Abstract

The inversion of remote sensing signatures of internal solitary waves (ISWs) can retrieve dynamic characteristics in the ocean interior. The ubiquitous large-amplitude ISWs limit the weakly nonlinear methods commonly used to retrieve wave parameters. We establish the relationship between surface features and internal characteristics of ISWs in laboratory experiments through the correspondence of the remote sensing signatures and the surface velocities of ISWs. The results show that the strong nonlinearity makes the solution of wave-induced velocity inseparable, and ISW theories under the weakly nonlinear assumption are inappropriate to describe strongly nonlinear ISWs from the surface. Therefore, the fully nonlinear model Dubreil–Jacotin–Long equation is used in the retrievals and has been well verified in both the laboratory and oceans. Mooring observations and the model show that stratification conditions differentiate the relationship between remote sensing signatures and ISW parameters in deep and shallow seas.

18 **Abstract**

19 The inversion of remote sensing signatures of internal solitary waves (ISWs) can retrieve

20 dynamic characteristics in the ocean interior. The ubiquitous large-amplitude ISWs limit the

21 weakly nonlinear methods commonly used to retrieve wave parameters. We establish the

22 relationship between surface features and internal characteristics of ISWs in laboratory

23 experiments through the correspondence of the remote sensing signatures and the surface

24 velocities of ISWs. The results show that the strong nonlinearity makes the solution of wave-

25 induced velocity inseparable, and ISW theories under the weakly nonlinear assumption are

26 inappropriate to describe strongly nonlinear ISWs from the surface. Therefore, the fully

27 nonlinear model Dubreil–Jacotin–Long equation is used in the retrievals and has been well

28 verified in both the laboratory and oceans. Mooring observations and the model show that

29 stratification conditions differentiate the relationship between remote sensing signatures and ISW

30 parameters in deep and shallow seas.

31

32 **Plain Language Summary**

33 Internal solitary waves (ISWs), as nonlinear internal waves, play an essential role in oceanic

34 human activities and ocean mixing. The surface current induced by ISWs can create rough and

35 smooth regions on the sea surface due to the modulated roughness, hence presenting alternating

36 bright and dark stripes in satellite images. Satellites can observe ISWs over a wide range via

37 surface manifestations, and the internal dynamics can be calculated from surface features using

38 retrieval methods. However, the availability of retrieval methods still needs to be verified, facing

39 the difficulty of matching mooring observations and satellite images of the same ISW in a short

40 time interval. According to the proportional relation of remote sensing signatures and wave-

41 induced velocities, this study establishes the relationship between surface features and internal

42 characteristics of ISWs in laboratory experiments. Different from the weakly nonlinear models

43 used in previous studies, a fully nonlinear model is used in the retrieval and has achieved good

44 results in the laboratory and oceans. The model and mooring observations show the critical role

45 of stratifications in the retrieval. This work provides a reliable dynamics model for the inversion

46 of remote sensing signatures of ISWs into characteristics in the ocean interior.

1 Introduction

Internal solitary waves (ISWs) are widespread in marginal seas (Jackson, 2007), and are usually generated due to the nonlinear steepening of internal tides (Ramp et al., 2010). With large amplitudes and strong currents, ISWs can damage ocean engineering and underwater vehicles (Huang et al., 2016; Klymak et al., 2006; Osborne & Burch, 1980). The breaking of ISWs during shoaling can cause enhanced mixing, change underwater acoustic transmission, and affect nearshore ecosystems (Alford et al., 2015; Chiu et al., 2013; Moum et al., 2003; Wang et al., 2007).

ISWs create convergence and divergence zones on the sea surface, resulting in rough and smooth regions on the sea surface due to the modulated roughness (Lenain & Pizzo, 2021; Yue et al., 2022) and presenting alternating bright and dark stripes in satellite images. The characteristics of ISWs, such as wave crest length, propagation direction and propagation speed can be acquired from the images (Jackson, 2007; Liu et al., 2014; Zhao et al., 2004), while other essential characteristics such as amplitude and wavelength cannot be directly obtained. Therefore, retrieval methods of ISW parameters based on physical models have been proposed, which establish the relation between the remote sensing characteristics and other wave parameters in the ocean interior. A variety of retrieval methods were established using different ISW theories and wave-induced velocity calculation methods.

A retrieval method based on the Korteweg-de Vries (KdV) equation was first proposed (Small et al., 1999; Zheng et al., 2001) and widely used for determining ISW parameters (Fan et al., 2015; Gong et al., 2021; Hong et al., 2016; Phaniharam et al., 2020; Wang et al., 2022; Xie et al., 2022). This method established the relation between the ISW distribution of stripes and their wavelengths. Then, the waveform and amplitude could be determined with stratifications. Retrieval methods using the Joseph–Kubota–Ko–Dobbs (JKKD) equation for finite depth (Pan et al., 2007), the Benjamin–Ono (BO) equation for infinite depth (Chen et al., 2011; C. Wang et al., 2019) and the extended KdV (eKdV) equation (Jia et al., 2019; Xue et al., 2013) were also proposed to analyze satellite images similarly. These methods above were based on a weakly nonlinear assumption, which assumes that the amplitude of ISWs is small compared with the intrinsic vertical scale (Choi & Camassa, 1999). Under the weakly nonlinear assumption, the solution of the wave-induced velocity is considered to be separable in the horizontal and vertical directions.

78   However, strongly nonlinear ISWs that do not satisfy the weak nonlinearity assumption

79   account for a large proportion of in-situ oceanic observations. (Chang et al., 2021; Huang et al.,

80   2022; Stanton & Ostrovsky, 1998; Yang et al., 2021). Although weakly nonlinear theories have

81   been used outside their formal range of validity in some cases (Helfrich & Melville, 2006), for a

82   detailed description of the dynamics of large-amplitude ISWs observed in the real ocean,

83   theoretical models with strong nonlinearity are needed (Vlasenko et al., 2000). The Miyata–

84   Choi–Camassa (MCC) equation, a fully nonlinear theory of long waves was proposed and agreed

85   well with laboratory experiments (Camassa et al., 2006; Kodaira et al., 2016). Meanwhile,

86   without any assumptions, the fully nonlinear Dubriel–Jacotin–Long (DJL) equation has been

87   applied effectively in the laboratory and the ocean (Camassa et al., 2018; Chang et al., 2021;

88   Lien et al., 2014; Luzzatto-Fegiz & Helfrich, 2014). Different from the separable solution of

89   velocity under weakly nonlinear approximation, the solution cannot be separated with strong

90   nonlinearity. To date, strongly nonlinear effects on the retrievals of wave parameters have not

91   been fully considered in the following two aspects: (1) the calculation of wave-induced velocities

92   and (2) the applicability of ISW theories. The adequate modeling of ISW dynamics should be

93   determined in the retrieval, as mentioned by Romeiser and Graber (2015).

94   To address the difficulty of matching mooring observations and satellite images of the

95   same ISW in a short time interval, this paper establishes the relationship between surface

96   features and internal characteristics of ISWs in laboratory experiments. Then the strongly

97   nonlinear effects on retrieving ISW parameters are evaluated in terms of wave-induced velocities

98   and ISW theories. Finally, we assess the retrieval of wave parameters in different oceanic

99   environments.

2   Methodology

101   2.1 Laboratory experiments and data processing

102   Experiments are conducted in the Key Laboratory of Physical Oceanography, Ocean

103   University of China. Two layers of fluid with thickness of h_1 and h_2 and densities of 1020kg/m^3

104   and 1040kg/m^3 are injected into the tank. The depth ratio of the lower and upper layers

105   h_2/h_1 vary from 3 to 10. The waves are generated by the lock–release method (Sutherland et al.,

106   2015), with nondimensional amplitudes η_0/h_1 ranging from 0.18 to 2.50; see Table S1 in the

107   supporting information for the detailed conditions. Two synchronous charge coupled device

108   (CCD) cameras with bandpass filters are set in front of the tank. The wave-induced velocity is

109   measured by particle image velocity (PIV) (Thielicke & Stamhuis, 2014; S. Wang et al., 2019),

110   and the waveform $\eta(x)$ is determined by identifying the depth where the maximal vertical

111   density gradient is located using the synthetic Schlieren technique (Dalziel et al., 2007). The

112   wavelength of ISWs is defined as

113
$$L_w = \frac{1}{2\eta_0} \int_{-\infty}^{\infty} \eta(x)\, \mathrm{d}x. \tag{1}$$

114

115   **Figure 1.** Schematic of experiments. (a) ISWs captured by ENVISAT on June 18, 2008, UTC.

116   (b) Relative image intensity along the direction of wave propagation (the red line in subfigure a).

117   (c) The surface horizontal velocity divergence of the ISW in the laboratory experiment. The gray

118   and black lines present the original and smoothed results, respectively. Red dashed lines indicate

119   the horizontal position corresponding to the maximum and minimum values. (d) Schematic

120   diagram of the experiment in the same case as subfigure c.

121   We consider the radar imaging theory which describes the influence of surface currents

122   on remote sensing imaging (Alpers, 1985) as

123
$$\frac{\Delta\sigma}{\sigma_0} \propto -\frac{\partial u_s}{\partial x},\tag{2}$$

124   where $\Delta\sigma = \sigma - \sigma_0$ denotes the deviation of the normalized radar cross-section intensity from its

125   mean value, u_s denotes the velocities of surface currents, and the x direction is defined as the

126   direction of wave propagation. This means that the signal in satellite images (Figure 1a and 1b)

127   can be calculated from the divergence of surface velocities induced by ISWs in an equilibrium

128   and steady environment. The distance between the positive peak and the adjacent negative peak

129   D_{p-p} in satellite images of ISWs is less affected by winds in most cases (Brandt et al., 1999;

130   Xue et al., 2013). Hence the peak-to-peak distance D_{p-p} is chosen to characterize the surface

131   features of ISWs in our experiments (Figure 1c and 1d), which is expressed as

132
$$D_{p-p} = \left| x_{\left|\frac{\partial u_s}{\partial x}=\min\left(\frac{\partial u_s}{\partial x}\right)\right.} - x_{\left|\frac{\partial u_s}{\partial x}=\max\left(\frac{\partial u_s}{\partial x}\right)\right.} \right|.\tag{3}$$

133   2.2 Theories

134   The weakly nonlinear ISW models we used are the KdV, JKKD, BO, and eKdV

135   equations. For strongly nonlinear ISWs models, we consider the MCC and DJL equations (see

136   Text S1).

137   The wave-induced velocity used for quantifying surface divergence can be determined by

138   the stream function (Stastna & Peltier, 2005) :

139
$$\psi(x,z) = c\eta(x,z).\tag{4}$$

140   For a given waveform $\eta(x)$, the solution of the induced horizontal velocity under weakly

141   nonlinear conditions has the following separable form, in which the vertical modes are

142   independent of the horizontal location:

143
$$u(x,z) = \frac{\partial \psi(x,z)}{\partial z} = c_0 \eta(x) \frac{\partial \phi_b(z)}{\partial z},$$
(5)

144 where c_0 is the linear phase speed and $\phi_b(z)$ is obtained by solving the Sturm–Liouville

145 equation, written as:

146
$$\left(\frac{d^2}{dz^2} + \frac{N_b^2(z)}{c_0^2} \right) \phi_b(z) = 0 \qquad \phi_b(-H) = \phi_b(0) = 0,$$
(6)

147 where $N_b(z)$ is the given background buoyancy frequency, calculated by:

148
$$N_b^2(z) = -\frac{g}{\rho_0} \frac{d\rho(z)}{dz},$$
(7)

149 where g is the gravitational acceleration, $\rho(z)$ is the density profile, and ρ_0 is the reference

150 density.

151 If strong nonlinearity is considered, the isopycnal displacement caused by ISWs should

152 be considered when calculating the vertical structure. Therefore, the vertical structure function

153 should depend on x as well (Apel, 2003). The solution of the induced horizontal velocity is

154 calculated in the following inseparable form:

155
$$u(x,z) = c\eta(x) \frac{\partial \phi_{wave}(x,z)}{\partial z},$$
(8)

156 where $\phi_{wave}(x,z)$ is the vertical structure function of strongly nonlinear ISWs, calculated by

157 iterating the changed stratification and $\eta(x,z)$ with the initial value of $\eta(x)$ (see Text S2).

3   Results

### 3.1 Separability of the solution of wave-induced velocity

Figure 2. Experimental results with h_2/h_1=5, $\eta_0/h_1 = 1.44$. (a) The solid black line is the background density profile measured by the conductivity probe, and the dashed line is the density profile at the wave crest calculated by iteration. (b) Horizontal velocity profile at the crest, the red line, blue line, and diamond are the velocities in the separable form, inseparable form, and experiment, respectively. The legend is the same in (b, d, e). (c) Waveform. (d) Surface horizontal velocity, (e) Divergence of horizontal velocity at the surface. The red and blue dashed lines indicate the horizontal positions where the divergences reach peaks.

To visually show the influence of strong nonlinearity on the structure of wave-induced velocities, here we take a case of h_2/h_1=5 and η_0/h_1 =1.44 as an example in which the amplitude is of the same magnitude as h_1 and shows significant nonlinearity. In terms of horizontal velocity magnitude and structure, there are differences between the velocity solutions in separable (Eq.5) and inseparable (Eq.8) forms (Figure 2b and 2d). The PIV measurements

173   match the velocity solution in inseparable form well in both the magnitude and the structure. In

174   the upper layer, the solution of velocity in separable form is more than twice the inseparable

175   form, while they are closer in the lower layer. This difference between observations and

176   theoretical solutions in separable form was also observed in the ocean, see Fig.13 of Rong et al.

177   (2023). This can be explained by the flow conservation that the influence of ISWs on the

178   stratification changed the thickness of the upper and lower layers. Figure 2e shows the distances

179   of divergence peaks, where the distance in inseparable form is larger. The differences reach a

180   maximum of 33% in the case of $\eta_0/h_1 = 2.20$. In previous studies, the relationship between

181   D_{p-p} and L_w can be obtained directly by calculating velocity in separable form, as $D_{p-p} = 1.32$

182   L_w in the KdV equation, and the ratio is independent of the amplitude. However, the

183   experimental results show that the ratio varies from 1.4 to 2.7 with increasing amplitude. The

184   results calculated in the inseparable form are consistent with the experiments (see Figure S1).

185   Therefore, the strong nonlinearity cannot be neglected in the velocity calculation, especially with

186   increasing wave amplitude. In Section 3.2, only the solution in inseparable form will be used to

187   calculate velocities.

188   3.2 Remote sensing characteristics of ISWs

189   The relationship between remote sensing characteristics and wave parameters will be

190   established in this section, and the applicability of each ISW theory will be evaluated by

191   comparing it with experimental results. Here we take two cases of $h_2/h_1=5$, $h_1=0.04$ m, and 0.08

192   m as examples. The results under the other stratifications are shown in Figures S2–S4. Our

193   experiments mainly focus on the ISWs under strong nonlinearity, and the small amplitude ISWs

194   have been fully proven to be consistent with the theoretical and experimental results in previous
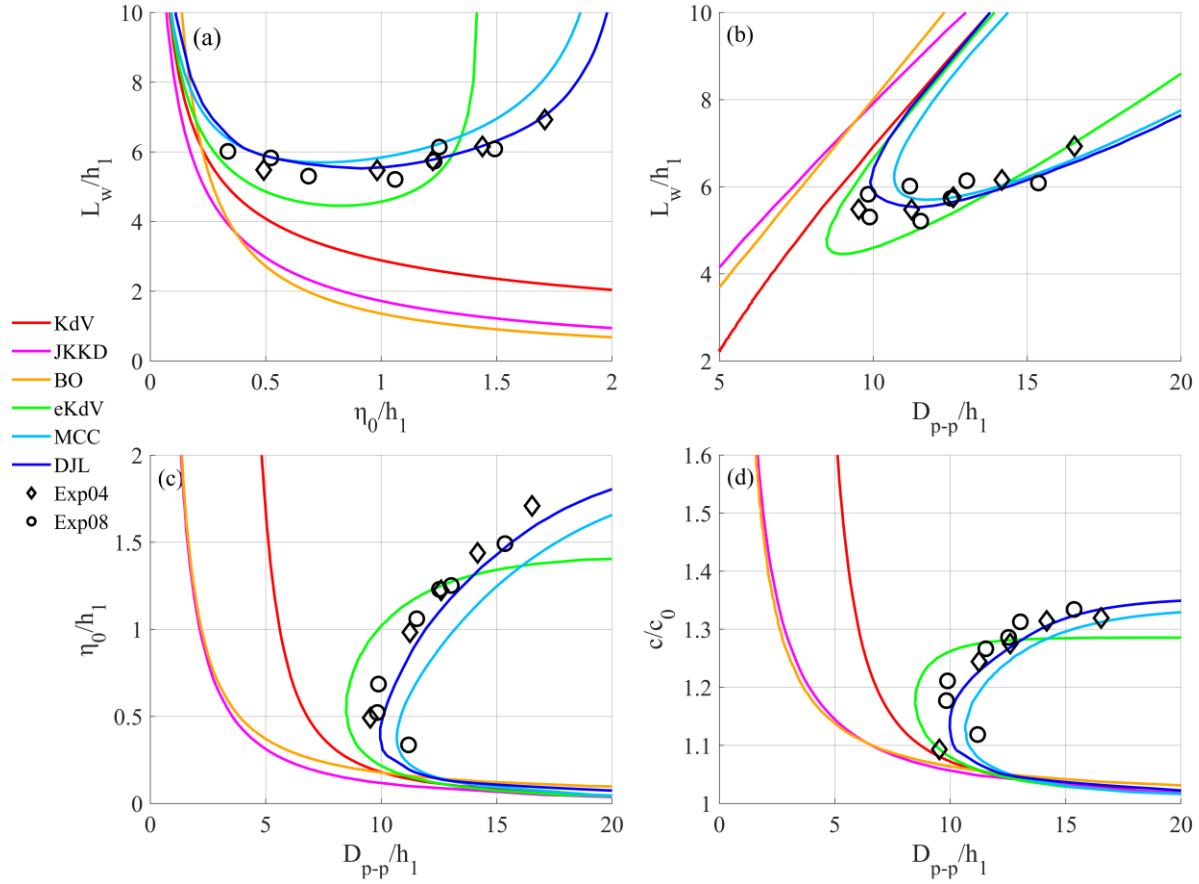

195   studies (Ostrovsky & Stepanyants, 2005).

196

Figure 3. Theoretical and experimental results with $h_2/h_1 = 5$, (a) the variation of L_w with η_0.
(b), (c), and (d) are the relationships between D_{p-p} and wavelength, amplitude, and phase speed,
respectively. The red, magenta, yellow, green, light blue, and dark blue lines represent the KdV,
JKKD, BO, eKdV, MCC, and DJL equations respectively. The black diamond (Exp04) and the
circle (Exp08) represent the experimental results for $h_1 = 0.04$ m and 0.08 m, respectively.

Figures 3b-3d show the variation in wave parameters with the peak-to-peak distance
D_{p-p}. The results from the KdV, JKKD, and BO equations show a similar pattern, in which
parameters change monotonically with D_{p-p}. However, for the eKdV, MCC, and DJL equations,
the relationship between the wave parameters and D_{p-p} is no longer monotonic. Its typical
feature is the existence of a turning point, which means that one D_{p-p} will correspond to two
parameters, that is, the existence of double solutions. The selection method for double solutions
can be determined by the properties of wave packets that the leading wave reaches the maximum
amplitude (Xue et al., 2013). In addition, both the eKdV equation and the fully nonlinear

210   equations have a limiting amplitude, which varies with different stratifications (Cui et al., 2021),

211   and the limiting amplitude of the eKdV equation is smaller than that of the MCC and DJL

212   equations. The comparison between the theoretical and experimental results shows that it is

213   feasible to describe the remote sensing characteristics of ISWs with theoretical models.

214   To quantitatively compare the differences between ISW theories and experimental results

215   in retrievals, we define the relative deviation (RD) as follows

$$\text{RD} = \left| \frac{\lambda_{theory} - \lambda_{exp}}{\lambda_{exp}} \right| * 100\%, \tag{9}$$

217   where λ_{theory} and λ_{exp} are any theoretical and experimental parameters under a specific D_{p-p}. If

218   the D_{p-p} of some experiments are smaller than the theoretical minimum value, the theoretical

219   turning point is used to calculate its RD. In Figure 4, the KdV equation is only applicable in

220   relatively small amplitudes at any stratification. For the eKdV equation, significant RD is caused

221   in the retrieval with dimensionless amplitude ranging between 0.5–1, corresponding to the

222   turning point with smaller D_{p-p} in this range. In addition, its limiting amplitude restricts its

223   application at large amplitudes. Therefore, the eKdV equation is applicable to ISWs with small

224   or nearly limiting amplitudes. For the MCC equation, the turning point gradually shifts to the

225   direction of D_{p-p} lengthening with increasing depth. The RD becomes larger with the gradual

226   failure of the long wave assumption. The DJL equation has great applicability in all conditions.

227   In laboratory conditions, the RD of wavelength and phase speed are less than 10% in retrievals,

228   and the RD of small amplitude is approximately 30% which is mainly caused by the relative

229   magnitude of variation, measurement errors, and dissipations, while RD of other amplitude is
230   reduced to 10%.

Figure 4. RD between theoretical and experimental results in retrievals using D_{p-p}. (a)-(d) are RD of KdV, eKdV, MCC, and DJL equations in retrieving wavelength, (e)-(h) are RD in retrieving amplitude, and (i)-(l) are RD in retrieving phase speed. The color bar indicates RD% in each condition, and the black dashed line in (f) indicates the limiting amplitude.

4 Discussion

The above work explores the retrieval of wave parameters in a quasi-two-layer procedure under laboratory conditions. However, the complex environments in the ocean introduce difficulties and variety to retrieval. Therefore, the applicability of the established method is further tested with oceanic observations.
Figure 5. Relationship between D_{p-p} and amplitude of each location calculated by the DJL equation. (a) The dark line, light blue, green, orange and red lines are the results of mooring stations with depths of 200 m, 600 m, 953 m, 2762 m, and 3745 m. Dashed lines of corresponding colors indicate the maximum amplitude of the observed ISW at each station. (b) The dark blue line is the results of stations with a depth of 200m, the dots represent the measured ISWs, and their colors indicate the upper layer depth before the arrival of ISWs. The horizontal axis represents the time interval of peak-to-peak in the mooring observation.

The results at several locations with long-term mooring are shown in Figure 5. The 200 m depth is S5 during the Asian Seas International Acoustics Experiment (ASIAEX) (Duda et al., 2004), the 600 m depth station is LR1 of Chang et al. (2021), and the 953 m, 2762 m, and 3745 m depth stations are M1, M6, and M10 of Huang et al. (2022). The yearly mean climatological WOA18 dataset is used in the DJL equation except for the location of 200 m. The stratification in 200 m depth is given by the average results of temperature profiles in observations before each

255   ISW arrives. In Figure 5b, 49 ISWs were observed during ASIAEX. The amplitude is defined as

256   the maximum isotherm displacement. Using the time series of upward-looking ADCP with an

257   interval of 1 min, we estimate D_{p-p} by

258
$$D_{p-p} = c \left| t_{\left|\frac{\partial u_s}{\partial t} = \min\left(\frac{\partial u_s}{\partial t}\right)\right.} - t_{\left|\frac{\partial u_s}{\partial t} = \max\left(\frac{\partial u_s}{\partial t}\right)\right.} \right|, \tag{10}$$

259   and the axis is set to D_{p-p}/c due to the absence of the phase speed c. Different from the

260   laboratory results, the relationship between surface features and amplitudes is relatively scattered

261   in the ocean. The amplitude will be greatly different under one condition. Even in a short period

262   of 15 days, the upper layer depth will change between 30 m and 60 m corresponding to the

263   amplitude difference, and this short-period change may be caused by surface forcing (Font et al.,

264   2022). As seen from the scatter, thicker and thinner upper layers usually correspond to smaller

265   and larger amplitudes, respectively. The amplitudes are affected by this variation in stratification

266   over a short period, as observed by Small et al. (1999) and Lien et al. (2014). The difficulty in

267   obtaining real-time stratification will cause errors in retrieving the parameters of a specific ISW.

268   Nevertheless, the DJL equation using an average stratification can still reveal the trend of wave

269   parameters with remote sensing characteristics, which will play an important role in the

270   statistical work of the properties of ISWs using satellite images.

271   The curves under the measured maximum amplitude show different patterns. The

272   amplitudes decrease approximately with the increase in D_{p-p} in a deep sea of more than 2700 m.

273   At approximately 1000 m, the amplitudes decrease monotonically except for a small area near

274   the turning point. For the 600 m and 200 m stations, the amplitudes above the turning point will

275   increase with increasing of D_{p-p} while those below the turning point will decrease. The

276   selection rule in the retrieval has been mentioned in Section 4.2. Different from other stations,

277   the maximum amplitude observed at 200 m exceeds the limitation calculated by averaged

278   stratification, which may be caused by variations in the upper layer and the shoaling of ISWs.

279   The relationship between the remote sensing characteristics and the wave parameters of ISWs is

280   different at those stations. In fact, the calculation results of the DJL equation under several

281   stratifications indicate that the different stratification characteristics in different areas are the

282   main factors that cause the differences in the retrievals, such as shallow waters with quasi-two-

283   layer stratifications and deep seas with a main thermocline that spans hundreds of meters.

284   Stratification plays a critical role in the retrieval of ISW parameters from satellite images.

285   In shallow seas, the climatological dataset cannot reflect the short-period variation in

286   stratification, and the retrieval of parameters of a specific ISW needs additional information to

287   improve. For the deep seas, the relatively stable stratification provides us with more possibilities

288   for accurate retrieval.

289   **5   Conclusions**

290   In this study, we establish the relationship between the surface and internal characteristics

291   of ISWs in dimensionless laboratory experiments. The strongly nonlinear effects of ISWs in the

292   retrieval of wave parameters are evaluated, and a fully nonlinear model is applied in oceans.

293   Strong nonlinearity causes the solution of the wave-induced velocity to be inseparable, and an

294   iterative method for calculating the velocity solution in inseparable form is proposed and fits

295   well with the experimental results. The difference in the retrieval between velocity solutions in

296   separable and inseparable forms reaches a maximum of 33% in the range of our experimental

297   parameters. ISW theories under weakly nonlinear assumptions have difficulty describing

298   strongly nonlinear ISWs from the surface. The fully nonlinear DJL equation is used in the

299   retrieval and compared with experimental results. The relative deviation of the retrieval of

300   wavelength, amplitude, and phase speed is less than 10% in laboratory experiments except in

301   small amplitude conditions.

302   The determination of ISW parameters from satellite images in oceans is significantly

303   affected by in-situ stratifications. The variation in stratification over a short period can bring

304   errors in retrieving the parameters of a specific ISW. However, the comparison of observations

305   and theory shows that the DJL equation using background stratifications can reveal reasonable

306   internal characteristics of ISWs from surface features. Stratification conditions make the

307   relationship between remote sensing signatures and ISW parameters differ in deep and shallow

308   seas. The amplitudes of ISWs decrease monotonically with increasing D_{p-p} in deep seas, but

309   double solutions should be considered in shallow seas.

310   This work provides a reliable hydrodynamics model for the inversion of remote sensing

311   signatures of ISWs into characteristics in the ocean interior. With the combination of the fully

312   nonlinear model and the satellite imaging mechanism, more underwater information can be

313   interpreted from remote sensing in further work.

10 **Key Points:**

11 • The relationship between the surface and internal characteristics of internal solitary
12   waves is established in laboratory experiments.

13 • A fully nonlinear model is used to determine wave parameters from surface features and
14   has been well verified.

15 • Stratification conditions differentiate the relationship between remote sensing signatures
16   and wave parameters in deep and shallow seas.

17

18 **Abstract**

19 The inversion of remote sensing signatures of internal solitary waves (ISWs) can retrieve

20 dynamic characteristics in the ocean interior. The ubiquitous large-amplitude ISWs limit the

21 weakly nonlinear methods commonly used to retrieve wave parameters. We establish the

22 relationship between surface features and internal characteristics of ISWs in laboratory

23 experiments through the correspondence of the remote sensing signatures and the surface

24 velocities of ISWs. The results show that the strong nonlinearity makes the solution of wave-

25 induced velocity inseparable, and ISW theories under the weakly nonlinear assumption are

26 inappropriate to describe strongly nonlinear ISWs from the surface. Therefore, the fully

27 nonlinear model Dubreil–Jacotin–Long equation is used in the retrievals and has been well

28 verified in both the laboratory and oceans. Mooring observations and the model show that

29 stratification conditions differentiate the relationship between remote sensing signatures and ISW

30 parameters in deep and shallow seas.

31

32 **Plain Language Summary**

33 Internal solitary waves (ISWs), as nonlinear internal waves, play an essential role in oceanic

34 human activities and ocean mixing. The surface current induced by ISWs can create rough and

35 smooth regions on the sea surface due to the modulated roughness, hence presenting alternating

36 bright and dark stripes in satellite images. Satellites can observe ISWs over a wide range via

37 surface manifestations, and the internal dynamics can be calculated from surface features using

38 retrieval methods. However, the availability of retrieval methods still needs to be verified, facing

39 the difficulty of matching mooring observations and satellite images of the same ISW in a short

40 time interval. According to the proportional relation of remote sensing signatures and wave-

41 induced velocities, this study establishes the relationship between surface features and internal

42 characteristics of ISWs in laboratory experiments. Different from the weakly nonlinear models

43 used in previous studies, a fully nonlinear model is used in the retrieval and has achieved good

44 results in the laboratory and oceans. The model and mooring observations show the critical role

45 of stratifications in the retrieval. This work provides a reliable dynamics model for the inversion

46 of remote sensing signatures of ISWs into characteristics in the ocean interior.

1 Introduction

Internal solitary waves (ISWs) are widespread in marginal seas (Jackson, 2007), and are usually generated due to the nonlinear steepening of internal tides (Ramp et al., 2010). With large amplitudes and strong currents, ISWs can damage ocean engineering and underwater vehicles (Huang et al., 2016; Klymak et al., 2006; Osborne & Burch, 1980). The breaking of ISWs during shoaling can cause enhanced mixing, change underwater acoustic transmission, and affect nearshore ecosystems (Alford et al., 2015; Chiu et al., 2013; Moum et al., 2003; Wang et al., 2007).

ISWs create convergence and divergence zones on the sea surface, resulting in rough and smooth regions on the sea surface due to the modulated roughness (Lenain & Pizzo, 2021; Yue et al., 2022) and presenting alternating bright and dark stripes in satellite images. The characteristics of ISWs, such as wave crest length, propagation direction and propagation speed can be acquired from the images (Jackson, 2007; Liu et al., 2014; Zhao et al., 2004), while other essential characteristics such as amplitude and wavelength cannot be directly obtained. Therefore, retrieval methods of ISW parameters based on physical models have been proposed, which establish the relation between the remote sensing characteristics and other wave parameters in the ocean interior. A variety of retrieval methods were established using different ISW theories and wave-induced velocity calculation methods.

A retrieval method based on the Korteweg-de Vries (KdV) equation was first proposed (Small et al., 1999; Zheng et al., 2001) and widely used for determining ISW parameters (Fan et al., 2015; Gong et al., 2021; Hong et al., 2016; Phaniharam et al., 2020; Wang et al., 2022; Xie et al., 2022). This method established the relation between the ISW distribution of stripes and their wavelengths. Then, the waveform and amplitude could be determined with stratifications. Retrieval methods using the Joseph–Kubota–Ko–Dobbs (JKKD) equation for finite depth (Pan et al., 2007), the Benjamin–Ono (BO) equation for infinite depth (Chen et al., 2011; C. Wang et al., 2019) and the extended KdV (eKdV) equation (Jia et al., 2019; Xue et al., 2013) were also proposed to analyze satellite images similarly. These methods above were based on a weakly nonlinear assumption, which assumes that the amplitude of ISWs is small compared with the intrinsic vertical scale (Choi & Camassa, 1999). Under the weakly nonlinear assumption, the solution of the wave-induced velocity is considered to be separable in the horizontal and vertical directions.

78   However, strongly nonlinear ISWs that do not satisfy the weak nonlinearity assumption

79   account for a large proportion of in-situ oceanic observations. (Chang et al., 2021; Huang et al.,

80   2022; Stanton & Ostrovsky, 1998; Yang et al., 2021). Although weakly nonlinear theories have

81   been used outside their formal range of validity in some cases (Helfrich & Melville, 2006), for a

82   detailed description of the dynamics of large-amplitude ISWs observed in the real ocean,

83   theoretical models with strong nonlinearity are needed (Vlasenko et al., 2000). The Miyata–

84   Choi–Camassa (MCC) equation, a fully nonlinear theory of long waves was proposed and agreed

85   well with laboratory experiments (Camassa et al., 2006; Kodaira et al., 2016). Meanwhile,

86   without any assumptions, the fully nonlinear Dubriel–Jacotin–Long (DJL) equation has been

87   applied effectively in the laboratory and the ocean (Camassa et al., 2018; Chang et al., 2021;

88   Lien et al., 2014; Luzzatto-Fegiz & Helfrich, 2014). Different from the separable solution of

89   velocity under weakly nonlinear approximation, the solution cannot be separated with strong

90   nonlinearity. To date, strongly nonlinear effects on the retrievals of wave parameters have not

91   been fully considered in the following two aspects: (1) the calculation of wave-induced velocities

92   and (2) the applicability of ISW theories. The adequate modeling of ISW dynamics should be

93   determined in the retrieval, as mentioned by Romeiser and Graber (2015).

94   To address the difficulty of matching mooring observations and satellite images of the

95   same ISW in a short time interval, this paper establishes the relationship between surface

96   features and internal characteristics of ISWs in laboratory experiments. Then the strongly

97   nonlinear effects on retrieving ISW parameters are evaluated in terms of wave-induced velocities

98   and ISW theories. Finally, we assess the retrieval of wave parameters in different oceanic

99   environments.

100   **2   Methodology**

101   2.1 Laboratory experiments and data processing

102   Experiments are conducted in the Key Laboratory of Physical Oceanography, Ocean

103   University of China. Two layers of fluid with thickness of h_1 and h_2 and densities of 1020kg/m^3

104   and 1040kg/m^3 are injected into the tank. The depth ratio of the lower and upper layers

105   h_2/h_1 vary from 3 to 10. The waves are generated by the lock–release method (Sutherland et al.,

106   2015), with nondimensional amplitudes η_0/h_1 ranging from 0.18 to 2.50; see Table S1 in the

107   supporting information for the detailed conditions. Two synchronous charge coupled device

108   (CCD) cameras with bandpass filters are set in front of the tank. The wave-induced velocity is

109   measured by particle image velocity (PIV) (Thielicke & Stamhuis, 2014; S. Wang et al., 2019),

110   and the waveform $\eta(x)$ is determined by identifying the depth where the maximal vertical

111   density gradient is located using the synthetic Schlieren technique (Dalziel et al., 2007). The

112   wavelength of ISWs is defined as

$$L_w = \frac{1}{2\eta_0} \int_{-\infty}^{\infty} \eta(x)\, dx. \tag{1}$$
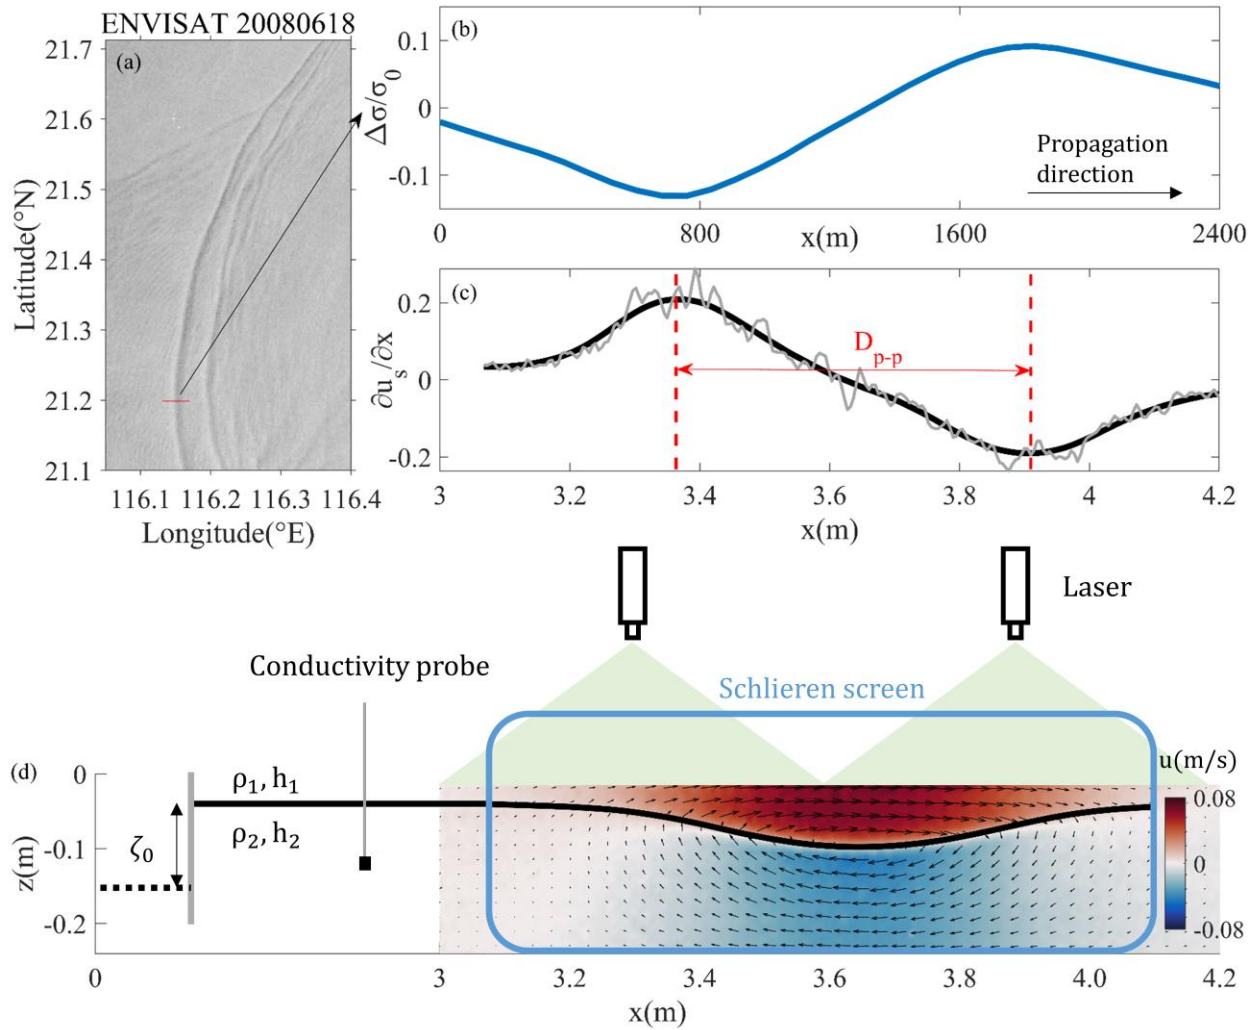

113

114

115   **Figure 1.** Schematic of experiments. (a) ISWs captured by ENVISAT on June 18, 2008, UTC.

116   (b) Relative image intensity along the direction of wave propagation (the red line in subfigure a).

117   (c) The surface horizontal velocity divergence of the ISW in the laboratory experiment. The gray

118   and black lines present the original and smoothed results, respectively. Red dashed lines indicate

119   the horizontal position corresponding to the maximum and minimum values. (d) Schematic

120   diagram of the experiment in the same case as subfigure c.

121   We consider the radar imaging theory which describes the influence of surface currents

122   on remote sensing imaging (Alpers, 1985) as

123
$$\frac{\Delta\sigma}{\sigma_0} \propto -\frac{\partial u_s}{\partial x}, \tag{2}$$

124   where $\Delta\sigma = \sigma - \sigma_0$ denotes the deviation of the normalized radar cross-section intensity from its

125   mean value, u_s denotes the velocities of surface currents, and the x direction is defined as the

126   direction of wave propagation. This means that the signal in satellite images (Figure 1a and 1b)

127   can be calculated from the divergence of surface velocities induced by ISWs in an equilibrium

128   and steady environment. The distance between the positive peak and the adjacent negative peak

129   D_{p-p} in satellite images of ISWs is less affected by winds in most cases (Brandt et al., 1999;

130   Xue et al., 2013). Hence the peak-to-peak distance D_{p-p} is chosen to characterize the surface

131   features of ISWs in our experiments (Figure 1c and 1d), which is expressed as

132
$$D_{p-p} = \left| x\big|_{\frac{\partial u_s}{\partial x}=\min\left(\frac{\partial u_s}{\partial x}\right)} - x\big|_{\frac{\partial u_s}{\partial x}=\max\left(\frac{\partial u_s}{\partial x}\right)} \right|. \tag{3}$$

133   2.2 Theories

134   The weakly nonlinear ISW models we used are the KdV, JKKD, BO, and eKdV

135   equations. For strongly nonlinear ISWs models, we consider the MCC and DJL equations (see

136   Text S1).

137   The wave-induced velocity used for quantifying surface divergence can be determined by

138   the stream function (Stastna & Peltier, 2005) :

139
$$\psi(x,z) = c\eta(x,z). \tag{4}$$

140   For a given waveform $\eta(x)$, the solution of the induced horizontal velocity under weakly

141   nonlinear conditions has the following separable form, in which the vertical modes are

142   independent of the horizontal location:

143
$$u(x,z) = \frac{\partial \psi(x,z)}{\partial z} = c_0 \eta(x) \frac{\partial \phi_b(z)}{\partial z}, \tag{5}$$

144 where c_0 is the linear phase speed and $\phi_b(z)$ is obtained by solving the Sturm–Liouville

145 equation, written as:

146
$$\left(\frac{d^2}{dz^2} + \frac{N_b^2(z)}{c_0^2}\right)\phi_b(z) = 0 \qquad \phi_b(-H) = \phi_b(0) = 0, \tag{6}$$

147 where $N_b(z)$ is the given background buoyancy frequency, calculated by:

148
$$N_b^2(z) = -\frac{g}{\rho_0}\frac{d\rho(z)}{dz}, \tag{7}$$

149 where g is the gravitational acceleration, $\rho(z)$ is the density profile, and ρ_0 is the reference

150 density.

151   If strong nonlinearity is considered, the isopycnal displacement caused by ISWs should

152 be considered when calculating the vertical structure. Therefore, the vertical structure function

153 should depend on x as well (Apel, 2003). The solution of the induced horizontal velocity is

154 calculated in the following inseparable form:

155
$$u(x,z) = c\eta(x) \frac{\partial \phi_{wave}(x,z)}{\partial z}, \tag{8}$$

156 where $\phi_{wave}(x,z)$ is the vertical structure function of strongly nonlinear ISWs, calculated by

157 iterating the changed stratification and $\eta(x,z)$ with the initial value of $\eta(x)$ (see Text S2).

3 Results

### 3.1 Separability of the solution of wave-induced velocity

Figure 2. Experimental results with h_2/h_1=5, $\eta_0/h_1 = 1.44$. (a) The solid black line is the background density profile measured by the conductivity probe, and the dashed line is the density profile at the wave crest calculated by iteration. (b) Horizontal velocity profile at the crest, the red line, blue line, and diamond are the velocities in the separable form, inseparable form, and experiment, respectively. The legend is the same in (b, d, e). (c) Waveform. (d) Surface horizontal velocity, (e) Divergence of horizontal velocity at the surface. The red and blue dashed lines indicate the horizontal positions where the divergences reach peaks.

To visually show the influence of strong nonlinearity on the structure of wave-induced velocities, here we take a case of h_2/h_1=5 and η_0/h_1 =1.44 as an example in which the amplitude is of the same magnitude as h_1 and shows significant nonlinearity. In terms of horizontal velocity magnitude and structure, there are differences between the velocity solutions in separable (Eq.5) and inseparable (Eq.8) forms (Figure 2b and 2d). The PIV measurements

173   match the velocity solution in inseparable form well in both the magnitude and the structure. In

174   the upper layer, the solution of velocity in separable form is more than twice the inseparable

175   form, while they are closer in the lower layer. This difference between observations and

176   theoretical solutions in separable form was also observed in the ocean, see Fig.13 of Rong et al.

177   (2023). This can be explained by the flow conservation that the influence of ISWs on the

178   stratification changed the thickness of the upper and lower layers. Figure 2e shows the distances

179   of divergence peaks, where the distance in inseparable form is larger. The differences reach a

180   maximum of 33% in the case of $\eta_0/h_1 = 2.20$. In previous studies, the relationship between

181   D_{p-p} and L_w can be obtained directly by calculating velocity in separable form, as $D_{p-p} = 1.32$

182   L_w in the KdV equation, and the ratio is independent of the amplitude. However, the

183   experimental results show that the ratio varies from 1.4 to 2.7 with increasing amplitude. The

184   results calculated in the inseparable form are consistent with the experiments (see Figure S1).

185   Therefore, the strong nonlinearity cannot be neglected in the velocity calculation, especially with

186   increasing wave amplitude. In Section 3.2, only the solution in inseparable form will be used to

187   calculate velocities.

188   3.2 Remote sensing characteristics of ISWs

189   The relationship between remote sensing characteristics and wave parameters will be

190   established in this section, and the applicability of each ISW theory will be evaluated by

191   comparing it with experimental results. Here we take two cases of $h_2/h_1=5$, $h_1=0.04$ m, and 0.08

192   m as examples. The results under the other stratifications are shown in Figures S2–S4. Our

193   experiments mainly focus on the ISWs under strong nonlinearity, and the small amplitude ISWs

194   have been fully proven to be consistent with the theoretical and experimental results in previous
195   studies (Ostrovsky & Stepanyants, 2005).

196

Figure 3. Theoretical and experimental results with $h_2/h_1 = 5$, (a) the variation of L_w with η_0.
(b), (c), and (d) are the relationships between D_{p-p} and wavelength, amplitude, and phase speed,
respectively. The red, magenta, yellow, green, light blue, and dark blue lines represent the KdV,
JKKD, BO, eKdV, MCC, and DJL equations respectively. The black diamond (Exp04) and the
circle (Exp08) represent the experimental results for $h_1 = 0.04$ m and 0.08 m, respectively.

Figures 3b-3d show the variation in wave parameters with the peak-to-peak distance
D_{p-p}. The results from the KdV, JKKD, and BO equations show a similar pattern, in which
parameters change monotonically with D_{p-p}. However, for the eKdV, MCC, and DJL equations,
the relationship between the wave parameters and D_{p-p} is no longer monotonic. Its typical
feature is the existence of a turning point, which means that one D_{p-p} will correspond to two
parameters, that is, the existence of double solutions. The selection method for double solutions
can be determined by the properties of wave packets that the leading wave reaches the maximum
amplitude (Xue et al., 2013). In addition, both the eKdV equation and the fully nonlinear

210 equations have a limiting amplitude, which varies with different stratifications (Cui et al., 2021),

211 and the limiting amplitude of the eKdV equation is smaller than that of the MCC and DJL

212 equations. The comparison between the theoretical and experimental results shows that it is

213 feasible to describe the remote sensing characteristics of ISWs with theoretical models.

214 To quantitatively compare the differences between ISW theories and experimental results

215 in retrievals, we define the relative deviation (RD) as follows

$$RD = \left| \frac{\lambda_{theory} - \lambda_{exp}}{\lambda_{exp}} \right| * 100\%, \tag{9}$$

217 where λ_{theory} and λ_{exp} are any theoretical and experimental parameters under a specific D_{p-p}. If

218 the D_{p-p} of some experiments are smaller than the theoretical minimum value, the theoretical

219 turning point is used to calculate its RD. In Figure 4, the KdV equation is only applicable in

220 relatively small amplitudes at any stratification. For the eKdV equation, significant RD is caused

221 in the retrieval with dimensionless amplitude ranging between 0.5–1, corresponding to the

222 turning point with smaller D_{p-p} in this range. In addition, its limiting amplitude restricts its

223 application at large amplitudes. Therefore, the eKdV equation is applicable to ISWs with small

224 or nearly limiting amplitudes. For the MCC equation, the turning point gradually shifts to the

225 direction of D_{p-p} lengthening with increasing depth. The RD becomes larger with the gradual

226 failure of the long wave assumption. The DJL equation has great applicability in all conditions.

227 In laboratory conditions, the RD of wavelength and phase speed are less than 10% in retrievals,

228 and the RD of small amplitude is approximately 30% which is mainly caused by the relative

229 magnitude of variation, measurement errors, and dissipations, while RD of other amplitude is
230 reduced to 10%.

Figure 4. RD between theoretical and experimental results in retrievals using D_{p-p}. (a)-(d) are RD of KdV, eKdV, MCC, and DJL equations in retrieving wavelength, (e)-(h) are RD in retrieving amplitude, and (i)-(l) are RD in retrieving phase speed. The color bar indicates RD% in each condition, and the black dashed line in (f) indicates the limiting amplitude.

4 Discussion

The above work explores the retrieval of wave parameters in a quasi-two-layer procedure under laboratory conditions. However, the complex environments in the ocean introduce difficulties and variety to retrieval. Therefore, the applicability of the established method is further tested with oceanic observations.
Figure 5. Relationship between D_{p-p} and amplitude of each location calculated by the DJL equation. (a) The dark line, light blue, green, orange and red lines are the results of mooring stations with depths of 200 m, 600 m, 953 m, 2762 m, and 3745 m. Dashed lines of corresponding colors indicate the maximum amplitude of the observed ISW at each station. (b) The dark blue line is the results of stations with a depth of 200m, the dots represent the measured ISWs, and their colors indicate the upper layer depth before the arrival of ISWs. The horizontal axis represents the time interval of peak-to-peak in the mooring observation.

The results at several locations with long-term mooring are shown in Figure 5. The 200 m depth is S5 during the Asian Seas International Acoustics Experiment (ASIAEX) (Duda et al., 2004), the 600 m depth station is LR1 of Chang et al. (2021), and the 953 m, 2762 m, and 3745 m depth stations are M1, M6, and M10 of Huang et al. (2022). The yearly mean climatological WOA18 dataset is used in the DJL equation except for the location of 200 m. The stratification in 200 m depth is given by the average results of temperature profiles in observations before each

255   ISW arrives. In Figure 5b, 49 ISWs were observed during ASIAEX. The amplitude is defined as

256   the maximum isotherm displacement. Using the time series of upward-looking ADCP with an

257   interval of 1 min, we estimate D_{p-p} by

258
$$D_{p-p} = c \left| t_{\left|\frac{\partial u_s}{\partial t} = \min\left(\frac{\partial u_s}{\partial t}\right)\right.} - t_{\left|\frac{\partial u_s}{\partial t} = \max\left(\frac{\partial u_s}{\partial t}\right)\right.} \right|, \tag{10}$$

259   and the axis is set to D_{p-p}/c due to the absence of the phase speed c. Different from the

260   laboratory results, the relationship between surface features and amplitudes is relatively scattered

261   in the ocean. The amplitude will be greatly different under one condition. Even in a short period

262   of 15 days, the upper layer depth will change between 30 m and 60 m corresponding to the

263   amplitude difference, and this short-period change may be caused by surface forcing (Font et al.,

264   2022). As seen from the scatter, thicker and thinner upper layers usually correspond to smaller

265   and larger amplitudes, respectively. The amplitudes are affected by this variation in stratification

266   over a short period, as observed by Small et al. (1999) and Lien et al. (2014). The difficulty in

267   obtaining real-time stratification will cause errors in retrieving the parameters of a specific ISW.

268   Nevertheless, the DJL equation using an average stratification can still reveal the trend of wave

269   parameters with remote sensing characteristics, which will play an important role in the

270   statistical work of the properties of ISWs using satellite images.

271   The curves under the measured maximum amplitude show different patterns. The

272   amplitudes decrease approximately with the increase in D_{p-p} in a deep sea of more than 2700 m.

273   At approximately 1000 m, the amplitudes decrease monotonically except for a small area near

274   the turning point. For the 600 m and 200 m stations, the amplitudes above the turning point will

275   increase with increasing of D_{p-p} while those below the turning point will decrease. The

276   selection rule in the retrieval has been mentioned in Section 4.2. Different from other stations,

277   the maximum amplitude observed at 200 m exceeds the limitation calculated by averaged

278   stratification, which may be caused by variations in the upper layer and the shoaling of ISWs.

279   The relationship between the remote sensing characteristics and the wave parameters of ISWs is

280   different at those stations. In fact, the calculation results of the DJL equation under several

281   stratifications indicate that the different stratification characteristics in different areas are the

282   main factors that cause the differences in the retrievals, such as shallow waters with quasi-two-

283   layer stratifications and deep seas with a main thermocline that spans hundreds of meters.

284   Stratification plays a critical role in the retrieval of ISW parameters from satellite images.

285   In shallow seas, the climatological dataset cannot reflect the short-period variation in

286   stratification, and the retrieval of parameters of a specific ISW needs additional information to

287   improve. For the deep seas, the relatively stable stratification provides us with more possibilities

288   for accurate retrieval.

5   Conclusions

290   In this study, we establish the relationship between the surface and internal characteristics

291   of ISWs in dimensionless laboratory experiments. The strongly nonlinear effects of ISWs in the

292   retrieval of wave parameters are evaluated, and a fully nonlinear model is applied in oceans.

293   Strong nonlinearity causes the solution of the wave-induced velocity to be inseparable, and an

294   iterative method for calculating the velocity solution in inseparable form is proposed and fits

295   well with the experimental results. The difference in the retrieval between velocity solutions in

296   separable and inseparable forms reaches a maximum of 33% in the range of our experimental

297   parameters. ISW theories under weakly nonlinear assumptions have difficulty describing

298   strongly nonlinear ISWs from the surface. The fully nonlinear DJL equation is used in the

299   retrieval and compared with experimental results. The relative deviation of the retrieval of

300   wavelength, amplitude, and phase speed is less than 10% in laboratory experiments except in

301   small amplitude conditions.

302   The determination of ISW parameters from satellite images in oceans is significantly

303   affected by in-situ stratifications. The variation in stratification over a short period can bring

304   errors in retrieving the parameters of a specific ISW. However, the comparison of observations

305   and theory shows that the DJL equation using background stratifications can reveal reasonable

306   internal characteristics of ISWs from surface features. Stratification conditions make the

307   relationship between remote sensing signatures and ISW parameters differ in deep and shallow

308   seas. The amplitudes of ISWs decrease monotonically with increasing D_{p-p} in deep seas, but

309   double solutions should be considered in shallow seas.

310   This work provides a reliable hydrodynamics model for the inversion of remote sensing

311   signatures of ISWs into characteristics in the ocean interior. With the combination of the fully

312   nonlinear model and the satellite imaging mechanism, more underwater information can be

313   interpreted from remote sensing in further work.

Tables S1

Figures S1 to S4

Text S1. Solutions of internal solitary wave theories

The Korteweg–de Vires (KdV) equation (Korteweg & de Vries, 1895) has the solution

$$\eta(x,t) = \eta_0 \text{sech}^2(X/\lambda), \tag{S1}$$

where $X = x - ct$, η_0 is the amplitude.

$$c_0 = \sqrt{\frac{g\Delta\rho}{\rho} \frac{h_1 h_2}{h_1 + h_2}}, \tag{S2}$$

$$c = c_0 + \frac{\alpha\eta_0}{3}, \tag{S3}$$

$$\lambda^2 = \frac{12\beta}{\alpha\eta_0}, \tag{S4}$$

where g is the gravitational acceleration, $\Delta\rho$ is the density difference, ρ is the reference density, h_1 and h_2 are the thickness of the upper layer and the lower layer, respectively. The parameters

$$\alpha = \frac{3}{2}c_0 \frac{h_1 - h_2}{h_1 h_2}, \tag{S5}$$

$$\beta = \frac{c_0 h_1 h_2}{6}. \tag{S6}$$

For Joseph–Kubota–Ko–Dobbs (JKKD) equation (Joseph, 1977; Kubota et al., 1978), we consider the solution used by Zheng et al. (1993)

$$\eta(x,t) = \frac{\eta_0}{[\cosh^2 aX + (\sinh^2 aX)/a^2 b^2]}, \tag{S7}$$

$$c_0 = \sqrt{\frac{g\Delta\rho h_1}{\rho_1}}, \tag{S8}$$

$$c = c_0\left\{1 + \frac{h_1}{2H}\left[1 + \frac{H}{b}(1 - a^2 b^2)\right]\right\}, \tag{S9}$$

$$b = \frac{4h_1^2}{3\eta_0}. \tag{S10}$$

The parameter a is parameter satisfying the relationship

$$ab\tan(aH) = 1. \tag{S11}$$

The Benjamin–Ono (BO) equation (Benjamin, 1967; Ono, 1975) has the solution

$$\eta(x,t) = \frac{\eta_0}{1 + (X/\lambda)^2}. \tag{S12}$$

$$c = c_0 + \frac{\alpha\eta_0}{4}, \tag{S13}$$

where c_0 is the same as in Eq. S8.

$$\lambda = \frac{4\beta}{\alpha\eta_0}, \tag{S14}$$

$$\alpha = -\frac{3c_0}{2h_1}, \tag{S15}$$

$$\beta = \frac{c_0 h_1 \rho_2}{2\rho_1}. \tag{S16}$$

If the higher-order nonlinear terms were took into account in the KdV equation, the extended KdV (eKdV) equation (Grimshaw et al., 2004; Kakutani & Yamasaki, 1978) has the solution

$$\eta(x,t) = \frac{\eta_0}{B + (1-B)\cosh^2(X/\lambda)}. \tag{S17}$$

$$c = c_0 + \frac{1}{3}\eta_0\left(\alpha + \frac{1}{2}\gamma\eta_0\right), \tag{S18}$$

$$\lambda^2 = \frac{12\beta}{\eta_0\left(\alpha + \frac{1}{2}\gamma\eta_0\right)}, \tag{S19}$$

$$B = \frac{-\gamma\eta_0}{2\alpha + \gamma\eta_0}, \tag{S20}$$

the parameters α and β are the same as in Eq. S5 and Eq. S6, the parameter

$$\gamma = \frac{3c_0}{(h_1 h_2)^2}\left[\frac{7}{8}(h_1 - h_2)^2 - \left(\frac{h_1^3 + h_2^3}{h_1 + h_2}\right)\right]. \tag{S21}$$

The solution of Miyata–Choi–Camassa (MCC) equation (Camassa et al., 2006; Choi & Camassa, 1999; Miyata, 1988) is a nonlinear ordinary differential equation

$$\left(\frac{\partial\eta(x,t)}{\partial X}\right)^2 = \delta\frac{\eta^2(\eta - a_-)(\eta - a_+)}{\eta - a_*}, \tag{S22}$$

the parameter

$$\delta = \frac{3g\Delta\rho}{c^2(\rho_1 h_1^2 - \rho_2 h_2^2)}, \tag{S23}$$

$$c^2 = \frac{c_0^2(h_1 - \eta_0)(h_2 + \eta_0)}{h_1 h_2 - (c_0^2/g)\eta_0}, \tag{S24}$$

where c_0 is the same as in Eq. S2.

$$a_* = \frac{h_1 h_2}{h_2 - h_1}, \tag{S25}$$

where a_- and a_+ are the two roots of a quadratic equation

$$\eta^2 + q_1\eta + q_2 = 0, \tag{S26}$$

$$q_1 = -(c^2/g) + h_2 - h_1, \ q_2 = h_1 h_2 (c^2/c_0^2 - 1). \tag{S27}$$

Without any assumption about the wavelength and amplitude, Dubreil–Jacotin–Long (DJL) (Long, 1953) is established, the equation is as follows

$$\nabla^2\eta + \frac{N^2(z - \eta)}{c^2}\eta = 0, \tag{S28}$$

where isopycnal displacement η is a function of x and z, c is the phase speed, N is the buoyancy frequency, expressed as:

$$N^2(z) = -\frac{g}{\rho_0}\frac{d\rho(z)}{dz}, \tag{S29}$$

where g is the gravitational acceleration, $\rho(z)$ is the density profile, ρ_0 is the reference density. It should be noted that the DJL equation does not have explicit solutions, which can only be solved by the numerical method (Dunphy et al., 2011; Stastna & Lamb, 2002).

Text S2. Iteration procedure of the solution of wave-induced velocity in inseparable form

When the ISW which has a waveform of $\eta(x)$ exists, the buoyancy frequency in the domain can be expressed as

$$N_{wave}^i[z + \eta^{i-1}(x,z)] = \begin{cases} 0 & 0 \le z \le -\eta^{i-1}(x,z) \\ N_b(z) & -H - \eta^{i-1}(x,z) \le z < 0 \end{cases}, \qquad \text{(S30)}$$

where H is the total depth of the domain, $N_b(z)$ is the background buoyancy frequency, i presents the iterations. The $\eta^{i-1}(x,z)$ is calculated by the following equation with the initial value of $\eta(x)$

$$\eta^i(x,z) = \eta(x)\phi_{wave}{}^i(x,z), \quad \eta^0(x,z) = \eta(x), \qquad \text{(S31)}$$

where the vertical structure function $\phi^i(x,z)$ is calculated by

$$\left(\frac{d^2}{dz^2} + \frac{N_{wave}^2{}^i(x,z)}{c_0^2}\right)\phi_{wave}{}^i(x,z) = 0 \qquad \phi_{wave}(x,-H) = \phi_{wave}(x,0) = 0, \quad \text{(S32)}$$

where c_0 is the linear phase speed. Therefore, according to the convergent iteration results, the solution of wave-induced horizontal velocity can be expressed as

$$u(x,z) = c\frac{\partial \eta(x,z)}{\partial z} = c\eta(x)\frac{\partial \phi_{wave}(x,z)}{\partial z}. \qquad \text{(S33)}$$

Table S1. Summary of experimental conditions

Case	h_1(m)	h_2(m)	h_2/h_1	η_0/h_1
1	0.04	0.12	3	0.21-0.89
2	0.04	0.16	4	0.18-1.21
3	0.04	0.20	5	0.49-1.71
3(b)	0.08	0.40	5	0.34-1.49
4	0.04	0.24	6	0.46-2.06
5	0.04	0.28	7	0.50-2.35
6	0.04	0.32	8	0.43-2.50
7	0.04	0.40	10	0.46-2.36
Figure S1. The variation of the ratio of D_{p-p} to wavelength with amplitude. The green dots are measured in experiments, and the red and blue dots are calculated by the solution of velocity in separable and inseparable forms, respectively. Each color from light to dark corresponds to the h_2/h_1 from 3 to 10.
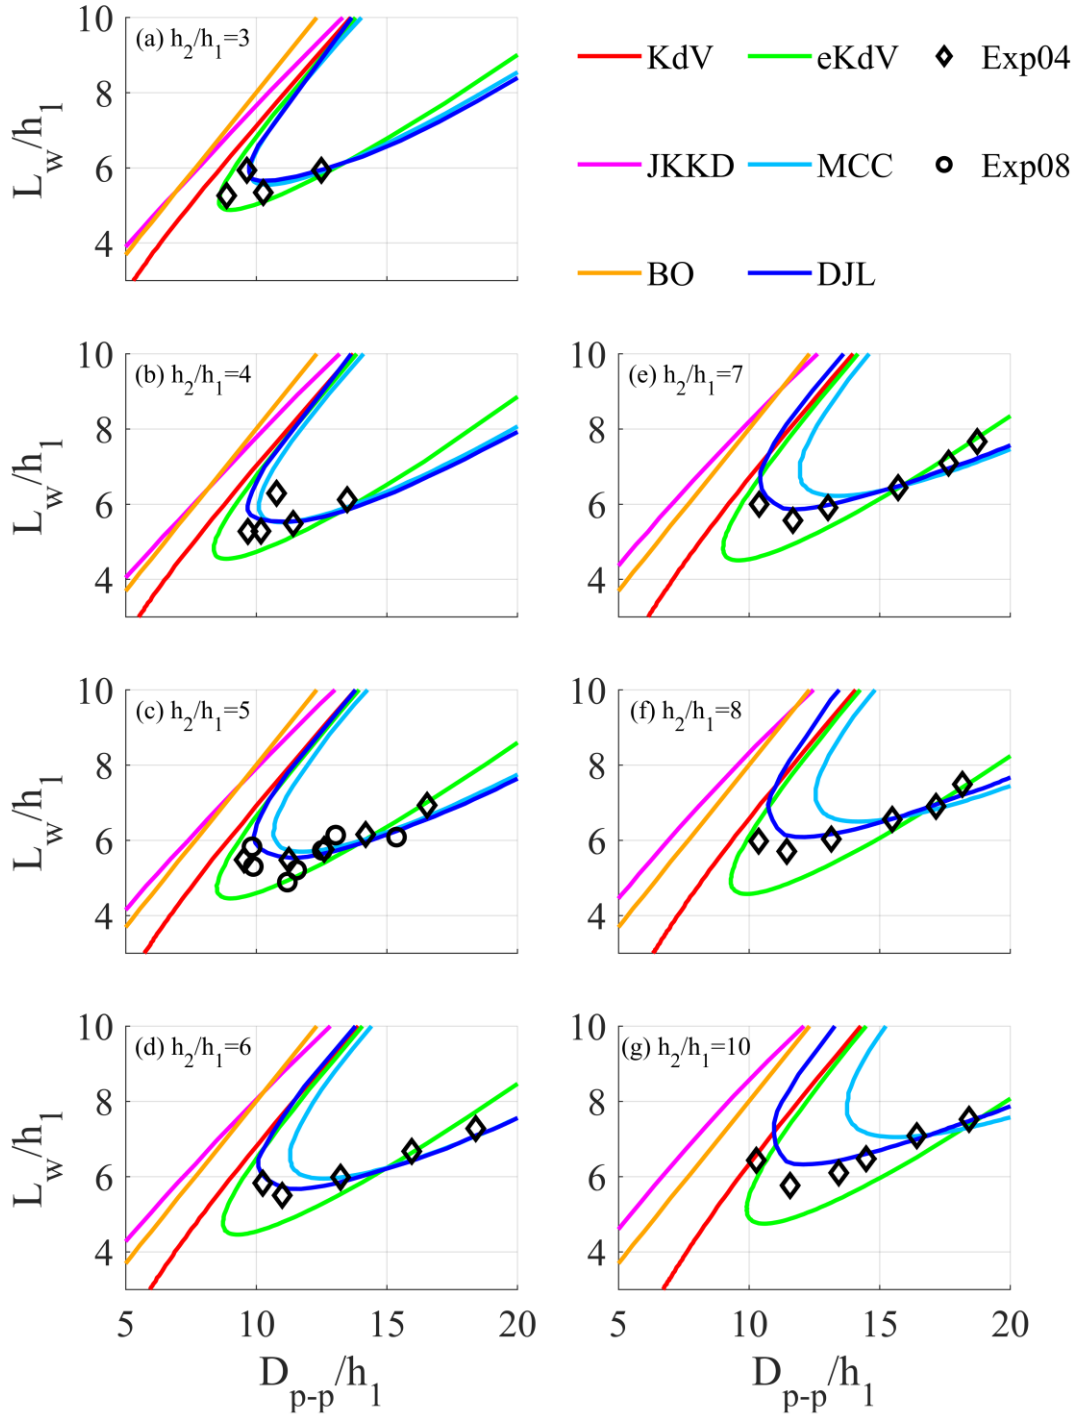

Figure S2. Theoretical and experimental results of wavelength retrievals under different stratifications, (a)-(g) are the relationships between D_{p-p} and wavelength with h_2/h_1 from 3 to 10 respectively. The red, magenta, yellow, green, light blue, and dark blue lines represent the KdV, JKKD, BO, eKdV, MCC, and DJL equations respectively, and the black diamond and circle represent the experimental results that $h_1 = 0.04$ m and 0.08 m, respectively.
Figure S3. Theoretical and Experimental results of amplitude retrievals under different stratifications, (a)-(g) are the relationships between D_{p-p} and amplitude with h_2/h_1 from 3 to 10 respectively. The red, magenta, yellow, green, light blue, and dark blue lines represent the KdV, JKKD, BO, eKdV, MCC, and DJL equations respectively, and the black diamond and circle represent the experimental results that $h_1 = 0.04$ m and 0.08 m, respectively.
Figure S4. Theoretical and Experimental results of phase speed retrievals under different stratifications, (a)-(g) are the relationships between D_{p-p} and phase speed with h_2/h_1 from 3 to 10 respectively. The red, magenta, yellow, green, light blue, and dark blue lines represent the KdV, JKKD, BO, eKdV, MCC, and DJL equations respectively, and the black diamond and circle represent the experimental results that $h_1 = 0.04$ m and 0.08 m, respectively.
