Abstract

Energetic electron precipitation (EEP) associated with pulsating aurora can transfer greater than 30 keV electrons from the outer radiation belt region into the upper atmosphere and can deplete atmospheric ozone via collisions that produce NOx and HOx molecules. Our knowledge of exactly how EEP occurs is incomplete. Previous studies have shown that pitch angle scattering between electrons and lower-band chorus waves can cause pulsating aurora associated with EEP and that substorms play an important role. In this work, we quantify the timescale of chorus wave decay following substorms and compare that to previously determined timescales. We find that the chorus decay e-folding time varies based on magnetic local time (MLT), magnetic latitude, and wave frequency. The fastest decay occurs for lower-band chorus in the 21 to 9 MLT region and compares well to the timescale of Troyer et al. (2022) for energetic pulsating aurora. We are able to further support this connection by modelling our findings in a quasi-linear diffusion simulation. These results provide observations of how chorus waves behave after substorms and add additional statistical evidence linking energetic pulsating aurora to substorm driven lower-band chorus waves.

Substorm Driven Chorus Waves: Decay Timescales and Implications for Pulsating Aurora

2 ABSTRACT

3 Energetic electron precipitation (EEP) associated with pulsating aurora can transfer greater than
4 30 keV electrons from the outer radiation belt region into the upper atmosphere and can deplete
5 atmospheric ozone via collisions that produce NOx and HOx molecules. Our knowledge of exactly
6 how EEP occurs is incomplete. Previous studies have shown that pitch angle scattering between
7 electrons and lower-band chorus waves can cause pulsating aurora associated with EEP and
8 that substorms play an important role. In this work, we quantify the timescale of chorus wave
9 decay following substorms and compare that to previously determined timescales. We find that
10 the chorus decay e-folding time varies based on magnetic local time (MLT), magnetic latitude,
11 and wave frequency. The fastest decay occurs for lower-band chorus in the 21 to 9 MLT region
12 and compares well to the timescale of Troyer et al. (2022) for energetic pulsating aurora. We
13 are able to further support this connection by modelling our findings in a quasi-linear diffusion
14 simulation. These results provide observations of how chorus waves behave after substorms
15 and add additional statistical evidence linking energetic pulsating aurora to substorm driven
16 lower-band chorus waves.

1 BACKGROUND

18 The outer Van Allen radiation belt is a region of space surrounding Earth, usually between $3 < L < 7$, that
19 is filled with energetic electrons (Baker et al., 2013). These particles are trapped in the magnetic mirror
20 created by the planet's approximate dipole magnetic field. During periods of low magnetic activity, particles
21 are generally stably trapped and $\overrightarrow{E} \times \overrightarrow{B}$, gradient, and curvature drift around the planet (Roederer, 1970).
22 However, there are several processes that can perturb these populations, causing them to precipitate into the
23 atmosphere. In this study, we focus on the interaction between the energetic electrons and electromagnetic
24 chorus waves. This interaction can precipitate energetic electrons into the atmosphere. Energetic electron
25 precipitation (EEP) is an important dynamic to the magnetosphere-ionosphere-thermosphere coupled

26 system (Lam et al., 2010). It represents a significant transfer of energy from magnetosphere to upper
27 atmosphere and can result in ozone depletion (Verronen et al., 2021; Turunen et al., 2016). Pulsating aurora
28 is a visual manifestation of the precipitating electrons and can be an excellent way to study EEP (Bland
29 et al., 2021). There are still many unknowns in the process that produces EEP and pulsating aurora (Lessard,
30 2013; Partamies et al., 2022). In this work, we provide additional statistical evidence for substorm driven
31 lower-band chorus waves as a source of energetic pulsating aurora. We do this by measuring chorus decay
32 e-folding times after substorms and comparing them to known pulsating aurora energy decay timescales.

33   Chorus waves are an important feature of the outer Van Allen radiation belt region and drive many of
34 this regions dynamics (Meredith et al., 2020; Hua et al., 2023a,b). They are characterized by frequency,
35 which typically ranges between the electron cyclotron frequency (f_{ce}) and one tenth of f_{ce}. There is a
36 clear gap at one half f_{ce}, likely due to Landau resonance, such that lower-band chorus waves (LBC) occur
37 between $0.1\,f_{ce}$ and $0.5\,f_{ce}$ while upper-band chorus waves (UBC) occur between $0.5\,f_{ce}$ and f_{ce} (Bortnik
38 et al., 2006; Li et al., 2019). In some cases low-frequency chorus can extend to $0.05\,f_{ce}$ or lower (Li et al.,
39 2013; Meredith et al., 2014). For our analysis we did not consider low-frequency chorus. Chorus waves
40 are named for their resemblance to the sound of birds chirping caused by sub-second rising and falling
41 tones in their frequency distributions (Isted and Millington, 1957; Tsurutani and Smith, 1974). In addition
42 to the sub-second timescales, chorus waves can also be modulated on the order of seconds (Jaynes et al.,
43 2015). Studies have directly linked modulations over seconds in the chorus power spectral density and
44 electron flux in the chorus region to instance of pulsating aurora, where an intensification corresponds to
45 the brightening of an auroral patch (Nishimura et al., 2011; Jaynes et al., 2013; Kasahara et al., 2018). Due
46 to the difficulty in connecting chorus activity to ground observations, these studies have only been able to
47 analyze a handful of events.

48   Pulsating aurora are a common subset of diffuse-like aurora. They appear as an uncoordinated symphony
49 of dim auroral patches that blink on and off across wide portions of the sky. The period of this blinking
50 can range up to around 20 seconds. Individual patches can be remarkably varied with differing periods,
51 shapes, and sizes typically between 10s to 100s of kilometers (Johnstone, 1978; Lessard, 2013). Pulsating
52 aurora often develop near the end of a substorm display and can continue for hours after (Jones et al.,
53 2011). There also is a relation between greater energy flux and closer temporal proximity to the substorm
54 (Hosokawa and Ogawa, 2015; Oyama et al., 2017; Troyer et al., 2022). Substorms are characterized by
55 a rapid dipolarization of Earth's nightside magnetic field that accelerates and injects electrons into the
56 inner magnetosphere (Akasofu, 1966). Some of these electrons accelerate directly into the atmosphere,
57 causing discrete aurora (Korth et al., 2014; Schroeder et al., 2021). Others are injected into the radiation
58 belt region and can drive wave activity (Tsurutani and Smith, 1974; Chepuri et al., 2023). Ground-based
59 magnetometers can detect substorms as an enhancement of the auroral electrojet and report this in the AE
60 index (Newell and Gjerloev, 2011).

61   While a correlation does exist between LBC waves and pulsating aurora for certain events, it is still an
62 open question as to how statistically significant this relationship is (Lessard, 2013; Borovsky and Partamies,
63 2022). That being said, there are known, indirect, statistical links between the two. For instance, both
64 LBC and pulsating aurora occur most frequently and with the strongest intensity between 3 and 6 MLT
65 (Oguti et al., 1981; Jones et al., 2011; Meredith et al., 2020). Additionally, pulsating aurora frequently have
66 significant energy contributions from 10s to 100s of keV electrons, which is the resonant energy range for
67 lower-band chorus (Nishimura et al., 2011; Tesema et al., 2020; Troyer et al., 2022). In this work we add to
68 that evidence by showing that lower-band chorus and pulsating aurora have similar decay timescales after
69 substorms.

A proposed process for this interaction is Doppler-shifted cyclotron resonance between 10s of keV electrons and lower-band chorus, which can simultaneously drive wave growth and pitch angle scatter electrons (Brice, 1964; Trakhtengerts et al., 2004; Miyoshi et al., 2020). Therefore, assuming pitch angle scattered electrons are responsible for pulsating aurora, a timescale in the aurora should correspond to a timescale in the waves. Troyer et al. (2022) found such a timescale for ≥ 30 keV electrons associated with pulsating aurora. They found that the differential energy flux from these electrons decayed after substorms with a timescale of just under an hour, suggesting that substorms are a primary driver of pulsating aurora EEP. Complementing this, Meredith et al. (2000) found a similar timescale when looking at post-substorm decay of chorus electric field amplitudes from the CRRES spacecraft. We hypothesize that energetic electrons injected into the outer radiation belt region during substorms drive chorus waves, and that pitch angle scattering from this interaction causes pulsating aurora. We provide evidence towards that hypothesis by expanding on Meredith et al. (2000) using the more recent and expansive Van Allen Probes dataset. In doing so, we confirmed that lower-band chorus waves decay after substorms with a similar timescale to pulsating aurora. We also discovered that this decay timescale depends on magnetic local time (MLT), magnetic latitude (MLAT), and wave frequency. Our quantified decay timescales add statistical evidence linking chorus waves, substorms, and pulsating aurora.

2 DATA

2.1 Electric and Magnetic Fields

Our primary dataset is from the Electric and Magnetic Field Instrument Suite and Integrated Science (EMFISIS) instruments aboard the Van Allen Probes. The Van Allen Probes were two identical spacecraft that orbited through the planet's radiation belt regions between 2012 and 2019 (Mauk et al., 2013). EMFISIS uses a tri-axial fluxgate magnetometer (MAG) and a tri-axial search coil magnetometer (MSC) to measure DC and wave magnetic fields respectively (Kletzing et al., 2013). EMFISIS also takes an analog electric field signal from the Electric Fields and Waves (EFW) experiment to measure the wave electric field (Wygant et al., 2013). The collective wave electric and magnetic field measurements are called the Waves experiment and cover the frequency range from 10 Hz up to 12 kHz. In survey mode, the Waves experiment provides a 6-second power spectral density for both the electric and magnetic fields in three orthogonal directions. We used the total electric/magnetic power spectral density, which is a sum of all three components.

A property of the double probe electric field sensors on the Van Allen Probes is that they become electrically coupled to the local plasma. To account for this, we use the sheath-corrected electric field measurements that provide an adjustment based on local electron density (Hartley et al., 2022). In addition, the electric field measurements contain noisy frequency bands at 1781 Hz and 3555 Hz, so we omitted this data for our analysis. We are more confident in the magnetic field measurements and used these for most of our findings.

2.2 Post-Substorm Identification

To detect substorm activity we used the SuperMAG collaboration's 1-minute SME index (Gjerloev, 2012). This index is designed to replicate the AE index using at least 100 of the SuperMAG magnetometers. Similar to AE, SME is measured in nT with larger positive values corresponding to a stronger auroral electrojet (Newell and Gjerloev, 2011).

109   The AE index, and thus SME, correlates well with particle injections in the inner magnetosphere
110 (Meredith et al., 2000). These injections are linked with substorms and reconnection in the magnetotail
111 (DeForest and McIlwain, 1971; Chepuri et al., 2023). We looked at the behavior of chorus wave events
112 during the quiet period following an injection. We identified these events with the following process:

113   1. Smooth the SME index with a rolling average of 6 minutes.

114   2. Identify periods where the smoothed SME index stayed below 150 nT for at least 10 minutes.

115   3. From these periods, select only those that were preceded by an enhancement in smoothed SME of
116   > 250 nT.

117   Our threshold of < 150 nT, representing the start of a quiet period, is based on Meredith et al. (2000) and
118 we found that > 250 nT was sufficient to identify enhanced periods without over-identifying.

119   We also measured the approximate substorm injection period length. We define this as the time from
120 when the smoothed SME went above 250 nT to when it dropped below 150 nT. Using this definition, our
121 median injection length from 6241 events was 1.73 ± 0.02 hr. However, these values should be taken with
122 a grain of salt as they assume that an enhanced SME corresponds to a continuous injection event. We've
123 included plots of our injection period and quiet period length distributions in the supplementary materials.

2.3   Chorus Selection

125   Within the quiet periods after injections, we further limited our search to the outer radiation belt region
126 ($3 \leq L \leq 6.6$) and considered all MLTs, and all magnetic latitudes sampled by the Van Allen Probes
127 ($-20° \leq$ MLAT $\leq 20°$).

128   To identify chorus we determined the local electron cyclotron frequency (f_{ce}) using the magnetic field
129 amplitude from the EMFISIS flux gate magnetometer (MAG) and the equation $f_{ce}[\text{Hz}] = \left| \vec{B}[\text{nT}] \right| \times 28$.
130 We then used local f_{ce} to select chorus from the power spectral density data. To qualify as a measurement
131 of LBC or UBC we required that the maximum magnetic field power spectral density over the respective
132 frequency range be $\geq 10^{-7} \text{nT}^2/\text{Hz}$ (Hartley et al., 2019). To reduce hiss noise, we ensured that the probes
133 were outside the plasmasphere by limiting our measurements to times when the electron density was less
134 than the smaller of $10 \times (6.6/L)^4$ or $50\,\text{cm}^{-3}$ (Lawrence et al., 1999; Sheeley et al., 2001; Aryan et al.,
135 2022). Note that in Sheeley et al. (2001) the equation is written as $10 \times (6.6/L)^{-4}$, but we believe that this
136 is a typograhpical mistake. Subsequent studies have implemented the equation we used to good results and
137 it is intuitive that the density threshold would decrease at larger L values (Li et al., 2015). For the density,
138 we used the estimated values provided by EMFISIS.

3   ANALYSIS

139 In total, we found 224,165 chorus measurements. Each measurement contains an integrated LBC and/or
140 UBC wave power, probe location, and a time since the start of the respective quiet period. We can use this
141 dataset to better understand how chorus waves behave after a substorm.

3.1   Variations with Magnetic Local Time (MLT)

143   We further subdivided our dataset into the following regions of MLT: 21 to 3, 3 to 6, 6 to 9, 9 to 12,
144 12 to 15, and 15 to 18. We excluded 18 to 21, and combined 21 to 24 and 0 to 3 due to limited chorus
145 observations in these region. While it isn't the purpose of this study, it is worth noting that our statistical
146 distribution does roughly agree with the previous understanding of chorus occurrence and wave power in

147 relation to MLT (Li et al., 2016; Meredith et al., 2020). Occurrence and wave power peaks post-midnight
148 and are lowest between 18 and 21 MLT.

149   For each MLT region we performed a least squares linear fit to the natural log transformed wave power.
150 This results in a a fitted exponential decay in form of

$$B = B_0 \, e^{-t/\tau}$$

151 where t is the time since the start of a quiet period. We limited this fit to the first 75 minutes. Figure 1
152 shows how the inverse of this decay timescales (τ) varies across our MLT regions. We chose to plot $|1/\tau|$
153 to better distinguish between differences in decay timescales. We split the decays into full chorus (solid),
154 LBC (dashed), and UBC (dotted) lines to visualize the differences between wave frequency. The error bars
155 correspond to the bootstrapped standard deviation of the timescale, which we explain in Section 3.6. Using
156 Figure 1 we find that the decay is faster in the night to early morning regions, with slower timescales on
157 the dayside. The fastest decay occurs between 3 to 6 MLT with the LBC decaying about twice as fast as
158 the UBC. This region of MLT also happens to be the most common region for pulsating aurora (Kvifte and
159 Pettersen, 1969), which we will discuss in Section 3.4.

3.2 Variations with Magnetic Latitude (MLAT)

161   In Figure 1 we saw that decay timescales on the nightside through dawn were faster than on the dayside.
162 To look at changes with magnetic latitude (MLAT), we divided our data into two MLT bins: 21 to 9, and 9
163 to 18. We would expect that close to the injection region (21 to 9 MLT), chorus would be more intense,
164 but also damped quicker away from the equator due to the presence of Landau resonant electrons with
165 energies on the order of 1 keV (Bortnik et al., 2007). Further away from the injection (9 to 18 MLT) we
166 would expect less damping at higher latitudes as the $\sim$ 1 keV electrons will be lost faster than the $\sim$ 30
167 keV ones responsible for chorus. In Figure 2 we compare the decay timescales between these two regions
168 and for $0°$ to $10°$ and $10°$ to $20°$ MLAT. Here the blue scatter points are the underlying data, the dashed
169 black lines are the least squares fits to the data, and the black scatter points are the geometric mean value of
170 the proceeding 10 minutes. We calculated the R^2 values based on the difference between the best fit line
171 and geometric mean values. In this figure, we see that the behavior roughly agrees with what we would
172 expect. During the daytime wave power is less intense and damped less at higher latitudes. We also see that
173 the fastest decay occurs near the equator in the 21 to 9 MLT region. The decay time at higher latitudes is
174 slower and not as uniform with an increase in wave power around 0.5 hours after the quiet period start. In
175 the 9 to 18 MLT region the opposite is true. At high latitudes the decay is more uniform and faster than
176 near the equator. Near the equator there is very little decay in wave power until around 1.25 to 1.5 hours
177 after the quiet period start. However, the decay timescale between 1.25 and 2.5 hours is 1.57 ± 0.15 hr
178 with an R^2 value of 0.87. We do not have a rigorous explanation for these variations, but it is interesting to
179 note that higher latitude waves, at a given L, may originate from higher L shells near the equator (Bortnik
180 et al., 2008). Drifts at higher L shells, for a given energy, are faster, thus could be responsible for the faster
181 response time that we see in Panel D compared to Panel B.

3.3 Comparison with Meredith et al. (2000)

183   Meredith et al. (2000) used electric field measurements from the CRRES spacecraft and found a chorus
184 amplitude decay timescale after injections of 1.1 ± 0.2 hr in the region 21 to 6 MLT and $3.8 \leq L < 6$.
185 This would correspond to a 0.55 hr decay in the wave power. To compare our data to this value we used
186 the EMFISIS electric field measurements. We then found the electric wave power decay in the region 21

187 to 6 MLT, $3.8 \leq L \leq 6$, and $\pm 5°$ MLAT, and fit our decay to the first 3 hours. Given these parameters
188 we find that the electric wave power decays with an e-folding time of 1.20 ± 0.07 hr. This is more than
189 double that of Meredith et al. (2000). There are a several possible reasons for this. One is the statistical
190 sample size of they were working with < 20 data points compared to our much larger dataset. A second is
191 the method of identifying injection periods. Our automated identification allows us to analyze the large
192 EMFISIS dataset, but may include weaker injection periods that a human identifier would overlook. A
193 third could be variations between our statistical sets. From Figure 3 of Meredith et al. (2000) it appears that
194 they had the most measurements in the MLT bins around midnight, while we had comparatively few in this
195 region. As we've seen in Figure 1, decay time is highly dependent on MLT. Thus, when averaging over a
196 large region of MLT, differences in the statistical distribution would likely change the results.

3.4   Comparison with Pulsating Aurora and Troyer et al. (2022)

198 Troyer et al. (2022) found that the contribution to the total energy flux from ≥ 30 keV electrons during
199 pulsating aurora decayed on the order of one hour after substorms. Figure 3 shows an extension of the
200 decay plot from Troyer et al. (2022). We have fit the exponential to the underlying distribution and provided
201 an uncertainty in the decay timescale as described in Section 3.6. In the plot, the blue scatter points are the
202 underlying data, the black points represent the geometric mean value of the surrounding 20 minutes, and
203 the red line is the best fit exponential. Here we see that ≥ 30 keV pulsating aurora electrons decay with an
204 e-folding time of 0.95 ± 0.11 hr after substorms. To compare our data to these findings we considered the
205 difference between chorus types as LBC has been directly linked to pulsating aurora, while UBC is more
206 commonly associated with the less energetic non-pulsating diffuse aurora (Meredith et al., 2009; Nishimura
207 et al., 2010). This is not surprising as LBC waves resonate with higher energy electrons (> 5 keV near
208 the loss cone) compared to UBC waves (< 5 keV) (Ni et al., 2008). In Figure 1 we binned by chorus type
209 in addition to MLT and saw that during the most common time for pulsating aurora (3 to 6 MLT), LBC
210 decays at a faster timescale than UBC (Kvifte and Pettersen, 1969; Jones et al., 2011). For a more direct
211 comparison to Troyer et al. (2022), in Figure 4, we show the difference between LBC and UBC in the
212 region 21 to 5 MLT, $3 < L < 6.6$, and $-20°$ to $20°$ MLAT. Here we can see a clear difference between the
213 two chorus types with LBC decaying nearly twice as quickly compared to UBC. The LBC decay is 1.07 hr
214 to 1.29 hr considering uncertainty, compared to 0.84 hr to 1.06 hr for the ≥ 30 keV electrons from Figure
215 3, showing excellent consistency between the two.

3.5   Simulation

As another test, we modelled the system using the quasi-linear, drift-averaged, diffusion simulation
described in Hua et al. (2022). To calculate the diffusion coefficients, we set the wave power in the 21 to 3,
3 to 6, and 6 to 9 MLT regions to

$$B_w(t) = B_0 \, e^{-t/\tau}$$

217 where t is the simulation time, τ is the decay e-folding time that we measured for the specific region, and
218 B_0 is the max wave intensity in the region taken from Meredith et al. (2020) at $L = 5$ and $100 \leq AE < 300$
219 nT. In all other regions we let $B_w(t) = B_0$.

220 We used the values of Meredith et al. (2020) for B_0 because they provide a large sample size over our
221 MLT bins and have been used in similar simulations (Hua et al., 2022, 2023a). Although it wasn't the
222 primary focus of this work, we can also derive B_0 from our data. Doing so, we find that it differs from
223 Meredith et al. (2020). For instance, we see a peak B_0 on the order of 20 pT in the 3 to 6 MLT region,
224 while for $AE < 100$ nT, Meredith et al. (2020) found it to be on the order of 40-50 pT. We believe this is

225 due to different averaging techniques. Meredith et al. (2020) used an arithmetic mean, while we used a
226 geometric mean because the chorus power distribution is spread over multiple orders of magnitude. Using
227 an arithmetic mean we get B_0 on the order of 40 pT.

228   Figure 5 summarizes the results of our simulation. Panel A shows how the initial electron energy
229 distribution decays over the simulation. We report the electron distribution in units of spin-averaged flux as
230 the Van Allen Probes ECT instrument would measure it (Spence et al., 2013; Boyd et al., 2019). We took
231 the initial flux as measured by ECT from the October 25, 2016 storm event (Hua et al., 2022). In panel
232 A we've marked the region of strong diffusion (14 keV to 125 keV) with solid black lines. We've also
233 marked 30 keV with a dashed red line to match the threshold of Troyer et al. (2022). Panel B shows the
234 summed electron flux, in the region of strong diffusion, for low-energy electrons (14 keV $\leq$ E $<$ 30 keV)
235 and high-energy electrons (30 keV $\leq$ E $\leq$ 125 keV).

236   Due to the drift-averaged nature of the simulation, we can't directly compare these decay times to
237 timescales measured in a specific region of MLT, although they are on the same order of magnitude. For
238 instance, electrons with 45 keV decay the fastest with an e-folding time of 1.78 hr. This decay time will
239 also vary depending on the peak chorus power, with higher power resulting in a faster e-folding time. We
240 can, however, investigate the relative differences between the higher and lower energy electrons. In Figure
241 5B we see that, in the first 30 minutes of the simulation, the $\geq$ 30 keV electrons decay with an e-folding
242 time of 2.04 hr, while for the $<$ 30 keV electrons the time is 4.17 hr. Clearly the flux of higher energy
243 electrons from the radiation belt region decays at a faster rate compared to the lower energy electrons.
244 Thus, after a substorm, we would expect to see a more dramatic change in the higher energy precipitating
245 electrons as measured on the ground. That agrees well with Troyer et al. (2022), who showed that the
246 post-substorm decay in energy flux during pulsating aurora was mainly due to a reduction in the $\geq$ 30 keV
247 electrons, with the $<$ 30 keV electrons changing relatively little.

3.6 Errors

249   To understand the quality of our exponential fits we used two different methods. We estimated the error
250 in τ by bootstrapping (Johnson, 2001). To bootstrap, we resampled our distribution 10,000 times, with
251 replacement, and found the slope for these new distributions. We then used the standard deviation of these
252 10,000 resampled slopes as the associated error, propagating this to our timescale given that slope = -1/τ. To
253 estimate the quality of each fit we calculated R^2 values between the best fit exponential and the geometric
254 means values of the distribution.

4 DISCUSSION

255 First order cyclotron resonance with injected energetic electrons is one proposed mechanism for chorus
256 wave growth (Brice, 1964; Kennel and Petschek, 1966). In this process the electron interacts with the
257 perpendicular electric field, causing it to transfer energy to the wave and reducing the pitch angle. To keep
258 wave growth active the average velocity of the electrons perpendicular to the magnetic field must be greater
259 than the average parallel velocity (Brice, 1964). Qualitatively, our results are consistent with this process.
260 During injections, electrons typically enter the outer radiation belt region just before magnetic midnight
261 (Gabrielse et al., 2014). They then gradient-curvature drift eastward, overtaking the slower, less energetic
262 (a few to $\sim$ 30 keV) plasmasheet electrons. The interaction of these two populations can provide the
263 anisotropies necessary for pitch angle scattering (Oguti, 1976). As time progresses the electron distribution,
264 and correspondingly wave activity, will tend towards an equilibrium Kennel and Petschek (1966). Thus,
265 chorus wave activity should have less time dependence further eastward (later MLT). This is what we see

266 in Figure 1, with the fastest decay timescales between 3 to 6 MLT and the slowest timescales in later MLT
267 bins.

268   Performing a quantitative analysis of the decay timescale is more challenging and not something we
269 attempt in this paper. To do so we would need to take several aspects of the system into consideration. One
270 is the energy dispersion due to gradient-curvature drift. Higher energy electrons will drift eastward at a
271 faster rate, meaning the lower energy electrons will last longer in a particular MLT region. A second is
272 the energy and pitch angle distribution of the injected electrons. The process that drives chorus growth
273 simultaneously reduces the electron energy and pitch angle. After enough interactions an electron that was
274 originally resonant will either precipitate into the atmosphere or lose enough energy that it is no longer
275 resonant. A third is the temporal and spatial scale of the injection. For a longer and wider injection, by the
276 time we take our measurement, the electron population will be spread over a larger region of MLT. We
277 were able to estimate the median length of the injections as 1.73 ± 0.02 hours, but have no measure of the
278 spatial extent. In Section 3.5 we were able to simulate an approximation of these events, but to understand
279 the underlying physics we would need to specifically model the processes just after a substorm. While we
280 did not perform that analysis, we hope that our measured decay timescales will provide a means to test
281 future models.

282   The decay timescale similarity between LBC in the 21 to 5 MLT region and the energy flux of energetic
283 pulsating aurora is striking, but also not a smoking gun. Our results should be considered as additional
284 statistical evidence linking energetic pulsating aurora to LBC and substorms. Combined with prior studies,
285 LBC certainly appear to play an important role in the formation of pulsating aurora, but the specific
286 processes are likely more complicated than we've outlined here.

4.1 Magnetic and Electric Field Differences

288   To compare with Meredith et al. (2000) we also analysed the electric wave power for our chorus
289 measurements. Due to data quality, we believe the magnetic field analysis is more reliable and so chose
290 to focus on it for our results. However, during our analysis, we did find several differences between the
291 magnetic and electric decay timescales. The largest difference was in the region 21 to 3 MLT, where
292 $\tau_{\text{electric}} < \tau_{\text{magnetic}}$, and for 3 to 6 MLT, where $\tau_{\text{electric}} > \tau_{\text{magnetic}}$. We've included a plot showing this in
293 the supplementary materials. We do not fully understand how this would occur, but there are a couple
294 possibilities. One is wave normal angle of the chorus that, as Li et al. (2016) found, varies with MLT. Waves
295 in the 3 to 6 MLT region are less field aligned (larger wave normal angle) than those close to midnight.
296 They also found that waves with angles $> 40°$ tend to have weaker magnetic field power compared with
297 angles $< 30°$, while the electric field is comparable. However, this connection is highly speculative and
298 we would need to conduct additional work to determine if it could cause our observed decay timescale
299 differences.

5 SUMMARY

300 We found that chorus waves exponentially decay in the quiet period following a substorm. The timescale
301 of this decay varies based on magnetic local time (MLT), magnetic latitude, and frequency range. The
302 fastest decay times occurred for lower-band chorus waves between 21 to 9 MLT with a peak at 3 to 6 MLT.
303 The lower-band chorus magnetic field power spectral density decays in the region 21 to 5 MLT with an
304 e-folding time of 1.18 ± 0.11 hr. This compares well with the 0.95 ± 0.11 hr timescale that Troyer et al.
305 (2022) measured for ≥ 30 keV pulsating aurora electrons after substorms. We also modeled our findings in
306 a quasi-linear diffusion simulation and found that ≥ 30 keV electrons decay around twice as fast compared

307 to the < 30 keV population. These statistical decay timescales provide a valuable metric that can be used
308 to track processes through the magnetosphere-ionosphere system and to test the validity of future models.

CONFLICT OF INTEREST STATEMENT

309 The authors declare that the research was conducted in the absence of any commercial or financial
310 relationships that could be construed as a potential conflict of interest.

AUTHOR CONTRIBUTIONS

311 RNT wrote the manuscript and performed the data analysis for the study. ANJ helped edit the manuscript
312 and provided feedback and advise for the data analysis. DPH helped with the chorus wave analysis. NPM
313 provided advice and suggestions as well as clarification of Meredith et al. (2000). MH and JB ran the
314 quasi-linear diffusion simulation.

FIGURES
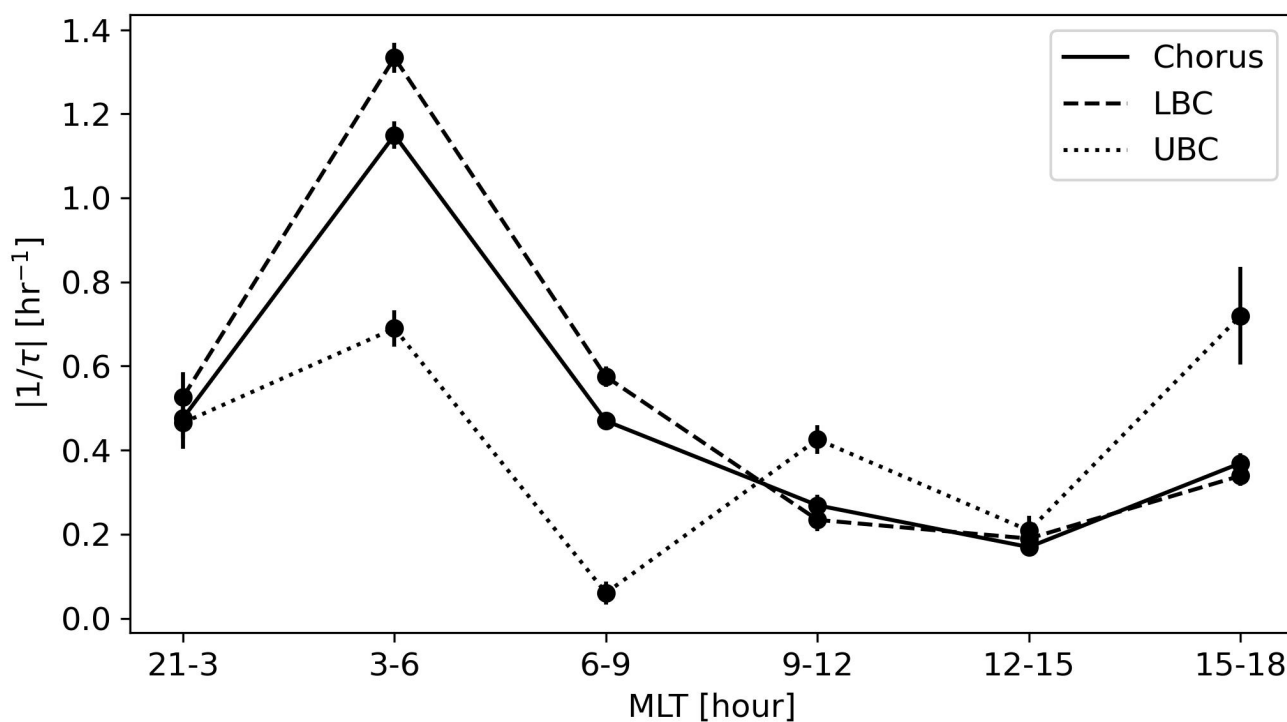

Figure 1. The inverse of magnetic field wave power decay timescales for the entire chorus range (solid), LBC (dashed), and UBC (dotted) versus MLT. For many of the points, the associated errors are smaller than the marker size. We combined the region 21 to 24 and 0 to 3 MLT and omitted 18 to 21 MLT due to statistical limitations.
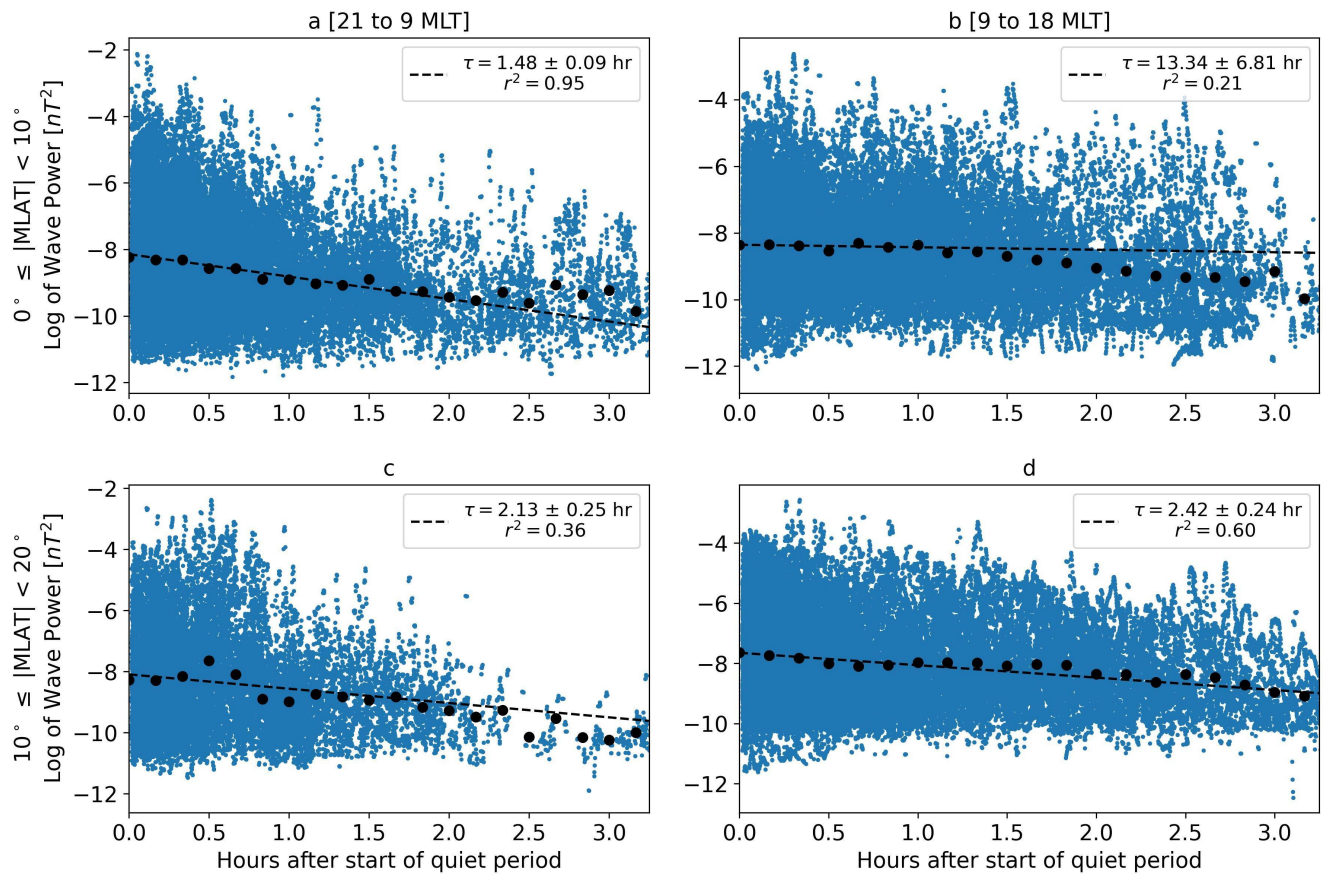

Figure 2. Statistical behavior, during the quiet period following substorms, of magnetic chorus wave power. The left (right) column of figures shows the behavior in the 21 to 9 MLT (9 to 18 MLT) region. The top (bottom) row of figures shows the behavior for $0°$ to $10°$ ($10°$ to $20°$) MLAT. The blue scatter points are the underlying data, the black scatter points are the geometric mean value of the proceeding 10 minutes of data. The dashed line is the best exponential decay to the first 75 minutes of data. Note that the wave power is natural log transformed.
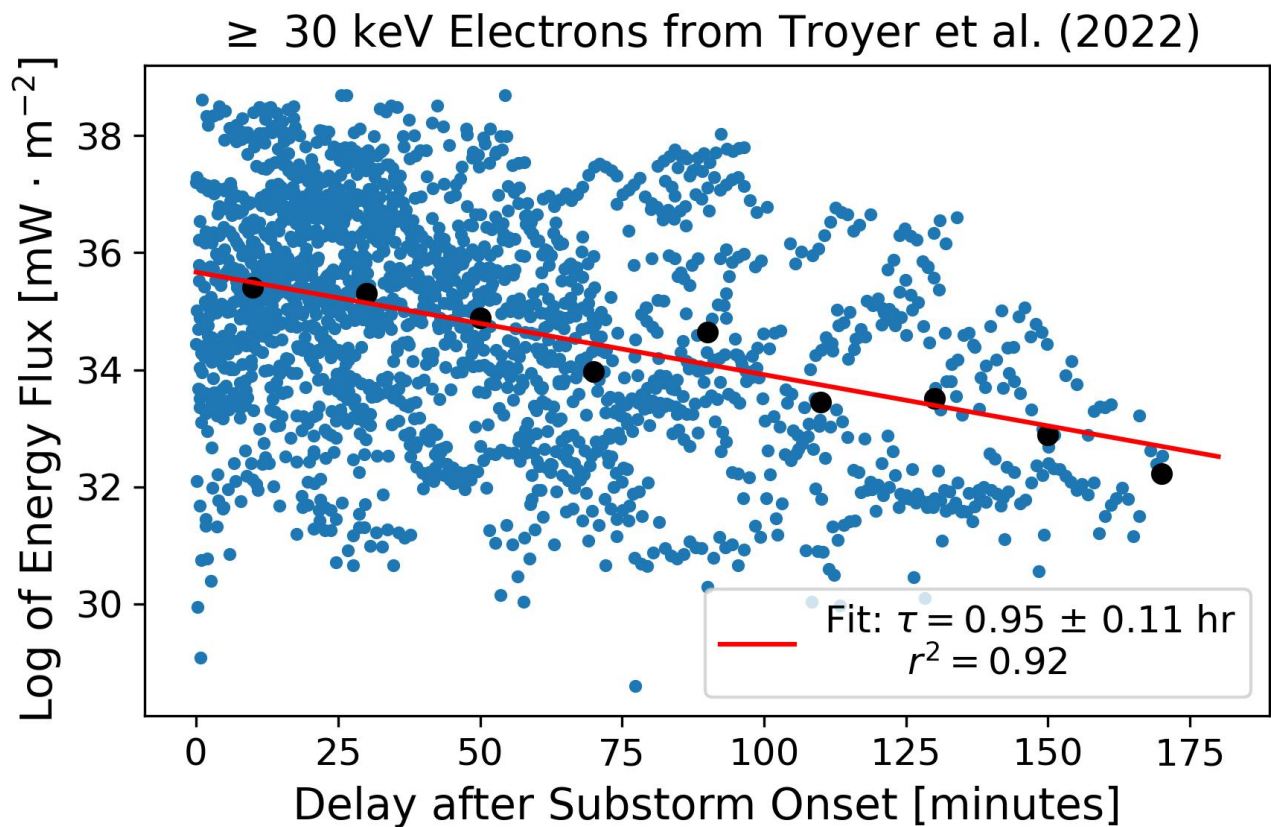

Figure 3. Updated figure from Troyer et al. (2022) showing the decay of ≥ 30 keV pulsating aurora electrons after substorms. The blue scatter points indicate the underlying data, the black scatter points are the geometric mean values of the surrounding 20 minutes of energy flux, and the red line is the best fit exponential decay. The r^2 value is based on the fit to the black scatter points. Note that the energy flux is natural log transformed.
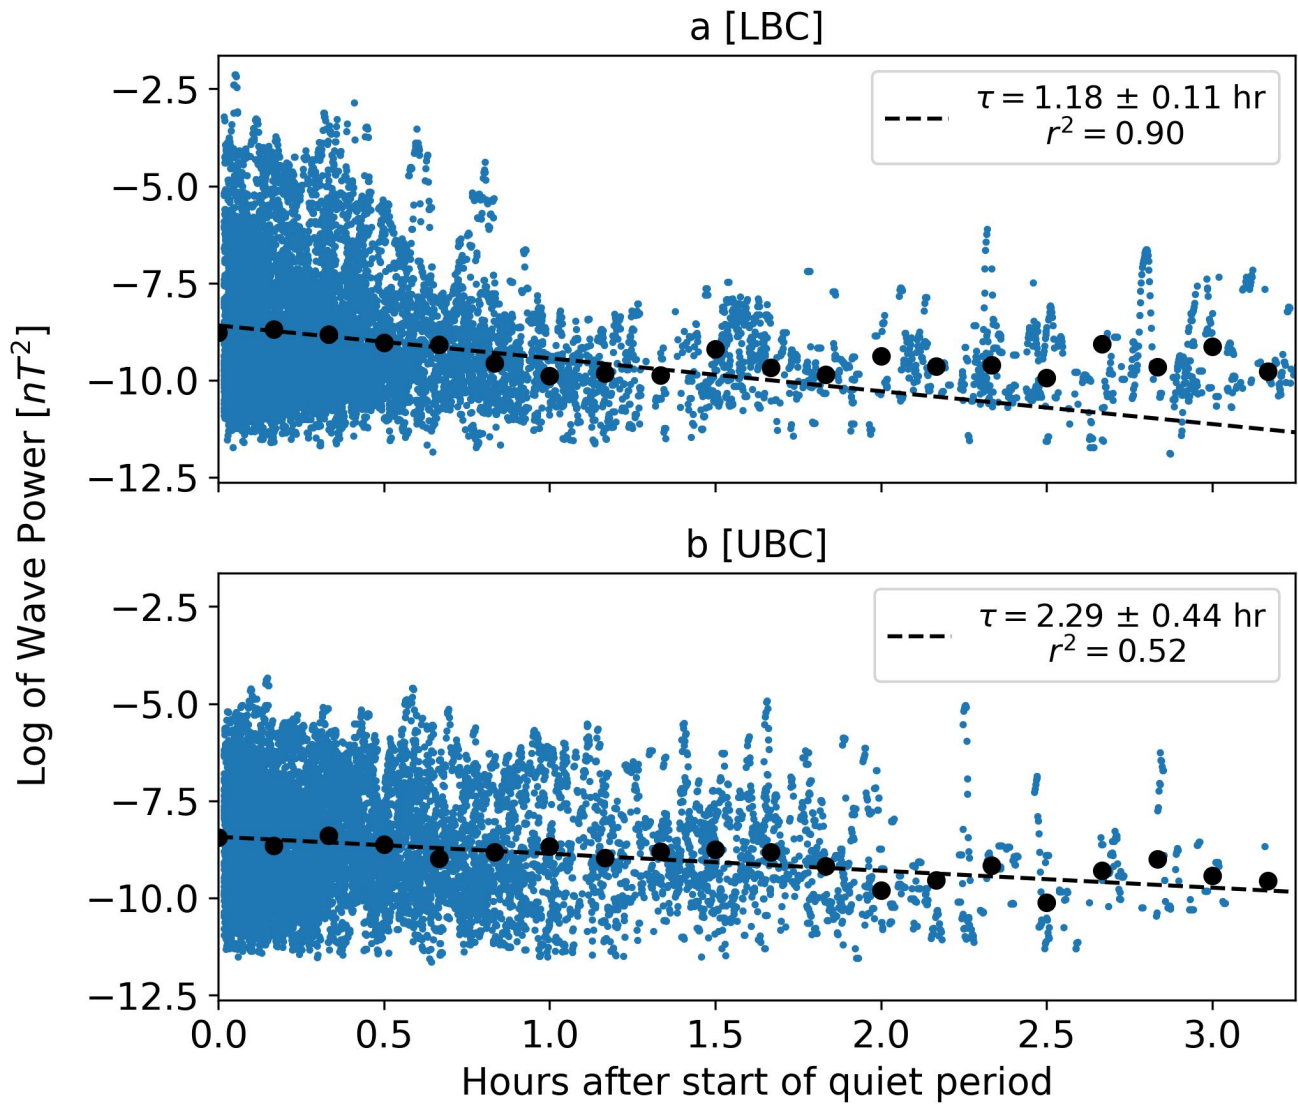

Figure 4. Statistical behavior of magnetic wave power, during the quiet period following substorms, from the LBC [a] and UBC [b] frequency ranges. Data in the figure is from the region 21 to 5 MLT, $3 < L < 6.6$, and $-20°$ to $20°$ MLAT. The blue scatter points indicate the underlying data, the black scatter points are the geometric mean value of the proceeding 10 minutes of data. The dashed black line is the best exponential decay to the first 75 minutes of data. Note that the wave power is natural log transformed.
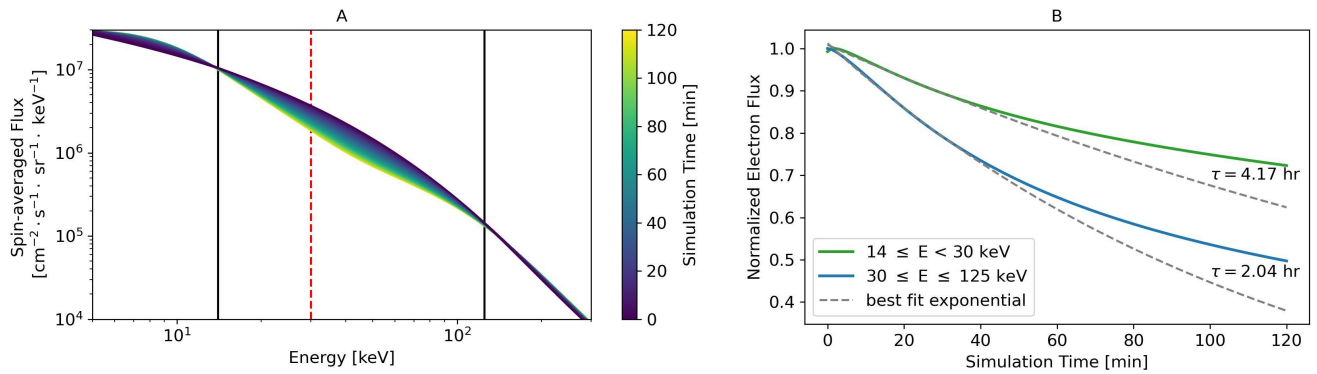

Figure 5. Results from our quasi-linear diffusion simulation of chorus waves. Panel A shows how the initial electron energy distribution decays over the simulation. The solid black lines indicate 14 keV and 125 keV and are the approximate bounds of strong diffusion. The dashed red line indicates 30 keV, which we define as the boundary between high and low energy electrons. Panel B shows the summed decay of low (14 keV $\leq$ E < 30 keV) and high (30 keV $\leq$ E $\leq$ 125 keV) electrons within the region of strong diffusion. The solid lines indicate the normalized flux decays, while the dashed gray lines are the best fit exponentials for the first 30 minutes of the simulation.

1 SUPPLEMENTARY TABLES AND FIGURES

1.1 Tables

Table S1. Full chorus, LBC, and UBC magnetic (B) and electric (E) power spectral density decay timescales (τ) and peak wave magnetic field (B_w) for the midnight (21 to 3 MLT) region. We included error, R^2 values, and the number of statistics for the magnetic field measurements (N_B) to contextualize the quality of each fit.

Type	τ_B	B_w	R_B^2	τ_E	R_E^2	N_B
Chorus	2.10 ± 0.43 hr	15.2 pT	0.85	0.73 ± 0.07 hr	0.61	12123
LBC	1.90 ± 0.43 hr	11.9 pT	0.70	1.00 ± 0.20 hr	0.80	7780
UBC	2.15 ± 0.57 hr	15.9 pT	0.57	0.97 ± 0.15 hr	0.18	6862

Table S2. Full chorus, LBC, and UBC magnetic (B) and electric (E) power spectral density decay timescales (τ) and peak wave magnetic field (B_w) for the predawn (3 to 6 MLT) region. We included error, R^2 values, and the number of statistics for the magnetic field measurements (N_B) to contextualize the quality of each fit.

Type	τ_B	B_w	R_B^2	τ_E	R_E^2	N_B
Chorus	0.87 ± 0.05 hr	19.0 pT	0.97	2.90 ± 0.69 hr	0.55	19495
LBC	0.75 ± 0.04 hr	18.7 pT	0.96	5.16 ± 3.09 hr	0.48	14341
UBC	1.45 ± 0.18 hr	14.5 pT	0.47	2.97 ± 0.80 hr	0.49	10041

Table S3. Full chorus, LBC, and UBC magnetic (B) and electric (E) power spectral density decay timescales (τ) and peak wave magnetic field (B_w) for the dawn (6 to 9 MLT) region. We included error, R^2 values, and the number of statistics for the magnetic field measurements (N_B) to contextualize the quality of each fit.

Type	τ_B	B_w	R_B^2	τ_E	R_E^2	N_B
Chorus	2.13 ± 0.19 hr	16.4 pT	0.54	2.61 ± 0.35 hr	0.85	35161
LBC	1.74 ± 0.15 hr	16.5 pT	0.58	2.87 ± 0.51 hr	0.73	28233
UBC	16.57 ± 15.28 hr	11.9 pT	0.23	7.53 ± 3.20 hr	0.03	12478

Table S4. Full chorus, LBC, and UBC magnetic (B) and electric (E) power spectral density decay timescales (τ) and peak wave magnetic field (B_w) for the morning (9 to 12 MLT) region. We included error, R^2 values, and the number of statistics for the magnetic field measurements (N_B) to contextualize the quality of each fit.

| Type	τ_B	B_w	R_B^2	τ_E	R_E^2	N_B
Chorus	3.72 ± 0.68 hr	18.9 pT	0.83	4.08 ± 0.87 hr	0.64	33133
LBC	4.27 ± 0.97 hr	19.3 pT	0.75	2.63 ± 0.42 hr	0.66	28816
UBC	2.35 ± 0.38 hr	12.3 pT	0.51	-3.61 ± 1.12 hr	0.12	9240

Table S5. Full chorus, LBC, and UBC magnetic (B) and electric (E) power spectral density decay timescales (τ) and peak wave magnetic field (B_w) for the afternoon (12 to 15 MLT) region. We included error, R^2 values, and the number of statistics for the magnetic field measurements (N_B) to contextualize the quality of each fit.

Type	τ_B	B_w	R_B^2	τ_E	R_E^2	N_B
Chorus	5.90 ± 1.49 hr	18.3 pT	0.34	-7.36 ± 2.52 hr	0.27	39868
LBC	5.27 ± 1.22 hr	18.3 pT	0.40	-5.70 ± 1.56 hr	0.46	38363
UBC	4.79 ± 1.63 hr	10.8 pT	0.58	4.72 ± 1.81 hr	0.30	5274

## 1.2 Figures

Table S6. Full chorus, LBC, and UBC magnetic (B) and electric (E) power spectral density decay timescales (τ) and peak wave magnetic field (B_w) for the evening (15 to 18 MLT) region. We included error, R^2 values, and the number of statistics for the magnetic field measurements (N_B) to contextualize the quality of each fit.

Type	τ_B	B_w	R^2_B	τ_E	R^2_E	N_B
Chorus	2.71 ± 0.35 hr	15.0 pT	0.25	1.35 ± 0.14 hr	0.67	14665
LBC	2.95 ± 0.42 hr	14.9 pT	0.22	1.27 ± 0.13 hr	0.69	14265
UBC	1.39 ± 0.45 hr	10.8 pT	0.07	3.75 ± 3.88 hr	0.03	937
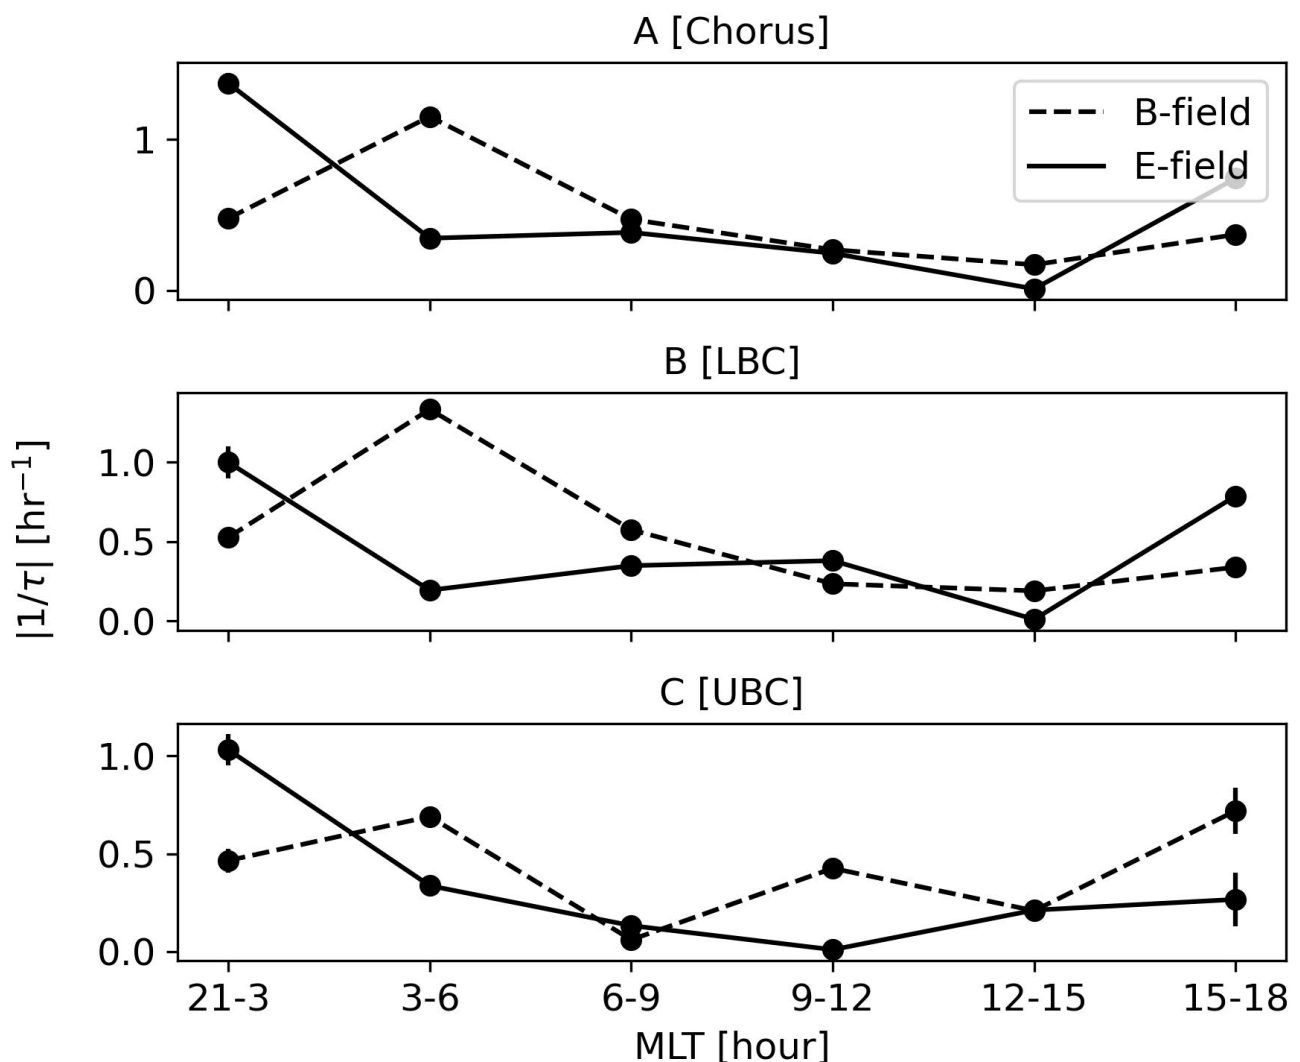

Figure S1. The inverse of magnetic (dashed) and electric (solid) field wave power decay timescales for the entire chorus range (Panel A), LBC (Panel B), and UBC (Panel C) versus MLT. For many of the points, the associated errors are smaller than the marker size. We combined the region 21 to 24 and 0 to 3 MLT and omitted 18 to 21 MLT due to statistical limitations.

Figure S2. Histograms of injection period lengths and quiet period lengths as estimated from the SME index. See Section 2.2 in the main document for the specifics on how we estimated these.
