10} M_0 - 9.05)/1.5. \tag{9}$$

The magnitude-frequency distributions of the SEs extracted from three experiments, 496 which are under the same normal load of 400 N but with three different loading rates, 497 are presented in Figure 14. The symbols with crosses represent the large stick-slip events 498 that involve all the asperities of the interface and subsequently with a size controlled by 499 the finite size of the interface. As evidenced already for finite systems, the distribution 500 of events is bimodal: exponentially distributed size for the events not reaching the in-501 terface and a peak for system-wide events (Fisher et al., 1997). Excluding system-wide 502 events, the observed distributions follow a typical Gutenberg-Richter distribution (Gutenberg 503 & Richter, 1944):  $\log_{10} N(m) = a - bm$ . For the three experiments under loading rates 504 of 5.0  $\mu$ m/s, 10.0  $\mu$ m/s, and 15.0  $\mu$ m/s and a normal load  $F_N = 400$  N, their b values 505 are  $1.21\pm0.05$ ,  $1.44\pm0.1$ , and  $1.35\pm0.12$ , respectively. A gray dashed line showing a ref-506 erence b value of 1.3 is displayed in Figure 14. We can observe that all these three ex-507 periments have a b value nearly similar to this reference. It shows that the b value has 508 no clear dependence on the loading rate of the system. In addition, our experimental re-509 sults show that the b value is insensitive as well to the imposed normal load (see Table 510 S2). 511

512

#### 4.3 Moment-Duration Scaling Relation

For regular earthquakes, a scaling relation between the moment and the duration is commonly observed and takes the form  $M_0 \propto T^3$  (Kanamori & Anderson, 1975). This relation can be understood from the representation of an earthquake as a circular crack expanding at a constant speed and with a constant stress drop. Another scaling relation has also been resolved for slow slip events observed in subduction megathrusts which follows the form  $M_0 \propto T$  (Gao et al., 2012; Ide et al., 2007).

We represent from our SEs the relation between their duration, T, defined as the time difference between its onset and end, and their moment,  $M_0$  (Figure 15a). The moment-

-28-

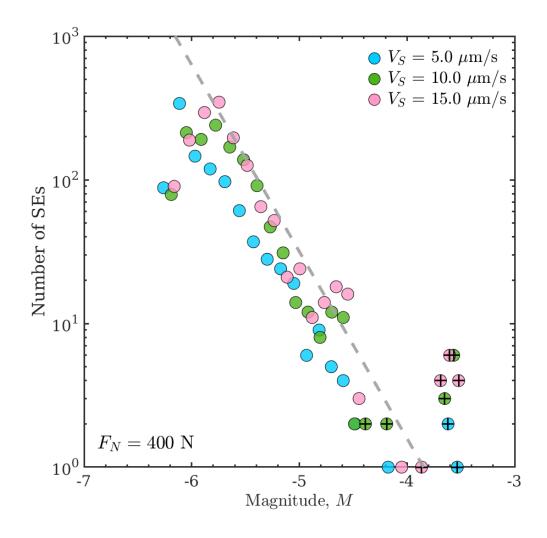

Figure 14. Magnitude-frequency distribution at different loading rates under the same normal load of 400 N. The circle symbols marked by crosses indicate the large stick-slip events at the global fault scale, which are excluded from the computation of the b value. The gray dashed line indicates a reference line with a b value of 1.3.

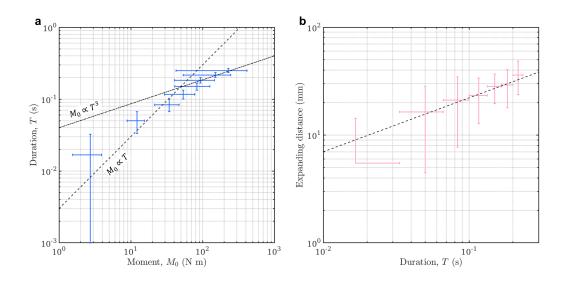

Figure 15. a: Moment-duration scaling relation obtained using SEs from all experiments at various normal loads and loading rates. The black dash-dotted line and dashed line represent the scaling relations of  $M_0 \propto T^3$  and  $M_0 \propto T$ , respectively. The largest slip events, reaching the edge of the sample have been excluded. b: Scaling relation between the expanding distance of SEs and their duration. The black dashed line represents the square-root scaling relation between the expanding distance and the duration.

- duration scaling is represented for all experiments with various normal loads and loading rates. In order to retain in this analysis only confined ruptures and not be influenced by the condition at the edge of the sample, the largest slip events reaching the edge of the sample are excluded. We evidence a linear scaling relation close to  $M_0 \propto T$  for all the experiments for  $M_0 < 100$  N m and a transition to the scaling for earthquakes ( $M_0 \propto T^3$ ) for the largest events.
- For each SE, excluding large-scale stick-slip events, we also compute the distance between the first and last slipping asperities. The duration and expanding distance are averaged to present their relation, as shown in Figure 15b. We observe a square-root scaling relation between the expanding distance and the duration.

#### 4.4 Temporal Decay of Slip Episodes

In order to investigate the possible time interaction between our identified SEs, we compute the time correlation between them, C(t) with

$$C(t) = \frac{1}{Tn_t} \sum_{i=1}^{n_t} \sum_{j=i+1}^n \Theta\left(t_j - t_i \in [t; t+T]\right), \tag{10}$$

where  $\Theta(\mathcal{P})$  of proposition  $\mathcal{P}$  is 1 if  $\mathcal{P}$  is true and 0 otherwise. In order to take into ac-535 count the time finiteness of the catalog, the first sum is performed up to  $n_t$  which is the 536 largest index i such that  $t_n - t_i < t + T$ , where T is the duration of the time bin. The 537 equation (10) actually gives the average rate of SEs at time t following a preceding slip 538 event and we represent an example of C(t) computed for an experiment under a normal 539 load of 200 N and a loading rate of 15  $\mu$ m/s (Figure 16). We observe a rapid decrease 540 of C(t) at a short time range, following a power law decay similar to 1/t. After a dura-541 tion of about 1 s, the average rate of SE stabilizes to a background rate of around 2 SEs 542 per second. This indicates that interactions between SE exist for a short time and that 543 they quickly decay. This evolution of the event's rate bares some analogy with Omori's 544 law observed after large earthquakes which gives as well a decay of the earthquake rate 545 following 1/t (Utsu et al., 1995). 546

#### 547 5 Discussion

548

531

534

#### 5.1 Interseismic Coupling

Our results indicate that the interseismic slip rate relative to the loading rate, i.e. 549 the interseismic coupling,  $\lambda$ , is related at first order to the normal stress imposed on the 550 asperities. The transition from small to high coupling is a function of the normal load 551 (the height of the asperity at this transition is decreasing with normal stress) but the 552 value of the coupling at high or low normal stress is the same for any normal load. This 553 is visible first as a global macroscopic effect affecting all asperities when we change the 554 imposed normal load in our experiments (Figure 11). This can also be observed at the 555 individual asperity scale where we observe that the asperity peak height is correlated with 556  $\lambda$ . Indeed, considering a simple Hertz contact model, a higher asperity height results in 557 higher normal stress. The distribution of asperity heights in our experiments, therefore, 558 leads to a distribution of normal stresses and a continuum of values of  $\lambda$  (Figure 11). 559

-31-

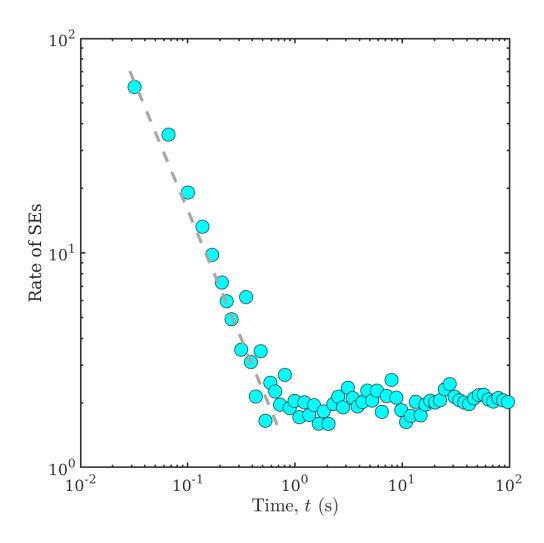

Figure 16. Temporal decay of SEs defined in an experiment under a normal load of 200 N and a loading rate of 15  $\mu$ m/s. The rate of SEs first decays rapidly with 1/t during about 1 s and then keeps stable as a background value of about 2 SEs per second.

It is tempting to relate the characteristic asperity height in our experiment to the 560 critical reduction in the normal force,  $\Delta F_N^*$ , that controls the transition from low to high 561 coupling, as identified in the model of Scholz and Campos (1995, 2012). We note how-562 ever that in this model the transition results from the sole effect of the global normal 563 load since the interface is considered as homogeneous. This approach is thus describing 564 the effective seismic coupling of the interface but not that of the asperities, which we can 565 achieve in our experiments. We interpret that the effective coupling of the interface is 566 a function of the quenched disorder of the fault and then indirectly of the normal stress. 567 If we assume the same height of all the asperities, there would be no variance in inter-568 seismic coupling at different asperities at the same time. Similarly, the whole interface 569 would have the same behavior as that of the asperities and lead to little collective effect. 570 We emphasize here that a large scale topography of a fault with variations of the asper-571 ity heights can influence the effective seismic coupling of the fault differently from a clas-572 sical normal stress level effect. This is a collective effect but related to the quenched dis-573 order of the asperities. 574

Finally, we acknowledge that the definition of interseismic coupling is not completely satisfactory as it fails to capture the variation of the slip velocity inferred on some asperities in between two large scale stick-slip events. Indeed, we highlighted some transient activity and non-steady slipping rate for asperities which indicate that the value we computed only represents an effective behavior of the asperity at the time scale between two large scale stick-slip events.

581

#### 5.2 Interfacial Elastic Energy

Our results evidence that for an interface composed of multiple asperities, as in our 582 system, local slip events with various sizes (see Figure 14) are taking place at all times. 583 We also note that large scale events that involve slips on all asperities of the interface 584 are also observed. These large scale slip events can only happen when sufficient large stress 585 has been accumulated on the strongest asperities. This requires that asperities at some 586 time are synchronized such that initiating the failure at one location triggers the cascad-587 ing rupture of all the asperities on the interface, thus generating the large scale stick-588 slip event. This is equivalent to a collective depinning induced by the long range elas-589 tic interactions in a slowly (quasi-static) loaded system. 590

We quantitatively illustrate such synchronization effect by computing the evolution of the interfacial elastic energy,  $E_h$ , and of the bulk elastic energy,  $E_t$ , following the definition of Schmittbuhl et al. (1996). The interfacial elastic energy,  $E_h$ , is quantified through the sum of the relative distance between two asperities over all the spatial links defined by the two-dimensional Delaunay triangulation:

596

607

$$E_h(t) = K_N \sum_{k=1}^{D} \left( l_k(t) - l_k(t_0) \right)^2, \qquad (11)$$

where  $l_k$  is the relative distance computed through the x positions of two asperities linked 597 spatially and D is the number of the spatial links between two asperities defined by the 598 Delaunay triangulation.  $K_N$  is the compressive stiffness between asperities, computed 599 through  $K_N = E_s \langle d_{asp} \rangle$ , where  $E_s$  denotes Young's modulus of the silicone block and 600  $\langle d_{asp} \rangle$  is the average distance between as perities which estimated to be 6 mm. The in-601 terfacial elastic energy,  $E_h$ , actually quantifies the variance of the change of distance be-602 tween neighboring asperities, thus is related to the elastic force interactions between as-603 perities. The bulk elastic energy,  $E_t$ , is the total elastic energy stored on the interface 604 through the global loading, which is characterized by the collective change in the abso-605 lute positions of all the asperities along the x direction: 606

$$E_t(t) = K_S \sum_{i=1}^{N} (d_i(t))^2, \qquad (12)$$

where  $K_S$  is the shear stiffness estimated using  $K_S = G_s L$ .  $G_s$  is estimated from Young's modulus of the silicone block, 1.1 MPa, while L is the size of the interface, 10 cm. N is the total number of asperities and  $d_i$  the displacement of each asperity.

We present the interfacial elastic energy,  $E_h$ , and the bulk elastic energy,  $E_t$ , as a 611 function of the PMMA plate displacement,  $d_P$ , for different experiments with various 612 normal loads but the same loading rate, as shown in Figure 17. We identify multiple large 613 scale stick-slip events and the corresponding fault strengthening phases from the large 614 abrupt drops of  $E_t$  and the slow accumulation of  $E_t$ , respectively. We also observe a sim-615 ilar pattern for the evolution of  $E_h$ , which is equivalent to the direct measure of the spread-616 ing of the x positions of the asperities apart from their initial position where  $E_h = 0$ . 617 Additionally, we observe a clear dependency of  $E_h$  and  $E_t$  on the normal load, which is 618 consistent with the mechanical response of the fault system shown in Figure 4. With the 619 increase of normal load, the interfacial elastic energy,  $E_h$ , and the bulk elastic energy, 620  $E_t$ , also increase. 621

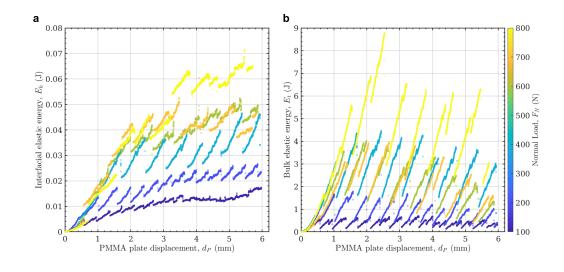

Figure 17. Evolution of (a) the interfacial elastic energy,  $E_h$ , and of (b) the bulk elastic energy,  $E_t$ , under different normal loads and the same loading rate. Both  $E_h$  and  $E_t$  accumulate slowly during the fault strengthening phases and drop when a large stick-slip event occurs. Both  $E_h$  and  $E_t$  show a clear dependency on the normal load.

Such evolution of the elastic energies during successive seismic cycles illustrates the 622 disordering effect of asperities and the build-up of the elastic energy during the strength-623 ening phase. We interpret the rising  $E_h$  as the disordering process of asperities, that is 624 the strong perturbation from the initial position which is supposed to be quenched in 625 the system. The sticking phases correspond to a period of increase of  $E_h$  during which 626 the asperities increase disordering, while a large scale event corresponds to the rapid de-627 crease of  $E_h$  (re-ordering of the asperities). We note that during such a large scale event, 628 while  $E_t$  drops significantly and returns to zero, the drop of  $E_h$  is only partially such that 629 a disorder, and elastic energy, is still present after a large event. It implies that there is 630 a memory effect over the cycles from the relative positions of the asperities. 631

We also observe a transient period at the beginning of the shearing where the evolution of  $E_h$  is similar for all experiments. As the normal stress is increased a larger level of  $E_h$  is reached in the system, so a larger disordering of the asperities. It implies that higher normal stress prevents the interface to come back to its initial state (with low  $E_h$ ) even during a LSE and so maintains a larger disorder in the system with internal stresses along the interface at any time.

The process of synchronization has been well documented notably in numerical sim-638 ulations and shows that only for forces larger than a critical force, that constitute a crit-639 ical point, the system will become unstable and sliding will extend to all sites of the in-640 terface (Fisher et al., 1997; Tanguy et al., 1998; Kammer et al., 2015; de Geus et al., 2019; 641 Albertini et al., 2021). This constitutes a depinning transition and this phenomenology 642 leads to stick-slip. In such models, this critical force is linked to a critical length scale, 643  $L_c$ , of an initiating slip pulse, that will invade all the interface if its extension becomes 644 larger than  $L_c$ . Most of these results were inferred from a homogeneous fault model. Here, 645 both the evolution of the macroscopic force (Figure 9) and the distribution of slip events 646 in Figure 14 are not in agreement with these predictions. Indeed, we first observe in Fig-647 ure 9 that the macroscopic force required to propagate a full scale event is not perfectly 648 constant but rather displays some fluctuations from one rupture to the other. Secondly, 649 the distribution of event magnitudes (Figure 14) shows almost no gap between the largest 650 avalanche and the whole interface avalanche. It, therefore, implies that avalanches of all 651 sizes can exist in the system without necessarily leading above a certain size to a com-652 plete failure. In such a case one would expect a larger gap in event size between the max-653 imum observed avalanche and the system wide event. Such different nucleation mode can 654 arise in the heterogeneous system as interactions between arrested small events could ex-655 ist and significantly modifies the process leading to a major rupture (Albertini et al., 2021). 656 Interpreting these results in terms of fault mechanics suggests that creeping faults cor-657 respond to the interface with an asperity disorder and a strengthening regime with dis-658 ordering of the interface by small destabilizing events that increase elastic interaction 659 between asperities but without impacting the global fault loading. 660

661

#### 5.3 Slip Intermittency

Our system is driven by a constant displacement rate for each experiment and we 662 measure a macroscopic velocity of the PMMA plate that is indeed constant (except dur-663 ing a large-scale event, where a small but noticeable displacement step is observed). This 664 macroscopic measurement mimics the measure that could be made around natural faults 665 by geodetic instruments located at the surface, and thus necessarily far away from the 666 slipping area at depth. It implies that such kind of measurement actually misses the ac-667 tual complexity of the slip distribution taking place on the interface at a short time and 668 spatial scale. Some fine measurements of the slip distribution in both time and space for 669

shallow creeping faults indeed reveal that the long term continuous creeping of faults is 670 actually accommodated during bursts of aseismic slip of various sizes (Jolivet et al., 2013, 671 2015; Rousset et al., 2016; Khoshmanesh & Shirzaei, 2018). During slow slip events, the 672 analysis of GPS signal in conjunction with the recording of low frequency earthquakes 673 (LFEs) also reveals that the large scale motion along the slab consists in the superpo-674 sition of numerous small slip episodes each acting for a limited duration (Frank, 2016; 675 Frank & Brodsky, 2019). The analysis of LFEs as a proxy for local slip on the interface 676 reveals as well that these slip episodes span a wide range of sizes and present both tem-677 poral and spatial correlation (Lengliné et al., 2017). All these results are well in agree-678 ment with the observations performed in this study where the interseismic slip on the 679 fault is characterized by slip events (SEs) of different sizes that act in a close temporal 680 relationship. 681

The slip events we characterized here are slow events in the sense that their du-682 ration with respect to their size is much lower than the Rayleigh wave speed of the ma-683 terial that constitutes the interface. Indeed, supposing a typical PMMA Rayleigh veloc-684 ity of 1255 m/s (Gvirtzman & Fineberg, 2021), this would imply that in one time frame 685 (1/29.97 s) a dynamic rupture front travels up to 42 m. This is inconsistent with the ob-686 servations of SEs that last several time frames. If we suppose that most of the stress trans-687 fer between asperities is actually mediated by the silicone base embedding the PMMA 688 beads, this gives a Rayleigh wave velocity of the order of 20 m/s, and then the propa-689 gation of a rupture front of 66 cm in one time frame. As the largest SEs have a typical 690 duration of 0.3 s and cover a maximum area with a characteristic dimension of half the 691 sample length (5 cm), this suggests that the SEs formed by our criterion actually cor-692 respond to slow events. It does not preclude local dynamic rupture to take place dur-693 ing such SEs, but their size might be limited to a single bead contact area (or smaller). 694 This implies that the moment-duration scaling we report in Figure 15 should be inter-695 preted as scaling attached to slow ruptures on the interface. The best-resolved trend shows 696  $M_0 \propto T$  in agreement notably with the observations of (Ide et al., 2007) that show that 697 many slow slip events on subduction zones follow this scaling law. We note however that 698 the scaling in our experiment is only resolved over a restricted range of moments. This 699 calls for future further experiments involving an increase in the number of beads and the 700 sampling rate of the optical device. This moment-duration scaling is also in agreement 701 with the observed evolution of the slip event characteristic distance with the square root 702

-37-

of duration. This, therefore, suggests that the slip events are driven by a diffusion process controlling the propagation of the rupture, similar to slow-slip events tracked with
tremor migration (Ide, 2010).

The slip event, SEs are characterized as a single rupture following the clustering 706 procedure we defined. It is not obvious how to select the merging condition which is im-707 posed partially in our case by the acquisition rate of the optical device. However, what 708 is the exact definition and extent of a slip event is not a question limited to our exper-709 iment. Indeed, the analysis of earthquakes for example, generally indicates that they are 710 actually composed of several sub-events. The identification of these sub-events, there-711 fore, questioned the definition of the earthquake rupture that consists of several connected 712 local slip episodes. As we discussed above, the same problem of definition arises for a 713 slow slip event which is actually made of a sum of local transient slip episodes connected 714 in time and space. Decreasing the time interval required to merge individual asperity 715 slips into the same cluster would ultimately lead to only isolated local slip events. On 716 the opposite, increasing this time interval would lead to a single slip event comprising 717 all the beads. Finally, we conclude that SEs are thus analyzed at the spatial and tem-718 poral scale imposed by our acquisition system which is a constraint imposed as well to 719 observations made on natural fault systems. 720

721

#### 5.4 Mechanics of the Strengthening Regime

Our system resolves confined rupture that takes place during the strengthening phase. 722 This contrasts with most frictional setups where only large scale ruptures are analyzed 723 during the weakening phase. Unlike these large scale ruptures that are largely controlled 724 by the machine loading stiffness (Leeman et al., 2016; Wu & McLaskey, 2019), partial 725 ruptures provide the opportunity to study the slip events taking place on an interface 726 without being actually influenced by the loading system. In our system, the events are 727 arrested because of stress heterogeneity that arises notably from the variable asperity 728 heights creating spatial differences in frictional strengths. We stress that the heteroge-729 neous nature of the interface only arises as a result of the topography and the position 730 distribution of the asperities with respect to their initial position (assessed by the inter-731 facial elastic energy  $E_h$ ), but that there is no variation of the material properties that 732 constitute the interface. In particular, it implies that the complex dynamic that we re-733 covered during our experiment is not the result of a heterogeneous spatial distribution 734

-38-

of the *a* and *b* parameters of the rate-and-state friction model as employed in several simulations of faulting (Barbot et al., 2012). We note that such approaches are based on a continuum description of the interface and do not model the failure of individual asperities where locations in between are contact-free and hence have zero frictional strength like in our case.

Our results indicate that the strengthening phase, which could be seen as the prepara-740 tory phase of large ruptures, includes a population of events that are multi-scale in size 741 (Gutenberg-Richter relation in Figure 14) and in duration (Figure 15). A similar multi-742 scale size distribution has also been reported by Nasuno et al. (1998) for the events that 743 occurred during the strengthening phase along a sheared fault gouge layer simulated by 744 spherical glass particles that are similar to our asperities. Such granular layers have also 745 been numerically modeled by Aharonov and Sparks (2004), which evidenced a transi-746 tion from weak to strong contacts accompanied by accelerating internal stress release of 747 grains before large stick-slip events. It suggests that such a transition of localized con-748 tacts during the strengthening phase could be considered as a precursor for the impend-749 ing large scale stick-slip. Combined with our results, it implies that the preparatory phase 750 of large earthquakes is very long with many foreshocks strongly related to the quenched 751 disorder. This result is highly reproducible with the same disorder in the asperity po-752 sitions. 753

754

#### 5.5 Limitations of the Experimental Setup

Our novel experimental setup builds a heterogeneous shear interface of multi-asperity 755 contacts. An important point resulting from the designed configuration is that the el-756 evated adhesion of the silicone block to the asperities is strong enough such that there 757 is no rolling of asperities caused by the shearing imposed on the PMMA plate. Similarly, 758 we also make sure that the silicone block is at no time in contact with the PMMA plate 759 during the experiment. Indeed, in such a case, the high adhesion of the silicone would 760 cause a local resistance to slip and modify the modeled physical process (from friction 761 to adhesion). This limits the maximum normal load we can impose on the system to ap-762 proximately 1500 N, at a higher imposed normal load, the silicone block starts to have 763 some local contacts with the PMMA plate. 764

-39-

The sampling rate of the camera employed directly determines the time resolution 765 for tracking the slips of asperities. Thus, the rapid slipping phase involving multiple as-766 perities cannot be analyzed in detail. For example, it is not sampled with a high enough 767 time resolution to capture a clear trend of the decay of the shear force as a function of 768 slip during these episodes (see Figure 9). Furthermore, the precise timing, migration, or 769 interactions of local bead slips during the high slipping phase is not accessible. Finally, 770 as we evidence, the overall rupture during such SEs is slow but it does not preclude that 771 locally during such slow transient, local dynamic rupture occurs such that some propor-772 tion of the resolved slip is actually taking place during such dynamic phase and radiate 773 elastic wave. The proportion of the slip taking place on the asperities as dynamic events 774 is presently not measurable but remains to be investigated for future studies. 775

The derivation of the moment,  $M_0$ , of the slip events required the computation of 776 an area,  $A_i$ , attached to each asperity (see Eq. 8). Here we take for each asperity the 777 area returned by the Voronoi cell including the asperity. Such a definition of the slip area 778 attached to an asperity probably over-estimate the real slipping area during an IAS. In-779 deed, the locked area of an asperity is presumably much lower than a circle of the as-780 perity radius (considering a Hertz contact model) (K. L. Johnson, 1987). Although some 781 slip deficit can extend beyond the fully locked area, it becomes negligible at a distance 782 typically greater than one asperity radius (L. R. Johnson, 2010). It then leads to an over-783 estimation of the computed moment. However, as the contact area for each asperity should 784 be nearly similar (considering again the Hertz contact model and the low stiffness of the 785 silicone) we can expect that the conclusion of the magnitude distribution presented in 786 Figure 14 would be unchanged if one could obtain a precise measurement of the slipping 787 area of each IAS. We thus acknowledge that the reported moment of slip events should 788 be mostly interpreted relatively than as absolute values. Such complexity of the slip dis-789 tribution is also observed for natural earthquakes with zones of little or no slip (Freymueller 790 et al., 2021). 791

Another ambiguity is involved in the calculation of the moment from equation (8). Indeed, the shear modulus used in this equation is taken as the shear modulus of the PMMA. However the PMMA is the dominant material only on one side of the system, the other side is composed of the PMMA beads embedded in the silicone block. Characterizing the shear modulus for such bi-material is not a trivial task and again further warns against a direct interpretation of the absolute values of  $M_0$ .

-40-

## 798 6 Conclusions

This study analyzes the collective behavior of numerous discrete asperities ( $N \approx$ 799 140) modeled on an analog fault interface during multiple seismic cycles. We show that 800 an interface composed of multiple discrete asperities can have a macroscopic behavior 801 that is distinct from that of its individual elements. The asperities present a diversity 802 of slips at various speeds. We evidence the dependency of the interseismic coupling of 803 the interface with the topographical map of the asperity summits and the normal load 804 imposed on the system. We notably show that topographic variations of the asperity sum-805 mits have a pronounced effect on this coupling. The slip intermittency of the activity 806 of clustered asperities indicates that the interface undergoes local episodes of creep that 807 ultimately lead to the global slip of the interface. The analysis of the evolution of the 808 elastic energy along the interface helps to track the disordering of the asperities with re-809 spect to their initial position. We show that this energy is typically higher for large nor-810 mal stress, which supports the conclusion that normal stress maintains a larger disor-811 der in the system. It shows as well that the disorder increases during the strengthening 812 phase and is only partially reduced during large slip events. Significant statistical fea-813 tures of slip widely observed in natural faults are reproduced by our experiments like the 814 Gutenberg-Richter law, Omori's law, and the moment-duration scaling, suggesting that 815 the obtained results can be extrapolated to natural fault systems. 816

#### 12 Abstract

The multi-scale roughness of a fault interface is responsible for multiple asperities that 13 establish a complex and discrete set of real contacts. Since asperities control the initi-14 ation and evolution of the fault slip, it is important to explore the intrinsic relationships 15 between the collective behavior of local asperities and the frictional stability of the global 16 fault. Here we propose a novel analog experimental approach, which allows us to cap-17 ture the temporal evolution of the slip of each asperity on a faulting interface. We find 18 that many destabilizing events at the local asperity scale occurred in the frictional strength-19 ening stage which is conventionally considered as the stable regime of a fault. We com-20 pute the interseismic coupling to evaluate the slipping behaviors of asperities during the 21 fault-strengthening stage. We evidence that the interseismic coupling can be affected by 22 the elastic interactions between asperities through the embedding soft matrix. Scaling 23 laws of natural slow slip events are reproduced by our setup in particular the moment-24 duration scaling. We also evidence an unexpected persistency of a disordering of the as-25 perities through the seismic cycles despite the relaxation effects of the large slip events. 26

#### 27 Plain Language Summary

Earthquakes are the results of a slip along a rough fault on which a complex and 28 discrete set of asperities establish the interfacial contacts and control the frictional sta-29 bility of the fault. We propose a novel experimental setup capable of measuring directly 30 the subtle motion of individual asperities on an analog faulting interface. By capturing 31 the temporal evolution of the slip of each asperity, we link the mechanical behavior of 32 the global fault with the collective behavior of local asperities. Many destabilizing events 33 at the local asperity scale are found during the globally stable stage of the fault. We prove 34 that the interseismic coupling of asperities is affected by the normal load, the peak height 35 of asperities, and the interactions between asperities. The spatiotemporal interactions 36 of asperities are quantified as slip episodes to mimic the ruptures including both stable 37 and unstable slips. With the catalog of slip episodes, we reproduce the significant char-38 acteristics and scaling laws observed in natural faults, such as the magnitude-frequency 39 distribution and the moment-duration scaling. Such upscaling suggests that our results 40 can be extrapolated to natural faults and provide insights into fault physics and mechan-41 ics. 42

## 43 1 Introduction

Crustal fault interfaces display geological heterogeneities at various scales (Faulkner 44 et al., 2003; Chester et al., 1993; Ben-Zion & Sammis, 2003). In particular, exhumed fault 45 surfaces exhibit a complex topography characterized by height variations at all scales (Candela 46 et al., 2009, 2012; Power et al., 1987; Schmittbuhl et al., 1993, 1995; Scholz, 2019). Sup-47 posing that the roughness of these interfaces is similar to those of active faults at depth, 48 it implies that the frictional interface is formed by a complex set of junctions across the 49 two opposite surfaces in contact (Schmittbuhl et al., 2006; Pohrt & Popov, 2012). These 50 junctions are commonly known as asperities (Bhushan, 1998). They have been charac-51 terized at the laboratory scale as microcontacts (Dieterich & Kilgore, 1994) where the 52 resistance to an imposed shear stress is shown to be governed by the initiation and evo-53 lution of the fault slip (Scholz, 2019). 54

The presence of these asperities on the fault is supported by the observation of small 55 repeating earthquakes, supposedly representing cohesive zones that fail periodically un-56 der constant loading (Nadeau & Johnson, 1998). The role of such asperities in the be-57 havior of earthquakes has long been recognized. For example, it is suggested that small 58 and scattered asperities on a subduction interface may lead only to a minor release of 59 the seismic moment (Ruff & Kanamori, 1983). On the other hand, a great earthquake 60 may involve the simultaneous rupture of multiple asperities, such as the 1960  $M_W$  9.5 61 Chile earthquake (Moreno et al., 2009) or the 2004  $M_W$  9.2 Sumatra-Andaman earth-62 quake (Subarya et al., 2006). Such examples have been interpreted in a framework draw-63 ing a strong link between the rupture synchronization of asperities and the magnitude 64 of the impending earthquake (Lay & Kanamori, 1981; Lay et al., 1982). This synchro-65 nization of asperities actually emphasizes a strong time-and-space dependent mechanism 66 for the underlying physics and corresponding mechanical response of fault slip. The role 67 of asperities on the behavior of the faulting interface is not limited to dynamic rupture 68 events. Indeed, the interseismic phase is also strongly impacted by the presence of such 69 strong contact areas. This notably arises as locked patches can create stress shadows which 70 lead to reduced interseismic slip rates on the surroundings of the asperity (Bürgmann 71 et al., 2005) and thus a spatial modulation of the interseismic coupling (Perfettini et al., 72 2010). 73

-3-

Numerical models have addressed the behavior of a fault interface comprising mul-74 tiple asperities. A number of simulations represent the interface notably in the context 75 of the rate-and-state friction framework (Dieterich, 1979; Ruina, 1983; Marone, 1998) 76 and asperities are presented as distinct patches spatially distributed over the fault plane 77 with distinct frictional parameters (Barbot et al., 2012; Dublanchet et al., 2013; Luo & 78 Ampuero, 2018; Li & Rubin, 2017). In these numerical models, the asperities are usu-79 ally considered as velocity weakening patches and are therefore defined to be potentially 80 unstable. These models indicate that the mechanical response of a fault is evidently af-81 fected by the interactions of discrete asperities surrounded by aseismic creep areas. For 82 instance, a variable density of asperities (Dublanchet et al., 2013), which is the ratio be-83 tween the total area covered by asperities and the total area of the fault plane is pro-84 posed and utilized to explain at which condition the fault will be ruptured entirely or 85 locally. Incorporating roughness on the fault plane (as fluctuations of the normal stress), 86 Cattania and Segall (2021) show that this heterogeneity modulates the slip stability across 87 the fault. Finally, Romanet et al. (2018) demonstrate that the sliding diversity of a fault 88 can be obtained from geometrical complexities alone, without the need for the complex-89 ity of the friction law. All these numerical approaches, therefore, point to the importance 90 of these asperities and their interactions in controlling fault mechanics. However, these 91 models are severely limited by the computational cost of simulating heterogeneities with 92 a variable size over a large time and space domain and inherently only describe a lim-93 ited aspect of the ongoing physics. 94

At the laboratory scale, numerous experiments on rock samples have also shown 95 that fault roughness plays a crucial role in fault slip behavior (Goebel et al., 2017; Har-96 bord et al., 2017; Morad et al., 2022; Zhou et al., 2021) as it controls actual stress con-97 ditions at contacting asperities (Aubry et al., 2020). These results imply that the stress 98 heterogeneity at local asperities is significant for influencing fault slip behavior. How-99 ever, these experiments usually analyze the effects of asperities by comparing the initial 100 and final roughness of the fault interface as the nontransparent rock slabs cannot pro-101 vide the possibility to capture what is happening on the interface during the fault slip 102 process. On the contrary, some other experiments take advantage of the transparency 103 of analog materials (e.g., Poly-methyl-methacrylate, PMMA) to optically observe the as-104 perities distributed on the interface (Lengliné et al., 2012; Jestin et al., 2019; Selvadu-105 rai & Glaser, 2015, 2017), which provides a possibility for the direct monitoring of the 106

-4-

faulting interface. Although the contacts were captured during these experiments, it was
 not possible to track the slip at each point during shearing.

Here we present a novel experimental setup that aims at capturing the slip as a func-109 tion of time for each asperity on a sheared interface. Our experimental setup is much 110 simpler than a complex fault zone system, which has no mineralogy, no fluid, and no chem-111 ical transformation, but the fundamental process of interest, the relationship between 112 the collective behavior of local asperities and the stability regime of the global fault sys-113 tem, remains similar. Specifically, this novel experimental approach allows a thick trans-114 parent PMMA plate to slide slowly on a customized surface with height variations, on 115 which asperities are modeled by numerous identical spherical PMMA beads embedded 116 in a softer polymer base. Thanks to a high-resolution camera, our setup is capable of 117 measuring directly the subtle motion of local asperities on the interface during the whole 118 slipping process, which helps to understand the time-and-space dependent behavior of 119 each single asperity. The mechanical response of the global fault system is well recorded 120 and explained through the collective behavior of local asperities. The link between the 121 fault topography and the interseismic coupling is also investigated. In addition, the spatio-122 temporal interactions of asperities are quantified as collective slip episodes mimicking 123 fault ruptures including both stable and unstable slips. To give some geophysical impli-124 cations, the effective upscaling from the analog interface to natural faults is demonstrated 125 by reproducing significant characteristics and scaling-laws observed in natural fault sys-126 tems. 127

128

## 2 Experimental Setup

We build an analog model of a shear interface that aims at reproducing the typ-129 ical mechanical structure of a natural fault core. We consider that a fault zone consists 130 of several key elements. At the interface, the roughness of the fault topography creates 131 contacts on a number of discrete sites, i.e. asperities, that are here modeled as PMMA 132 beads. The core of the fault, which consists generally in a heavily fractured medium (Chester 133 & Chester, 1998; Schulz & Evans, 2000) is represented in our setup with a soft material 134 surrounding the PMMA beads. At a greater distance from the fault, the number of dam-135 age decreases (Ben-Zion & Sammis, 2003; Mitchell & Faulkner, 2009; Stierman, 1984), 136 and the fault becomes stiffer which translates in our setup in a rigid base attached to 137 the soft material (Figure 1). The asperities are in contact with a top rigid block and es-138

-5-

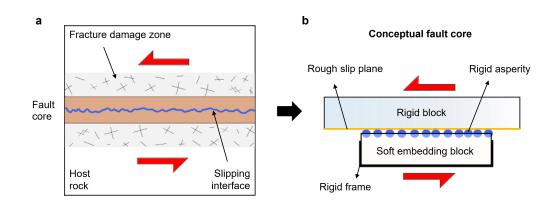

Figure 1. a: Sketch of a typical natural fault zone showing a rough frictional slipping interface subjected to shear. b: Conceptual model of the analog shear interface derived from the natural fault core structure. The rigid asperities embedded in the soft thick block establish a rough slip plane beneath the top rigid block.

tablish a rough slip plane, while the soft embedding block fixed within the bottom rigid
frame is easily deformed. This thick, rough, and deformable interface allows us to study
the interactions of asperities and their collective behavior with respect to the frictional
stability of the fault interface.

#### 143

### 2.1 Sample Preparation and Characterization

To prepare such a model of multi-asperity contact, numerous identical spherical 144 PMMA beads (a total number of 175) with a radius R of 3 mm are embedded in a soft 145 block. The soft block is composed of silicone (BLUESIL RTV 3428 A&B product from 146 the Elkem company), with dimensions  $10 \times 10 \times 3.0$  cm. The preparation of the sam-147 ple consists in first pouring a thin layer (of the thickness of a bead radius) of edible gelatin 148 mixed with water at the bottom of a mold. Then PMMA beads are dropped randomly 149 in this layer all over the interface. After the gelatin layer solidifies, we then pour the liq-150 uid silicon into the mold to cover the beads and wait for at least 24 hours at room tem-151 perature for its solidification. Finally, we take out the upside-down sample and remove 152 the mixture of gelatin and water. Following the procedures above, we customize an ex-153 perimental sample and its picture is displayed in Figure 2. The resulting sample is made 154 such that all beads have nearly the same height while being scattered randomly over the 155 sample. Physical characteristics of the silicone are derived from the technical datasheet, 156

-6-

the relation of Gent (1958) for converting durometer values to Young's modulus, and laboratory measurements of the P-wave velocity of the material. We obtain a P-wave velocity for this material of 1000 m/s, an S-wave velocity of 19 m/s, a Young's modulus of 1.1 MPa, and a density of 1100 kg/m<sup>3</sup>.

In order to precisely describe the so-formed interface and get the summit heights 161 of all the beads, we measure a high-resolution topographical map for the interface. The 162 data are acquired by a digital microscope profiler (RH-2000, HIROX) and a non-contact 163 Nano Point Scanner (NPS, HIROX). The system uses a white light confocal LED beam 164 with grids of 28  $\mu$ m and 100  $\mu$ m in the x- and y-directions, respectively. The topograph-165 ical map of the interface is shown in Figure 3a, where the blueish part indicates the em-166 bedding silicone block while the discrete circles represent the asperities with different heights. 167 We determine the peak heights of all the asperities (Figure 3b) and statistically analyze 168 their distribution (Figure 3c). The peak heights of asperities (relative to the average sil-169 icone upper face level) range from 1.31 mm to 3.15 mm, with most of them within the 170 peak height interval [1.4, 2.6]. The average peak height is 2.02 mm and the standard de-171 viation of the peak heights is 0.39 mm, which indicates a small variance in the peak heights 172 of asperities. We notice that there is a large-scale trend across the entire sample of this 173 peak bead height. This is most likely due to the non-perfect planarity of the gelatin layer. 174 Removing this large-scale trend, we observe that the height difference between neigh-175 boring asperities is low. In addition, we compute the average peak height difference be-176 tween two asperities as a function of the distance in x and y direction (Figure 3d). We 177 find a pattern highlighting the large scale variation of the peak height but no other cor-178 relation of the peak heights emerges. 179

180

#### 2.2 Mechanical Loading

To simulate a large-scale, far-field, loading imposed on a fault, the shear of the whole 181 analog interface system is induced by imposing a small displacement rate to the PMMA 182 plate under well-controlled normal loads (Figure 2). PMMA has been widely used, as 183 an analog material, to simulate numerous mechanical processes taking place within the 184 Earth. In particular, frictional processes taking place on natural faults have been inves-185 tigated using this material, such as fault creep and nucleation phases (e.g., McLaskey 186 & Glaser, 2011; McLaskey et al., 2012; Selvadurai & Glaser, 2015) but also ruptures (e.g., 187 Ben-David et al., 2010; Gvirtzman & Fineberg, 2021; Schmittbuhl & Måløy, 1997). Due 188

-7-

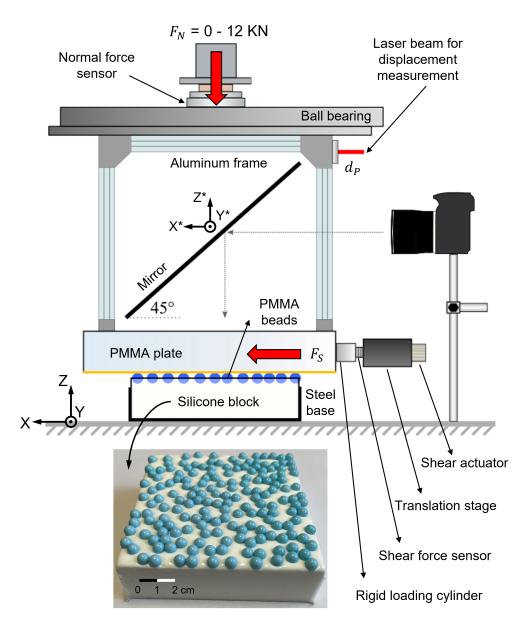

Figure 2. Schematic diagram of the technical experimental setup (side view). The normal force,  $F_N$ , and shear force,  $F_S$ , are measured by their corresponding sensors. A laser is employed to measure the displacement of the PMMA plate,  $d_P$ . A high-resolution camera is utilized with a mirror to monitor the positions of the PMMA beads during the whole shear process. Two axis systems, one attached to the ground and another one attached to the mirror, are represented. The yellow line indicates a rough slip plane established between the PMMA plate and the PMMA beads. The inset shows an image of the PMMA beads embedded in the soft silicone block.

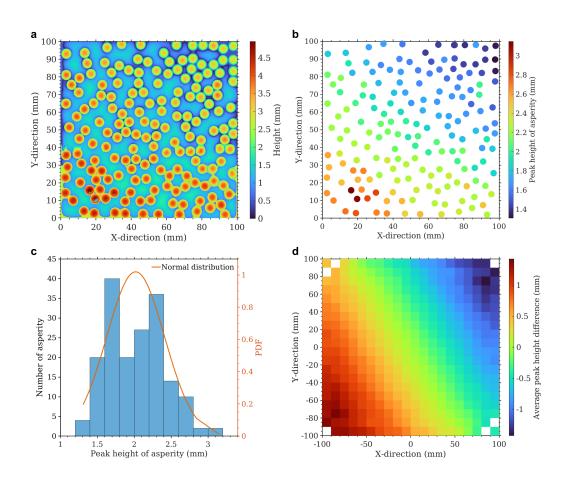

Figure 3. a: Topographical map of the analog fault interface. The blueish part is the embedding silicone block while the colored circles are the asperities created by the PMMA beads. There are a few non-measured points in the bottom-left corner that have little effect on characterizing the interface. b: Peak height of each asperity. The minimum and the maximum are 1.31 mm and 3.15 mm, respectively. c: Distribution of the peak heights of all the asperities. The asperities with peak heights ranging from 1.4 to 2.6 mm account for the majority. A standard deviation of 0.39 mm indicates a small variance in the peak heights. d: Average peak height difference as a function of the x and y direction. This highlights the large scale variation of the peak heights.

to its transparency, the PMMA enables a clear direct observation of the deforming medium
(Lengliné et al., 2012; Jestin et al., 2019). The shear modulus of the PMMA is estimated
as 2277.1 MPa (Selvadurai & Glaser, 2015).

The normal force  $F_N$  is applied by the vertical movement of the rigid load platen 192 driven by a high-precision micro stepper motor (LoadTrac II), and uniformly transferred 193 to the PMMA plate through the ball bearing and the rigid aluminum frame. A sensor 194 of resolution 0.01 N is utilized to record the normal force and maintain a constant nor-195 mal load throughout the whole duration of an experiment. We run the shear actuator, 196 a combination of servo and stepper motor, with a constant displacement rate  $V_S$  to drive 197 the translation stage and the rigid loading cylinder to impose the shear force  $F_S$  while 198 maintaining a normal force  $F_N$  on the PMMA plate. The loading cylinder is composed 199 of the aluminium alloy 2017A, with a stiffness of 78 N/ $\mu$ m. The shear force  $F_S$  is mea-200 sured using a sensor placed between the cylinder and the translation stage, with a res-201 olution of 0.01 N. The stiffness of this sensor is  $1 \text{ N}/\mu\text{m}$ , thus most of the loading stage 202 deformation is actually taking place within the force sensor. We employ a laser (Keyence 203 IL-S025), range 10 mm and resolution 0.1  $\mu$ m, to measure the displacement of the PMMA 204 plate,  $d_P$  (Figure 2). For all the experiments, we keep the initial value of  $d_P$  the same 205 to ensure each fault slip starts from the same position. 206

Prior to performing the experiments, we fix the PMMA plate to the aluminum frame 207 and attach the silicone block to the rigid steel base and clamp it. We use a digital level 208 to make sure that the whole experimental system, especially the slip plane, is flat hor-209 izontal. Each experiment begins at the moment when the shear force starts to increase 210 on the PMMA plate, given the analog fault has been previously loaded by a stable nor-211 mal load. The duration of each experiment is set to 600 s. We performed 28 experiments 212 by applying various normal loads ranging from 10 N to 1000 N and displacement rates 213 ranging from 5.0  $\mu$ m/s to 15.0  $\mu$ m/s (Table S1). We define the x-direction as the slid-214 ing direction of the PMMA plate while the direction y is set perpendicular to the x-direction. 215

To demonstrate the transition from steady slip to stick-slip in our analog fault system, the evolution of the shear force,  $F_S$ , under multiple normal loads,  $F_N$ , maintaining the same loading rate  $V_S$  of 5.0  $\mu$ m/s is presented in Figure 4. We clearly observe the steady sliding of the interface when the normal load is quite small (e.g.,  $F_N = 10$  N). On the other hand, multiple stick-slips are observed when the normal load becomes greater

-10-

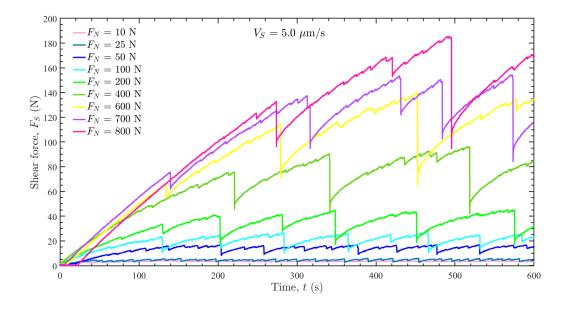

Figure 4. Temporal evolution of the shear force under multiple normal loads. The interface slips steadily when the normal load is quite small while evident stick-slips occur when the normal load becomes greater than 50 N. With the increase of the normal load, the shear force drop also increases.

than 50 N (Figure 4). In addition, the shear force drop of each stick-slip increases with the increase of the normal load.

223

#### 2.3 Optical Monitoring

To capture the positions of asperities and compute their slips during the experi-224 ments, we use a high-resolution camera (Nikon D800) with a lens (Nikon 105 mm f/2.8 D225 AF Micro-Nikkor) in automatic focus mode to record videos. A mirror fixed inside the 226 aluminum frame, which is inclined at 45 degrees, reflects the interface and moves with 227 the sliding of the PMMA plate during the experiments (Figure 2). The main settings 228 of the optical system are as follows: aperture size f/14, exposure time 1/30 s, and pho-229 tosensitivity (ISO) 100. Two LED lights are placed behind the camera to supplement 230 sufficient light for the clear observation of the interface. We record videos of dimensions 231 in  $1920 \times 1080$  pixels with a sampling rate of 29.97 frames per second. In addition, to 232 synchronize the force measurement and the optical monitoring, we send an electrical syn-233 chronization signal and correct the time base of each record. 234

For each experiment, we extract all pictures taken by the camera between the times  $t_0$  and  $t_f$  which are respectively the times at the beginning and the end of an experiment. From this set of pictures, we extract the slip of each individual asperity as a function of time. Denoting  $x_i(t)$  and  $y_i(t)$  the positions of the center of asperity *i* in a fixed reference frame (attached to the ground) we can define the displacement,  $d_i(t)$ , of an asperity along the loading direction in this fixed frame,

 $d_i(t) = x_i(t) - x_i(t_0).$ 

241

245

248

Similarly, we define  $x_P(t)$  as the position of the center of the mirror in the same fixed frame and then its displacement (which corresponds to the displacement of the PMMA plate as well), is computed as:

$$d_P(t) = x_P(t) - x_P(t_0).$$
 (2)

(1)

The cumulative slip of asperity i at time t is defined as the difference of the displacement between the two sides of the interface (i.e., the asperity and the PMMA plate):

$$u_i(t) = d_i(t) - d_P(t).$$
 (3)

As the camera and the silicone block are both fixed to the ground while the mirror moves 249 with the sliding PMMA plate, the position of each asperity, i, on pictures taken by the 250 camera is relative to the moving frame of the mirror and is noted  $(x_i^*(t), y_i^*(t))$ . It fol-251 lows that the displacement of an asperity in this moving frame is simply  $d_i^*(t) = x_i^*(t) - x_i^*(t)$ 252  $x_i^*(t_0)$ . From the definition of the cumulative slip introduced before, this displacement, 253  $d_i^*(t)$ , corresponds exactly to the cumulative slip,  $u_i(t)$  of asperity i. Consequently, the 254 cumulative slip of each asperity is obtained by tracking the evolution of its position,  $x_i^*(t)$ , 255 between time  $t_0$  and time  $t_f$ . 256

We developed a two steps procedure for tracking the evolution of the position  $x_i^*(t)$ of each asperity *i* in the moving frame of the mirror. In the first step, we applied the circular Hough transform algorithm implemented within MATLAB for automatically detecting circular objects (Yuen et al., 1990; Davies, 2005). From the first and last pictures at times  $t_0$  and  $t_f$  respectively, we extract the initial position  $x_i^*(t_0)$  and final position  $x_i^*(t_f)$  of asperity *i*. We also estimate the initial position of the beads,  $y_i^*(t_0)$  in the direction perpendicular to the slip direction.

The initial positions of asperities detected at time  $t_0$  are shown in Figure 5. The asperities marked by red circles, with a total number of N = 144, are retained in our

analysis while the asperities with blue markers are excluded from the subsequent image 266 analysis because they are located too close to one of the image edges. We note the value 267 of N may change with different experiments mainly due to the field view of the camera, 268 but it fluctuates around 140. In addition, we obtain the radius R, which is 36 pixels, and 269 compute the scaling of the image from the known radius of the PMMA beads (R = 3270 mm), 12 pixels/mm. Based on the initial and final positions of asperities, we are able 271 to estimate the total slip  $u_i^*(t_f) = x_i^*(t_f) - x_i^*(t_0)$  of each asperity. Due to the con-272 stant loading rate, a simple linear trend between these two positions gives an approx-273 imate position,  $x_i^*(t)$  of asperity i at each time step. This provides a first order estimate 274 of each asperity location during the experiment. In the second step, in order to obtain 275 the most accurate locations, we applied an image correlation technique (Sutton et al., 276 2009) to refine these first measurements. 277

To quantify the slip of each asperity, a square window for image correlation with 278 a size of  $\sqrt{2R}$  is defined at the center of each asperity based on our previous estimates 279 of  $x_i^*(t)$  and  $y_i^*(t_0)$ . We extract the image defined by the square correlation window of 280 each asperity at all frames. For each asperity, we compute the FFT (fast Fourier transform)-281 based two-dimensional cross-correlation between the extracted window defined at time 282  $t_k$  and the window defined at time  $t_{k-1}$ . From the correlation map, we isolate the po-283 sition of the maximum value which gives the displacement of the bead. We then shift 284 the correlation window of the second frame based on this displacement and repeat the 285 procedure until the computed displacement is null. At this last stage, we then extract 286 a sub-sample displacement by interpolating the correlation map around its maximum. 287 The final displacement of the bead between the two time frames is then obtained by sum-288 ming all displacements computed during this iterative process. Repeating this procedure 289 for all time frames and for each bead we are able to obtain the cumulative slip of each 290 asperity during the whole duration of an experiment. The typical resolution of the re-291 solved displacement in each direction is of the order of 0.01 mm. 292

Due to the geometry of our experimental setup, the non-parallelism which may result from the non-perfect 45 degree inclination of the mirror and/or the non-parallel view between the camera lens and the slip plane (Figure 2), can create a non-linear scaling along the x axis. In order to eliminate this effect, we correct the cumulative slip of asperity *i* based on its total slip  $u_i(t_f)$ , which is supposed to be no greater than the displacement  $d_P(t_f)$  of the PMMA plate at time  $t_f$ . Given the corrected cumulative slip

-13-

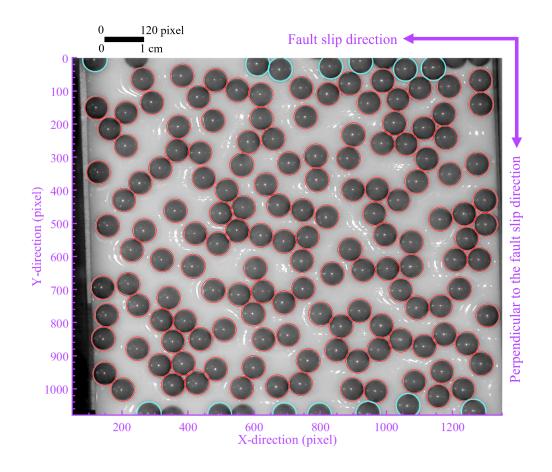

Figure 5. Typical automatic detection results indicating the initial positions of asperities at time  $t_0$ , on the interface within a region of interest of dimensions  $1300 \times 1080$  pixels (i.e.,  $108.33 \times 90$  mm). The asperities without markers represent the undetected ones while the asperities with blue circles correspond to the excluded ones as their correlation windows exceed the image boundary. A total of N = 144 asperities marked by red circles are kept and their positions  $x_i^*(t_0)$  are taken as the initial positions for computing the slip through the image correlation.

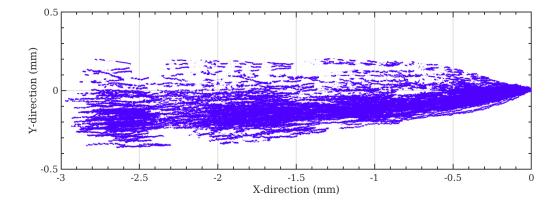

Figure 6. Trajectories of all the asperities during the whole duration of an experiment under a normal load of 400 N and a loading rate of 5  $\mu$ m/s. The onset of each trajectory is superimposed to be at the origin (0,0). The prominent gaps correspond to the large stick-slip events.

 $u_i(t)$  of asperities, we then update the displacement  $d_i(t)$  of asperities following the equation (3).

Finally, we also note that the asperities also exhibit slips perpendicular to the load-301 ing direction. These cumulative slips are near-evenly distributed around zero and the 302 maximum cumulative slip is quite small compared to the cumulative slip along the fault-303 ing direction. We present the trajectories of all the asperities during the whole exper-304 imental duration in Figure 6, where the onset of the trajectory of each asperity is set to 305 be at the origin (0,0). The total slip during this experiment is of the order of the asper-306 ity size, R = 3 mm, and the slip in the x direction is about 10 times larger than that 307 in the y direction. There is a fan shape of the trajectories with a mean y-direction that 308 is close to zero. We observe several prominent gaps that correspond to the large stick-309 slip events during the faulting. For the other experiments under different loading char-310 acteristics, the total slip of asperities in the x direction is dependent on the loading rate 311 and the experimental duration while that in the y direction is generally of the same or-312 der of  $\sim 0.3$  mm. 313

314

# 3 Collective Behavior of Asperities

315

#### 3.1 Temporal Evolution of the Cumulative Slips of Asperities

To understand the individual behaviors of asperities as well as the relationship be-316 tween each local asperity and the whole interface, we present the temporal evolution of 317 the cumulative slips of individual asperities. For a better visibility, only 20 asperities, 318 randomly selected out of 144 asperities, are presented in Figure 7. The cumulative slips 319 of the 20 asperities are color-coded by their initial positions  $y_i(t_0)$ . We also indicate in 320 Figure 7 the loading rate of the interface which is 15.0  $\mu$ m/s here. Any asperity follow-321 ing this trend could be considered then as fully sliding. On the contrary, a fully stick-322 ing asperity would accumulate no relative slip with respect to the loading plate. Its be-323 havior would appear as a horizontal line in Figure 7. 324

The stepping feature of cumulative slip evolution of the asperities in Figure 7 il-325 lustrates the repetitive stick-slip events of the interface (20 events in Figure 7a and a zoom 326 on one of them in Figure 7b). These events involve all the asperities of the interface. In 327 the time interval between these whole stick-slip episodes, during the sticking phase, the 328 asperities show distinct behaviors. We observe that all the slipping rates are smaller than 329 that of imposed loading rate (see the slopes of the cumulative slip of the asperities and 330 the PMMA plate) but with a non-horizontal trend, which indicates that, actually, the 331 asperities are slipping at a low rate during the sticking phase, instead of being fully locked. 332

It is noteworthy that the slips accumulated during each sticking period are not the 333 same for different asperities. This proves that different asperities can slip at different rates, 334 though they are all in the quasi-static regime (i.e. the sticking phase of the interface stick-335 slip behavior). Another interesting finding is that there are also some small visible slips 336 that occurred at different single asperities during the overall sticking phase and corre-337 spond to small stick-slip events at the scale of several asperities. These small episodes 338 contrast with global slip episodes, when all the local asperities slip rapidly in a synchronous 339 way and that we define as a large stick-slip event (LSE). Moreover, the observation that 340 the slips on all asperities after a LSE do not reach the imposed loading slip, indicates 341 that accumulated stress is only partly released during such a whole scale event. 342

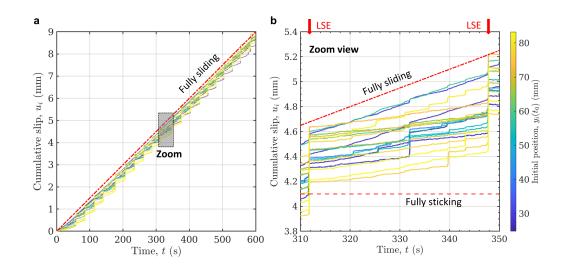

Figure 7. a: Temporal evolution of the cumulative slip in the x direction for 20 asperities during an experiment under a normal load of 200 N and a loading rate of 15.0  $\mu$ m/s. The cumulative slips of the 20 asperities are colored-coded by their initial y positions at time  $t_0$ . b: Zoom view of Figure 7a showing the detailed behaviors of asperities during one time interval between two large stick-slip events (LSE) and ranging from 310 s to 350 s. Fully sticking indicates a locked state while fully sliding gives the slope of the imposed displacement rate to the system.

#### 343

## 3.2 Slip Velocity of Asperities

344 345

346

347

Slip velocity reflects the slipping rate of asperities, which is estimated using a given discretization of the time (i.e., time step) during the whole experiment. The slip velocity  $v_i(t_k)$  of each asperity *i* is computed as

$$v_i(t_k) = \frac{s_i(t_k)}{\Delta t} = \frac{u_i(t_k) - u_i(t_{k-1})}{\Delta t},$$
(4)

where  $s_i(t_k)$  is the slip of the asperity *i* at time  $t_k$  and  $\Delta t$  is the fixed time step of 1/29.97 348 s determined by the sampling rate of the camera, i.e.,  $t_k - t_{k-1}$ . Following the same ex-349 perimental data used in Figure 7, for illustration, the slip velocity of all the 144 asper-350 ities ranging from time 330 s to time 350 s is shown in Figure 8, where the asperities are 351 sorted in ascending order by their initial positions  $x_i(t_0)$ . A LSE involving the synchronous 352 slipping of all the asperities is observed at the time 348 s. We also observe several small 353 stick-slip events that share the same characteristic, which is the synchronized sliding of 354 only a part of the asperities. 355

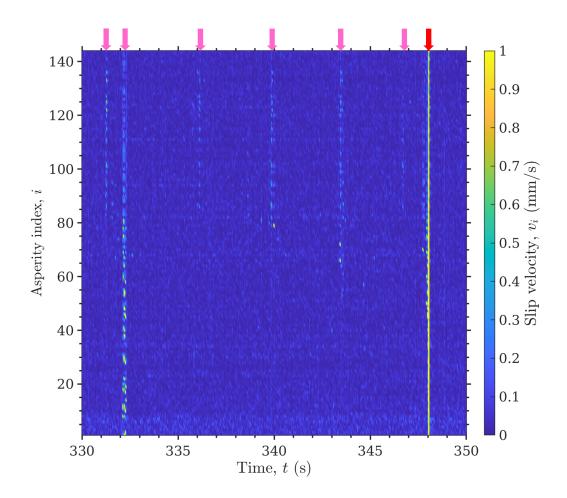

Figure 8. Slip velocity of all the asperities during the time period ranging from 330 s to 350 s of the same experiment shown in Figure 7. The asperities are sorted in ascending order by their initial x positions at time  $t_0$ ,  $x_i(t_0)$ . A large stick-slip event (LSE) indicated by the red arrow occurred at time 348 s observed, where all the asperities are synchronously slipping. During the sticking phase, there are also several small stick-slip events (SEs) which are indicated by the pink arrows involving the slipping of a part of asperities.

#### 3.3 Mechanical Response of the Interface

356

360

In order to document the mechanical response of the frictional interface, we analyze how the friction coefficient,  $\mu = F_S/F_N$ , evolves as a function of slip. We compute the spatial average of the cumulative slip,  $\langle u(t) \rangle$ , over all asperities, N, following

$$\langle u(t) \rangle = \frac{1}{N} \sum_{i=1}^{N} u_i(t), \tag{5}$$

which is a global indicator of the collective behavior of all the asperities. As multiple seis-361 mic cycles (i.e., large stick-slip events) are produced during a single experiment, we re-362 port in Figure 9a the evolution of  $\mu$  as a function of  $\langle u(t) \rangle$ , for all the cycles of a single 363 experiment. Each cycle is separated based on the onset of a large scale slip event LSE 364 (observed when  $\mu$  reaches a local maximum before an abrupt decrease). The value of the 365 friction coefficient mainly ranges between 0.10 and 0.23, which is a low friction coeffi-366 cient but comparable to the values in other PMMA-PMMA interfaces (Baumberger & 367 Caroli, 2006; Selvadurai & Glaser, 2015). We observe, in each cycle, an overall frictional 368 strengthening stage during the sticking phase and a weakening stage during the slipping 369 phase. 370

To focus on the sticking phase of the whole faulting process, the variations of fric-371 tion coefficient,  $\Delta \mu$ , and of the average cumulative slip,  $\Delta \langle u(t) \rangle$ , are both computed rel-372 ative to their respective values at the onset of these large scale slips. We plot the fric-373 tion coefficient variation,  $\Delta \mu$ , as a function of the variation of the average cumulative 374 slip of all the asperities,  $\Delta \langle u(t) \rangle$ , by superimposing all the sticking phases and the slip-375 ping phases, where each onset of the slipping phase is set to be  $\Delta \mu = 0$  and  $\Delta \langle u(t) \rangle =$ 376 0 (Figure 9b). The curves represent the sticking phase while the circles represent only 377 a few time steps after the onset of the LSE. We observe a good similarity between all 378 seismic cycles, proving the repeatability of our observations. We observe that the fric-379 tion coefficient during the period preceding the large scale event (LSE) is increasing. This 380 strengthening of the interface is occurring while the interface is slipping. We observe that 381 during this overall increase of the friction coefficient, there exist multiple instances where 382  $\mu$  actually drops significantly compared to the error of the friction coefficient measure-383 ment. The strengthening of the interface (an overall increase of  $\mu$ ) is thus not a homo-384 geneous process and is slip-controlled in a non-linear manner. This shows as well that 385 this strengthening stage, conventionally considered as the stable regime of a fault, ac-386 tually consists of many small-scale destabilizing events. The rapid slip that occurs dur-387

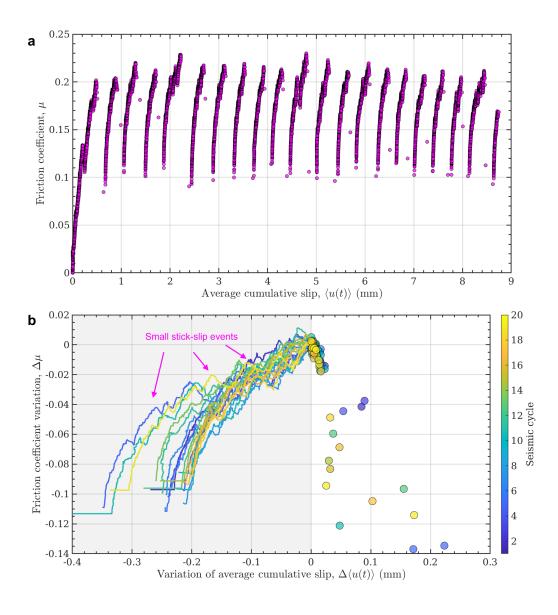

Figure 9. a: Evolution of the friction coefficient,  $\mu$ , as a function of the average cumulative slip,  $\langle u(t) \rangle$ , during the same experiment shown in Figure 7 with multiple seismic cycles. b: Friction coefficient variation,  $\Delta \mu$ , as a function of the variation of the average cumulative slip of all the asperities,  $\Delta \langle u(t) \rangle$ , for the same experiment shown in Figure 9a. All the seismic cycles represented by different colors are superimposed together by setting the onset of each slipping phase as the origin. The colored curves in the shadow indicate different sticking phases while the circles denote the corresponding slipping phases.

ing a LSE is not well captured by our experiments mainly because of the limited time
resolution of the camera that does not allow a sufficient time sampling during this stage.
It is also possible that the weakening part is velocity dependent which is not well captured here since Figure 9b represents the friction coefficient as a function of slip with no
information on the velocity.

393

403

# 3.4 Topographical Effect on Interseismic Slipping Behaviors

Our results show that many small stick-slip events accompanied by friction coef-394 ficient drops are found during every fault strengthening stage (Figure 9). These inter-395 seismic, small stick-slip events result from the slip of a limited number of asperities on 396 the interface. In order to identify what controls the number and the amount of these par-397 tial slips, we document the interseismic slipping behaviors of the asperity using the in-398 terseismic coupling coefficient (Hyndman et al., 1997). We denote the onset times of the 399 j and the j+1 large stick-slip events as t(LSE(j)) and t(LSE(j+1)), respectively. To 400 describe the extent of the slipping of the asperity i during the interseismic phase between 401 t(LSE(j)) and t(LSE(j+1)), the interseismic coupling,  $\lambda_{i,j+1}$ , is computed as 402

$$\lambda_{i,j+1} = 1 - \frac{u_i(t(\text{LSE}(j+1))) - u_i(t(\text{LSE}(j)))}{d_P(t(\text{LSE}(j+1))) - d_P(t(\text{LSE}(j)))}.$$
(6)

We note that  $\lambda$  is in the range [0, 1], where  $\lambda = 0$  indicates no coupling or fully sliding while  $\lambda = 1$  denotes a fully coupled interface or sticking. For experiments with multiple seismic cycles, we compute the final interseismic coupling for each asperity *i* by averaging  $\lambda_i$  over all of the interseismic phases.

With the experimental data used in Figure 9, we present the interseismic coupling 408 of these asperities along the interface (Figure 10). We observe a large scale trend of this 409 interseismic coupling that we can link with the same trend observed from the peak height 410 of asperity derived from the topographical map (Figure 3b). A higher peak height of as-411 perity corresponds to a higher interseismic coupling while a smaller peak height is cor-412 responding to a lower interseismic coupling. This can be interpreted in terms of normal 413 stress on the asperity where a higher peak height causes a greater normal stress, and there-414 fore creates the locking of the asperity which increases the interseismic coupling. On the 415 contrary, the asperities with smaller peak heights have a low normal stress and thus can-416 not accumulate large shear stress (and consequently large slip deficit) and will fail more 417 often during the interseismic phase and have a low coupling, i.e., low values of  $\lambda$ . 418

-21-

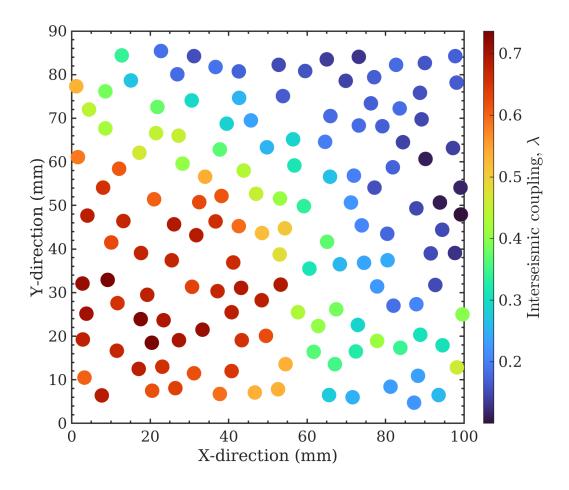

Figure 10. Map of the interseismic coupling of asperities along the interface using the same experimental data shown in Figure 9. A similar pattern between the peak heights of asperity (Figure 3b) and the interseismic coupling is observed, which shows that a larger peak height corresponds to a larger interseismic coupling whereas a smaller peak height corresponds to a lower interseismic coupling.

We also investigate the direct effect of the macroscopic normal load on the inter-419 seismic coupling, as shown in Figure 11. For all experiments with the same normal load, 420 we compute the interseismic coupling of each asperity, which is indicated by the color 421 circles. The average evolution of the interseismic coupling with peak heights conceals some 422 scattering. Indeed, we can observe from Figure 11 that for the same normal load and 423 the same asperity height, different values of  $\lambda$  are computed. To present the evolution 424 of the interseismic coupling as a function of the peak height of asperity, we average the 425 interseismic coupling values over peak heights within a bin width of 0.10 mm. It evidences 426 that, when the normal load is low: 10 N and 25 N, all the asperities have a quite small 427 interseismic coupling, a value that is not distinguishable from zero. The interseismic cou-428 pling shows no dependency on the peak height. This is consistent with the mechanical 429 response of the fault system shown in Figure 4, where the global fault slips almost steadily 430 under the normal loads of 10 N and 25 N. 431

As the normal load increases and becomes large enough such that large stick-slips 432 of the whole fault system are observed, we evidence that interseismic coupling is then 433 dependent on the peak height of asperities. The asperities with low peak heights cor-434 respond to low normal stresses, thus inducing the small stick-slip events observed in be-435 tween the large stick-slip events due to a small interseismic coupling. For the same peak 436 height of asperity, the interseismic coupling increases with the increase of normal stress, 437 which strengthens the locking of the asperities. The maximum value of the interseismic 438 coupling is about 0.55 which is significantly lower than 1. This is consistent with the par-439 tial slipping of asperities shown in Figure 7b and Figure 8. It is interesting to note a tran-440 sition of the interseismic coupling, for a given normal load, at a specific peak height thresh-441 old. This peak height threshold is decreasing as a function of the increased normal stress 442 (from about 2.67 mm at 50 N to about 1.85 mm at 700 N). The interseismic coupling 443 above this peak height threshold converges for all loading conditions to a constant value 444 of around 0.6. Below the threshold,  $\lambda$  decreases towards 0. 445

446

# 4 Interactions between Asperities during the Strengthening Phase

447

# 4.1 Collective Slip Episodes

To investigate the spatiotemporal interactions of asperities, we use a two-step procedure in order to define and characterize slip episodes (SEs). In the first step, we an-

-23-

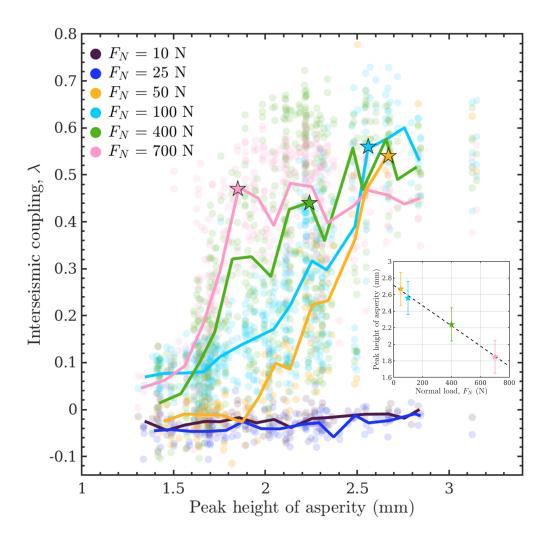

Figure 11. Evolution of the interseismic coupling at different peak heights of asperity under multiple normal loads. The circles with one filled color are the dataset computed for all the experiments under the corresponding normal load. Each curve is obtained by averaging the interseismic coupling over the peak height of asperity with a bin width of 0.10 mm. The inset displays the peak height of asperity at transitions from high to low coupling (stars) as a function of the normal load, where the peak height of asperity decreases with the increase of the normal load.

alyze individually each asperity to isolate individual asperity slips (IASs) from their slip history. In the second step, we identify collective behavior by clustering IASs based on their time and space connection to build slip episodes. The first step is realized by thresholding the velocity  $v_i(t)$  for each asperity *i*. We use a threshold  $\Gamma_i$  specifically for each asperity *i*, which is determined by considering the median  $\tilde{v}_i$  and the median absolute deviation  $D_i^{med}$  of the slip velocity  $v_i(t)$ ,

$$\Gamma_i = \tilde{v}_i + c \cdot D_i^{med},\tag{7}$$

We test several values of the coefficient c in front of  $D_i^{med}$  (see Figure S1) and found 457 that the value retained here (c = 6) is best able to separate noise from slip event. Fol-458 lowing equation (7), we define the IASs as periods with  $v_i(t) > \Gamma_i$  while the others with 459  $v_i(t) \leq \Gamma_i$  are taken as minor slip events and possible noise, and are not included in the 460 catalog of IASs. Figure 12 presents the slip events (blue stars) of one single asperity (i461 = 98) for the same experiment displayed in Figure 7 and its corresponding threshold  $\Gamma_{98}$ 462 (thick magenta line). We find a diversity of slip velocities of IASs. To display the IASs 463 with low slip velocities during the interseismic phase, we zoom in on Figure 12 during 464 a time interval between two large stick-slip events, ranging from 310 s to 350 s (the same 465 time period exhibited in Figure 7b). The observation that several IASs with moderate 466 maximum slip velocity are observed for this asperity is actually consistent with the small 467 stick-slip events found during the fault strengthening stage shown in Figure 9. For each 468 experiment, we establish a complete catalog of IASs by computing the slip velocity  $v_i(t)$ 469 of all the asperities and the corresponding threshold  $\Gamma_i$ . 470

To cluster in space and time all the IASs defined at different asperities into collec-471 tive SEs covering multiple asperities and time steps, we analyze the time and space con-472 nections of these IASs. We define a link between a pair of IASs if the two events are sep-473 arated in time by one or less time step and if they have a spatial connection (i.e., they 474 are nearest neighbor), introducing a two-dimensional Delaunay triangulation, and con-475 sidering the location of each asperity as a vertex (Lee & Schachter, 1980). The edges of 476 the resulting triangulation give the spatial connection between asperities used to make 477 clusters. Additionally, we assume that an asperity is always spatially linked with itself. 478 The IASs simultaneously connected in time and space scales are clustered as a new SE 479 using a single linkage clustering algorithm (Gan et al., 2020). IASs that are not linked 480 to other neighboring IASs are considered as individual SEs. Figure 13 shows one SE last-481

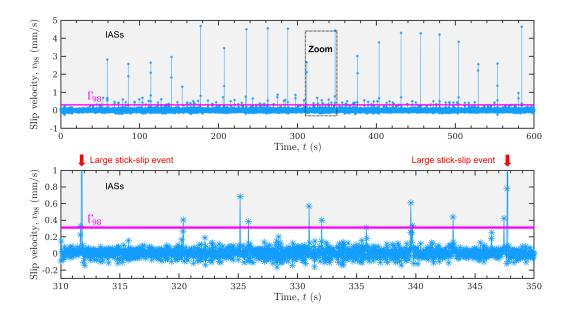

Figure 12. Time-localized slip events produced by a single asperity (i = 98) in the same experiment shown in Figure 7. The blue stars and the thick magenta line represent slip events and the corresponding threshold  $\Gamma_{98}$  specifically computed for this asperity. The slip events localized in the shadow region with slip velocity greater than the threshold are defined as IASs while the others indicating minor slip events and noise are removed. A zoom view showing the low amplitude IASs during an interseismic phase ranging from 310 s to 350 s is presented below. Several IASs with low slip velocities are observed.

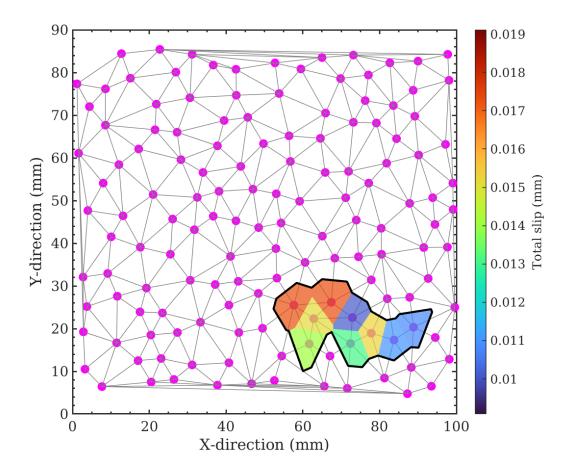

Figure 13. Example of one SE lasting one time step which is composed of nine IASs (polygons with different colors) colored by their total slips. The magenta dots and gray lines indicate the bead locations and the spatial connections all over the interface determined by the Delaunay triangulation, respectively.

ing only one time step, and composed of nine IASs. The polygons with different colors
represent the slip area allocated to each IAS and are determined by the Voronoi diagram
corresponding to the performed triangulation (Fortune, 1995). We, therefore, are able
to build the catalog of spatiotemporal SEs for each experiment.

486

# 4.2 Magnitude-Frequency Distribution

In order to characterize the so-formed slip events, we first investigate their magnitude distribution. The magnitude of the slip event is estimated based on the computation of their moment,  $M_0$ . For one SE containing *n* IASs, its seismic moment is com<sup>490</sup> puted as:

495

$$M_0 = \sum_{i=1}^n G \cdot A_i \cdot s_i,\tag{8}$$

where G is the shear modulus of the PMMA,  $A_i$  and  $s_i$  are respectively the slip area and the slip of each IAS *i* that compose this SE. Then, we can calculate the magnitude Mof each SE following (Hanks & Kanamori, 1979) as:

$$M = (\log_{10} M_0 - 9.05)/1.5. \tag{9}$$

The magnitude-frequency distributions of the SEs extracted from three experiments, 496 which are under the same normal load of 400 N but with three different loading rates, 497 are presented in Figure 14. The symbols with crosses represent the large stick-slip events 498 that involve all the asperities of the interface and subsequently with a size controlled by 499 the finite size of the interface. As evidenced already for finite systems, the distribution 500 of events is bimodal: exponentially distributed size for the events not reaching the in-501 terface and a peak for system-wide events (Fisher et al., 1997). Excluding system-wide 502 events, the observed distributions follow a typical Gutenberg-Richter distribution (Gutenberg 503 & Richter, 1944):  $\log_{10} N(m) = a - bm$ . For the three experiments under loading rates 504 of 5.0  $\mu$ m/s, 10.0  $\mu$ m/s, and 15.0  $\mu$ m/s and a normal load  $F_N = 400$  N, their b values 505 are  $1.21\pm0.05$ ,  $1.44\pm0.1$ , and  $1.35\pm0.12$ , respectively. A gray dashed line showing a ref-506 erence b value of 1.3 is displayed in Figure 14. We can observe that all these three ex-507 periments have a b value nearly similar to this reference. It shows that the b value has 508 no clear dependence on the loading rate of the system. In addition, our experimental re-509 sults show that the b value is insensitive as well to the imposed normal load (see Table 510 S2). 511

512

#### 4.3 Moment-Duration Scaling Relation

For regular earthquakes, a scaling relation between the moment and the duration is commonly observed and takes the form  $M_0 \propto T^3$  (Kanamori & Anderson, 1975). This relation can be understood from the representation of an earthquake as a circular crack expanding at a constant speed and with a constant stress drop. Another scaling relation has also been resolved for slow slip events observed in subduction megathrusts which follows the form  $M_0 \propto T$  (Gao et al., 2012; Ide et al., 2007).

We represent from our SEs the relation between their duration, T, defined as the time difference between its onset and end, and their moment,  $M_0$  (Figure 15a). The moment-

-28-

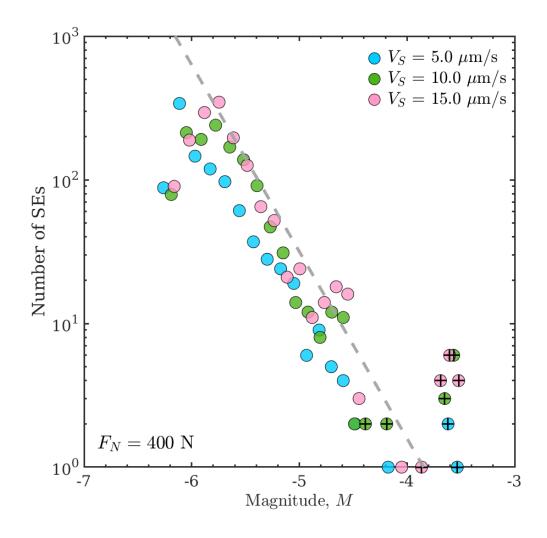

Figure 14. Magnitude-frequency distribution at different loading rates under the same normal load of 400 N. The circle symbols marked by crosses indicate the large stick-slip events at the global fault scale, which are excluded from the computation of the b value. The gray dashed line indicates a reference line with a b value of 1.3.

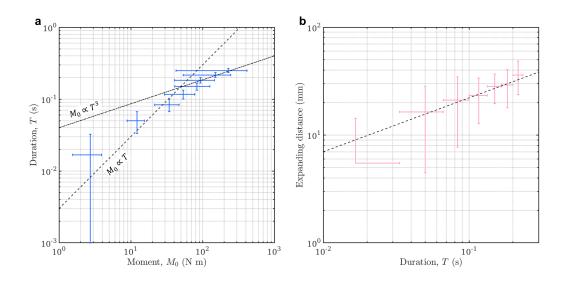

Figure 15. a: Moment-duration scaling relation obtained using SEs from all experiments at various normal loads and loading rates. The black dash-dotted line and dashed line represent the scaling relations of  $M_0 \propto T^3$  and  $M_0 \propto T$ , respectively. The largest slip events, reaching the edge of the sample have been excluded. b: Scaling relation between the expanding distance of SEs and their duration. The black dashed line represents the square-root scaling relation between the expanding distance and the duration.

- duration scaling is represented for all experiments with various normal loads and loading rates. In order to retain in this analysis only confined ruptures and not be influenced by the condition at the edge of the sample, the largest slip events reaching the edge of the sample are excluded. We evidence a linear scaling relation close to  $M_0 \propto T$  for all the experiments for  $M_0 < 100$  N m and a transition to the scaling for earthquakes ( $M_0 \propto T^3$ ) for the largest events.
- For each SE, excluding large-scale stick-slip events, we also compute the distance between the first and last slipping asperities. The duration and expanding distance are averaged to present their relation, as shown in Figure 15b. We observe a square-root scaling relation between the expanding distance and the duration.

#### 4.4 Temporal Decay of Slip Episodes

In order to investigate the possible time interaction between our identified SEs, we compute the time correlation between them, C(t) with

$$C(t) = \frac{1}{Tn_t} \sum_{i=1}^{n_t} \sum_{j=i+1}^n \Theta(t_j - t_i \in [t; t+T]), \qquad (10)$$

where  $\Theta(\mathcal{P})$  of proposition  $\mathcal{P}$  is 1 if  $\mathcal{P}$  is true and 0 otherwise. In order to take into ac-535 count the time finiteness of the catalog, the first sum is performed up to  $n_t$  which is the 536 largest index i such that  $t_n - t_i < t + T$ , where T is the duration of the time bin. The 537 equation (10) actually gives the average rate of SEs at time t following a preceding slip 538 event and we represent an example of C(t) computed for an experiment under a normal 539 load of 200 N and a loading rate of 15  $\mu$ m/s (Figure 16). We observe a rapid decrease 540 of C(t) at a short time range, following a power law decay similar to 1/t. After a dura-541 tion of about 1 s, the average rate of SE stabilizes to a background rate of around 2 SEs 542 per second. This indicates that interactions between SE exist for a short time and that 543 they quickly decay. This evolution of the event's rate bares some analogy with Omori's 544 law observed after large earthquakes which gives as well a decay of the earthquake rate 545 following 1/t (Utsu et al., 1995). 546

#### 547 5 Discussion

548

531

534

#### 5.1 Interseismic Coupling

Our results indicate that the interseismic slip rate relative to the loading rate, i.e. 549 the interseismic coupling,  $\lambda$ , is related at first order to the normal stress imposed on the 550 asperities. The transition from small to high coupling is a function of the normal load 551 (the height of the asperity at this transition is decreasing with normal stress) but the 552 value of the coupling at high or low normal stress is the same for any normal load. This 553 is visible first as a global macroscopic effect affecting all asperities when we change the 554 imposed normal load in our experiments (Figure 11). This can also be observed at the 555 individual asperity scale where we observe that the asperity peak height is correlated with 556  $\lambda$ . Indeed, considering a simple Hertz contact model, a higher asperity height results in 557 higher normal stress. The distribution of asperity heights in our experiments, therefore, 558 leads to a distribution of normal stresses and a continuum of values of  $\lambda$  (Figure 11). 559

-31-

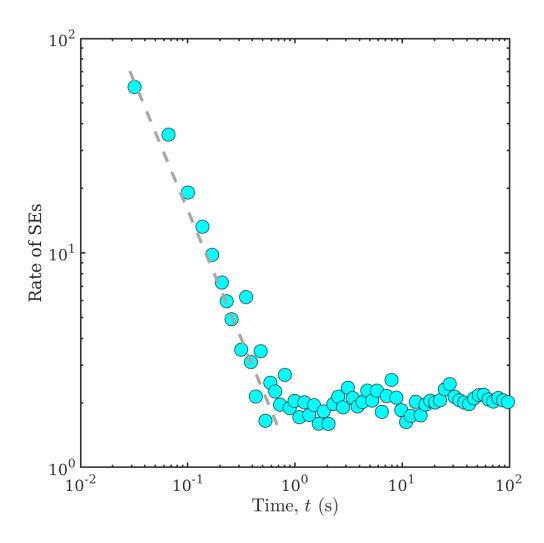

Figure 16. Temporal decay of SEs defined in an experiment under a normal load of 200 N and a loading rate of 15  $\mu$ m/s. The rate of SEs first decays rapidly with 1/t during about 1 s and then keeps stable as a background value of about 2 SEs per second.

It is tempting to relate the characteristic asperity height in our experiment to the 560 critical reduction in the normal force,  $\Delta F_N^*$ , that controls the transition from low to high 561 coupling, as identified in the model of Scholz and Campos (1995, 2012). We note how-562 ever that in this model the transition results from the sole effect of the global normal 563 load since the interface is considered as homogeneous. This approach is thus describing 564 the effective seismic coupling of the interface but not that of the asperities, which we can 565 achieve in our experiments. We interpret that the effective coupling of the interface is 566 a function of the quenched disorder of the fault and then indirectly of the normal stress. 567 If we assume the same height of all the asperities, there would be no variance in inter-568 seismic coupling at different asperities at the same time. Similarly, the whole interface 569 would have the same behavior as that of the asperities and lead to little collective effect. 570 We emphasize here that a large scale topography of a fault with variations of the asper-571 ity heights can influence the effective seismic coupling of the fault differently from a clas-572 sical normal stress level effect. This is a collective effect but related to the quenched dis-573 order of the asperities. 574

Finally, we acknowledge that the definition of interseismic coupling is not completely satisfactory as it fails to capture the variation of the slip velocity inferred on some asperities in between two large scale stick-slip events. Indeed, we highlighted some transient activity and non-steady slipping rate for asperities which indicate that the value we computed only represents an effective behavior of the asperity at the time scale between two large scale stick-slip events.

581

#### 5.2 Interfacial Elastic Energy

Our results evidence that for an interface composed of multiple asperities, as in our 582 system, local slip events with various sizes (see Figure 14) are taking place at all times. 583 We also note that large scale events that involve slips on all asperities of the interface 584 are also observed. These large scale slip events can only happen when sufficient large stress 585 has been accumulated on the strongest asperities. This requires that asperities at some 586 time are synchronized such that initiating the failure at one location triggers the cascad-587 ing rupture of all the asperities on the interface, thus generating the large scale stick-588 slip event. This is equivalent to a collective depinning induced by the long range elas-589 tic interactions in a slowly (quasi-static) loaded system. 590

We quantitatively illustrate such synchronization effect by computing the evolution of the interfacial elastic energy,  $E_h$ , and of the bulk elastic energy,  $E_t$ , following the definition of Schmittbuhl et al. (1996). The interfacial elastic energy,  $E_h$ , is quantified through the sum of the relative distance between two asperities over all the spatial links defined by the two-dimensional Delaunay triangulation:

596

607

$$E_h(t) = K_N \sum_{k=1}^{D} \left( l_k(t) - l_k(t_0) \right)^2, \tag{11}$$

where  $l_k$  is the relative distance computed through the x positions of two asperities linked 597 spatially and D is the number of the spatial links between two asperities defined by the 598 Delaunay triangulation.  $K_N$  is the compressive stiffness between asperities, computed 599 through  $K_N = E_s \langle d_{asp} \rangle$ , where  $E_s$  denotes Young's modulus of the silicone block and 600  $\langle d_{asp} \rangle$  is the average distance between a sperities which estimated to be 6 mm. The in-601 terfacial elastic energy,  $E_h$ , actually quantifies the variance of the change of distance be-602 tween neighboring asperities, thus is related to the elastic force interactions between as-603 perities. The bulk elastic energy,  $E_t$ , is the total elastic energy stored on the interface 604 through the global loading, which is characterized by the collective change in the abso-605 lute positions of all the asperities along the x direction: 606

$$E_t(t) = K_S \sum_{i=1}^{N} (d_i(t))^2, \qquad (12)$$

where  $K_S$  is the shear stiffness estimated using  $K_S = G_s L$ .  $G_s$  is estimated from Young's modulus of the silicone block, 1.1 MPa, while L is the size of the interface, 10 cm. N is the total number of asperities and  $d_i$  the displacement of each asperity.

We present the interfacial elastic energy,  $E_h$ , and the bulk elastic energy,  $E_t$ , as a 611 function of the PMMA plate displacement,  $d_P$ , for different experiments with various 612 normal loads but the same loading rate, as shown in Figure 17. We identify multiple large 613 scale stick-slip events and the corresponding fault strengthening phases from the large 614 abrupt drops of  $E_t$  and the slow accumulation of  $E_t$ , respectively. We also observe a sim-615 ilar pattern for the evolution of  $E_h$ , which is equivalent to the direct measure of the spread-616 ing of the x positions of the asperities apart from their initial position where  $E_h = 0$ . 617 Additionally, we observe a clear dependency of  $E_h$  and  $E_t$  on the normal load, which is 618 consistent with the mechanical response of the fault system shown in Figure 4. With the 619 increase of normal load, the interfacial elastic energy,  $E_h$ , and the bulk elastic energy, 620  $E_t$ , also increase. 621

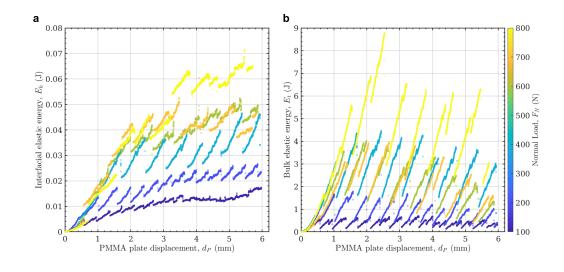

Figure 17. Evolution of (a) the interfacial elastic energy,  $E_h$ , and of (b) the bulk elastic energy,  $E_t$ , under different normal loads and the same loading rate. Both  $E_h$  and  $E_t$  accumulate slowly during the fault strengthening phases and drop when a large stick-slip event occurs. Both  $E_h$  and  $E_t$  show a clear dependency on the normal load.

Such evolution of the elastic energies during successive seismic cycles illustrates the 622 disordering effect of asperities and the build-up of the elastic energy during the strength-623 ening phase. We interpret the rising  $E_h$  as the disordering process of asperities, that is 624 the strong perturbation from the initial position which is supposed to be quenched in 625 the system. The sticking phases correspond to a period of increase of  $E_h$  during which 626 the asperities increase disordering, while a large scale event corresponds to the rapid de-627 crease of  $E_h$  (re-ordering of the asperities). We note that during such a large scale event, 628 while  $E_t$  drops significantly and returns to zero, the drop of  $E_h$  is only partially such that 629 a disorder, and elastic energy, is still present after a large event. It implies that there is 630 a memory effect over the cycles from the relative positions of the asperities. 631

We also observe a transient period at the beginning of the shearing where the evolution of  $E_h$  is similar for all experiments. As the normal stress is increased a larger level of  $E_h$  is reached in the system, so a larger disordering of the asperities. It implies that higher normal stress prevents the interface to come back to its initial state (with low  $E_h$ ) even during a LSE and so maintains a larger disorder in the system with internal stresses along the interface at any time.

The process of synchronization has been well documented notably in numerical sim-638 ulations and shows that only for forces larger than a critical force, that constitute a crit-639 ical point, the system will become unstable and sliding will extend to all sites of the in-640 terface (Fisher et al., 1997; Tanguy et al., 1998; Kammer et al., 2015; de Geus et al., 2019; 641 Albertini et al., 2021). This constitutes a depinning transition and this phenomenology 642 leads to stick-slip. In such models, this critical force is linked to a critical length scale, 643  $L_c$ , of an initiating slip pulse, that will invade all the interface if its extension becomes 644 larger than  $L_c$ . Most of these results were inferred from a homogeneous fault model. Here, 645 both the evolution of the macroscopic force (Figure 9) and the distribution of slip events 646 in Figure 14 are not in agreement with these predictions. Indeed, we first observe in Fig-647 ure 9 that the macroscopic force required to propagate a full scale event is not perfectly 648 constant but rather displays some fluctuations from one rupture to the other. Secondly, 649 the distribution of event magnitudes (Figure 14) shows almost no gap between the largest 650 avalanche and the whole interface avalanche. It, therefore, implies that avalanches of all 651 sizes can exist in the system without necessarily leading above a certain size to a com-652 plete failure. In such a case one would expect a larger gap in event size between the max-653 imum observed avalanche and the system wide event. Such different nucleation mode can 654 arise in the heterogeneous system as interactions between arrested small events could ex-655 ist and significantly modifies the process leading to a major rupture (Albertini et al., 2021). 656 Interpreting these results in terms of fault mechanics suggests that creeping faults cor-657 respond to the interface with an asperity disorder and a strengthening regime with dis-658 ordering of the interface by small destabilizing events that increase elastic interaction 659 between asperities but without impacting the global fault loading. 660

661

#### 5.3 Slip Intermittency

Our system is driven by a constant displacement rate for each experiment and we 662 measure a macroscopic velocity of the PMMA plate that is indeed constant (except dur-663 ing a large-scale event, where a small but noticeable displacement step is observed). This 664 macroscopic measurement mimics the measure that could be made around natural faults 665 by geodetic instruments located at the surface, and thus necessarily far away from the 666 slipping area at depth. It implies that such kind of measurement actually misses the ac-667 tual complexity of the slip distribution taking place on the interface at a short time and 668 spatial scale. Some fine measurements of the slip distribution in both time and space for 669

shallow creeping faults indeed reveal that the long term continuous creeping of faults is 670 actually accommodated during bursts of aseismic slip of various sizes (Jolivet et al., 2013, 671 2015; Rousset et al., 2016; Khoshmanesh & Shirzaei, 2018). During slow slip events, the 672 analysis of GPS signal in conjunction with the recording of low frequency earthquakes 673 (LFEs) also reveals that the large scale motion along the slab consists in the superpo-674 sition of numerous small slip episodes each acting for a limited duration (Frank, 2016; 675 Frank & Brodsky, 2019). The analysis of LFEs as a proxy for local slip on the interface 676 reveals as well that these slip episodes span a wide range of sizes and present both tem-677 poral and spatial correlation (Lengliné et al., 2017). All these results are well in agree-678 ment with the observations performed in this study where the interseismic slip on the 679 fault is characterized by slip events (SEs) of different sizes that act in a close temporal 680 relationship. 681

The slip events we characterized here are slow events in the sense that their du-682 ration with respect to their size is much lower than the Rayleigh wave speed of the ma-683 terial that constitutes the interface. Indeed, supposing a typical PMMA Rayleigh veloc-684 ity of 1255 m/s (Gvirtzman & Fineberg, 2021), this would imply that in one time frame 685 (1/29.97 s) a dynamic rupture front travels up to 42 m. This is inconsistent with the ob-686 servations of SEs that last several time frames. If we suppose that most of the stress trans-687 fer between asperities is actually mediated by the silicone base embedding the PMMA 688 beads, this gives a Rayleigh wave velocity of the order of 20 m/s, and then the propa-689 gation of a rupture front of 66 cm in one time frame. As the largest SEs have a typical 690 duration of 0.3 s and cover a maximum area with a characteristic dimension of half the 691 sample length (5 cm), this suggests that the SEs formed by our criterion actually cor-692 respond to slow events. It does not preclude local dynamic rupture to take place dur-693 ing such SEs, but their size might be limited to a single bead contact area (or smaller). 694 This implies that the moment-duration scaling we report in Figure 15 should be inter-695 preted as scaling attached to slow ruptures on the interface. The best-resolved trend shows 696  $M_0 \propto T$  in agreement notably with the observations of (Ide et al., 2007) that show that 697 many slow slip events on subduction zones follow this scaling law. We note however that 698 the scaling in our experiment is only resolved over a restricted range of moments. This 699 calls for future further experiments involving an increase in the number of beads and the 700 sampling rate of the optical device. This moment-duration scaling is also in agreement 701 with the observed evolution of the slip event characteristic distance with the square root 702

-37-

of duration. This, therefore, suggests that the slip events are driven by a diffusion process controlling the propagation of the rupture, similar to slow-slip events tracked with
tremor migration (Ide, 2010).

The slip event, SEs are characterized as a single rupture following the clustering 706 procedure we defined. It is not obvious how to select the merging condition which is im-707 posed partially in our case by the acquisition rate of the optical device. However, what 708 is the exact definition and extent of a slip event is not a question limited to our exper-709 iment. Indeed, the analysis of earthquakes for example, generally indicates that they are 710 actually composed of several sub-events. The identification of these sub-events, there-711 fore, questioned the definition of the earthquake rupture that consists of several connected 712 local slip episodes. As we discussed above, the same problem of definition arises for a 713 slow slip event which is actually made of a sum of local transient slip episodes connected 714 in time and space. Decreasing the time interval required to merge individual asperity 715 slips into the same cluster would ultimately lead to only isolated local slip events. On 716 the opposite, increasing this time interval would lead to a single slip event comprising 717 all the beads. Finally, we conclude that SEs are thus analyzed at the spatial and tem-718 poral scale imposed by our acquisition system which is a constraint imposed as well to 719 observations made on natural fault systems. 720

721

#### 5.4 Mechanics of the Strengthening Regime

Our system resolves confined rupture that takes place during the strengthening phase. 722 This contrasts with most frictional setups where only large scale ruptures are analyzed 723 during the weakening phase. Unlike these large scale ruptures that are largely controlled 724 by the machine loading stiffness (Leeman et al., 2016; Wu & McLaskey, 2019), partial 725 ruptures provide the opportunity to study the slip events taking place on an interface 726 without being actually influenced by the loading system. In our system, the events are 727 arrested because of stress heterogeneity that arises notably from the variable asperity 728 heights creating spatial differences in frictional strengths. We stress that the heteroge-729 neous nature of the interface only arises as a result of the topography and the position 730 distribution of the asperities with respect to their initial position (assessed by the inter-731 facial elastic energy  $E_h$ ), but that there is no variation of the material properties that 732 constitute the interface. In particular, it implies that the complex dynamic that we re-733 covered during our experiment is not the result of a heterogeneous spatial distribution 734

-38-

of the *a* and *b* parameters of the rate-and-state friction model as employed in several simulations of faulting (Barbot et al., 2012). We note that such approaches are based on a continuum description of the interface and do not model the failure of individual asperities where locations in between are contact-free and hence have zero frictional strength like in our case.

Our results indicate that the strengthening phase, which could be seen as the prepara-740 tory phase of large ruptures, includes a population of events that are multi-scale in size 741 (Gutenberg-Richter relation in Figure 14) and in duration (Figure 15). A similar multi-742 scale size distribution has also been reported by Nasuno et al. (1998) for the events that 743 occurred during the strengthening phase along a sheared fault gouge layer simulated by 744 spherical glass particles that are similar to our asperities. Such granular layers have also 745 been numerically modeled by Aharonov and Sparks (2004), which evidenced a transi-746 tion from weak to strong contacts accompanied by accelerating internal stress release of 747 grains before large stick-slip events. It suggests that such a transition of localized con-748 tacts during the strengthening phase could be considered as a precursor for the impend-749 ing large scale stick-slip. Combined with our results, it implies that the preparatory phase 750 of large earthquakes is very long with many foreshocks strongly related to the quenched 751 disorder. This result is highly reproducible with the same disorder in the asperity po-752 sitions. 753

754

#### 5.5 Limitations of the Experimental Setup

Our novel experimental setup builds a heterogeneous shear interface of multi-asperity 755 contacts. An important point resulting from the designed configuration is that the el-756 evated adhesion of the silicone block to the asperities is strong enough such that there 757 is no rolling of asperities caused by the shearing imposed on the PMMA plate. Similarly, 758 we also make sure that the silicone block is at no time in contact with the PMMA plate 759 during the experiment. Indeed, in such a case, the high adhesion of the silicone would 760 cause a local resistance to slip and modify the modeled physical process (from friction 761 to adhesion). This limits the maximum normal load we can impose on the system to ap-762 proximately 1500 N, at a higher imposed normal load, the silicone block starts to have 763 some local contacts with the PMMA plate. 764

-39-

The sampling rate of the camera employed directly determines the time resolution 765 for tracking the slips of asperities. Thus, the rapid slipping phase involving multiple as-766 perities cannot be analyzed in detail. For example, it is not sampled with a high enough 767 time resolution to capture a clear trend of the decay of the shear force as a function of 768 slip during these episodes (see Figure 9). Furthermore, the precise timing, migration, or 769 interactions of local bead slips during the high slipping phase is not accessible. Finally, 770 as we evidence, the overall rupture during such SEs is slow but it does not preclude that 771 locally during such slow transient, local dynamic rupture occurs such that some propor-772 tion of the resolved slip is actually taking place during such dynamic phase and radiate 773 elastic wave. The proportion of the slip taking place on the asperities as dynamic events 774 is presently not measurable but remains to be investigated for future studies. 775

The derivation of the moment,  $M_0$ , of the slip events required the computation of 776 an area,  $A_i$ , attached to each asperity (see Eq. 8). Here we take for each asperity the 777 area returned by the Voronoi cell including the asperity. Such a definition of the slip area 778 attached to an asperity probably over-estimate the real slipping area during an IAS. In-779 deed, the locked area of an asperity is presumably much lower than a circle of the as-780 perity radius (considering a Hertz contact model) (K. L. Johnson, 1987). Although some 781 slip deficit can extend beyond the fully locked area, it becomes negligible at a distance 782 typically greater than one asperity radius (L. R. Johnson, 2010). It then leads to an over-783 estimation of the computed moment. However, as the contact area for each asperity should 784 be nearly similar (considering again the Hertz contact model and the low stiffness of the 785 silicone) we can expect that the conclusion of the magnitude distribution presented in 786 Figure 14 would be unchanged if one could obtain a precise measurement of the slipping 787 area of each IAS. We thus acknowledge that the reported moment of slip events should 788 be mostly interpreted relatively than as absolute values. Such complexity of the slip dis-789 tribution is also observed for natural earthquakes with zones of little or no slip (Freymueller 790 et al., 2021). 791

Another ambiguity is involved in the calculation of the moment from equation (8). Indeed, the shear modulus used in this equation is taken as the shear modulus of the PMMA. However the PMMA is the dominant material only on one side of the system, the other side is composed of the PMMA beads embedded in the silicone block. Characterizing the shear modulus for such bi-material is not a trivial task and again further warns against a direct interpretation of the absolute values of  $M_0$ .

### 798 6 Conclusions

This study analyzes the collective behavior of numerous discrete asperities ( $N \approx$ 799 140) modeled on an analog fault interface during multiple seismic cycles. We show that 800 an interface composed of multiple discrete asperities can have a macroscopic behavior 801 that is distinct from that of its individual elements. The asperities present a diversity 802 of slips at various speeds. We evidence the dependency of the interseismic coupling of 803 the interface with the topographical map of the asperity summits and the normal load 804 imposed on the system. We notably show that topographic variations of the asperity sum-805 mits have a pronounced effect on this coupling. The slip intermittency of the activity 806 of clustered asperities indicates that the interface undergoes local episodes of creep that 807 ultimately lead to the global slip of the interface. The analysis of the evolution of the 808 elastic energy along the interface helps to track the disordering of the asperities with re-809 spect to their initial position. We show that this energy is typically higher for large nor-810 mal stress, which supports the conclusion that normal stress maintains a larger disor-811 der in the system. It shows as well that the disorder increases during the strengthening 812 phase and is only partially reduced during large slip events. Significant statistical fea-813 tures of slip widely observed in natural faults are reproduced by our experiments like the 814 Gutenberg-Richter law, Omori's law, and the moment-duration scaling, suggesting that 815 the obtained results can be extrapolated to natural fault systems. 816

Figure S1. Natural earthquakes usually show the characteristic of the cluster of seismicity which actually implies that the isolated events are uncommon. In our experiments, we consider the percentage of isolated slip episodes as a function of different values of the coefficient of  $D_i^{med}$ . We find the percentage first decreases sharply and then keeps relatively constant. We, therefore, determine the value of 6 which controls the transition as the optimal coefficient of  $D_i^{med}$ .

Table S1. Details of the parameters for each experiment are listed in Table S1.

:

Table S2. We list the b value of each experiment with a specific normal load and displacement rate in Table S2. It shows that the b value has no clear dependence on the loading rate of the system. In addition, our experimental results show that the b value is insensitive as well to the imposed normal load.

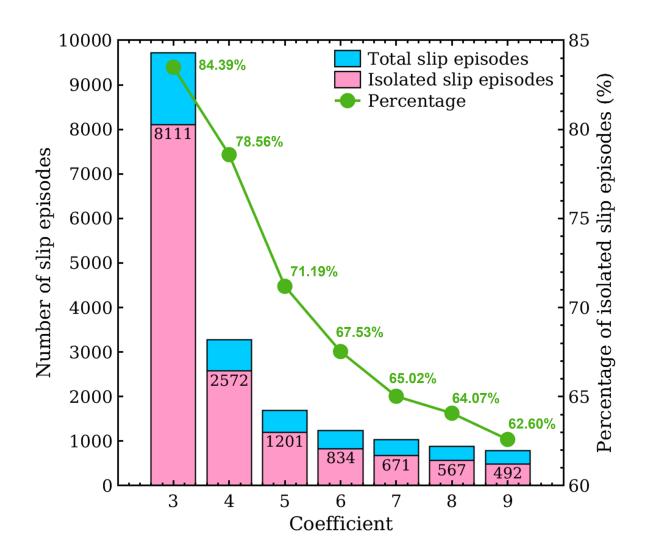

Figure S1. Quantitative comparison for determining the optimal value of the coefficient of  $D_i^{med}$ . With the increase of the value of the coefficient, the percentage of isolated slip episodes first decreases sharply and then keeps relatively stable. The value of 6 that controls the transition is determined as the optimal coefficient of  $D_i^{med}$ .

Table S1.	Parameters	of each	experiment
TUNIO NTI	I GIGINIOUOID	or coon	onpornition

March 8, 2023, 9:33pm

:

Experiment	Normal load (N)	Displacement rate $(\mu m/s)$	b value
1	200	5.0	$1.08 \pm 0.13$
2	400	5.0	$1.22 {\pm} 0.08$
3	600	10.0	$1.16 {\pm} 0.11$
4	800	10.0	$1.17 {\pm} 0.13$
5	1000	15.0	$1.05 {\pm} 0.14$
6	100	5.0	$1.25 {\pm} 0.11$
7	100	10.0	$1.28 {\pm} 0.11$
8	100	15.0	$1.08{\pm}0.08$
9	200	5.0	$1.35 {\pm} 0.11$
10	200	10.0	$1.49 {\pm} 0.15$
11	200	15.0	$1.40 {\pm} 0.15$
12	400	5.0	$1.21 {\pm} 0.05$
13	400	10.0	$1.44{\pm}0.10$
14	400	15.0	$1.35 {\pm} 0.12$
15	600	5.0	$1.28 {\pm} 0.12$
16	600	10.0	$1.19 {\pm} 0.09$
17	600	15.0	$1.29 {\pm} 0.10$
18	700	5.0	$1.17 {\pm} 0.10$
19	700	10.0	$1.17 {\pm} 0.10$
20	700	15.0	$1.45 {\pm} 0.07$
21	800	5.0	$1.18 {\pm} 0.15$
22	800	10.0	$1.13 {\pm} 0.10$
23	800	15.0	$1.88 {\pm} 0.16$
24	50	5.0	$1.58 {\pm} 0.10$
25	25	5.0	$1.60{\pm}0.09$
26	10	5.0	$2.04{\pm}0.09$
27	100	15.0	$1.30{\pm}0.08$
28	100	15.0	$1.11 \pm 0.05$
