#### Abstract

Our understanding of tree stem methane (CH4) emissions is evolving rapidly. Few studies have combined seasonal measurements of soil, water and tree stem CH4 emissions from forested wetlands, inhibiting our capacity to constrain the tree stem CH4 flux contribution to total wetland CH4 flux. Here we present annual data from a subtropical freshwater Melaleuca quinquenervia wetland forest, spanning an elevational topo-gradient (Lower, Transitional and Upper zones). Eight field-campaigns captured an annual hydrological flood-dry-flood cycle, measuring stem fluxes on 30 trees, from four stem heights, and up to 30 adjacent soil or water CH4 fluxes per campaign. Tree stem CH4 fluxes ranged several orders of magnitude between hydrological seasons and topo-gradient zones, spanning from small CH4 uptake to ~203 mmol m-2 d-1. Soil CH4 fluxes were similarly dynamic and shifted from maximal CH4 emission (saturated soil) to uptake (dry soil). In Lower and Transitional zones respectively, tree stem CH4 contribution to the net ecosystem flux was greatest during flooded conditions (49.9 and 70.2 %) but less important during dry periods (3.1 and 28.2 %). Minor tree stem emissions from the Upper elevation zone still offset the Upper zone CH4 soil sink capacity by ~51% during dry conditions. Water table height was the strongest driver of tree stem CH4 fluxes, however tree emissions peaked once the soil was inundated and did not increase with further water depth. This study highlights the importance of quantifying the wetland tree stem CH4 emissions pathway as an important and seasonally oscillating component of wetland CH4 budgets.

#### 27 Abstract

Our understanding of tree stem methane  $(CH_4)$  emissions is evolving rapidly. Few studies 28 29 have combined seasonal measurements of soil, water and tree stem CH<sub>4</sub> emissions from 30 forested wetlands, inhibiting our capacity to constrain the tree stem  $CH_4$  flux contribution to 31 total wetland  $CH_4$  flux. Here we present annual data from a subtropical 32 freshwater Melaleuca quinquenervia wetland forest, spanning an elevational topo-gradient 33 (Lower, Transitional and Upper zones). Eight field-campaigns captured an annual 34 hydrological flood-dry-flood cycle, measuring stem fluxes on 30 trees, from four stem 35 heights, and up to 30 adjacent soil or water  $CH_4$  fluxes per campaign. Tree stem  $CH_4$  fluxes 36 ranged several orders of magnitude between hydrological seasons and topo-gradient zones, spanning from small CH<sub>4</sub> uptake to ~203 mmol  $m^{-2}$   $d^{-1}$ . Soil CH<sub>4</sub> fluxes were similarly 37 38 dynamic and shifted from maximal CH<sub>4</sub> emission (saturated soil) to uptake (dry soil). In 39 Lower and Transitional zones respectively, tree stem  $CH_4$  contribution to the net ecosystem 40 flux was greatest during flooded conditions (49.9 and 70.2 %) but less important during dry 41 periods (3.1 and 28.2 %). Minor tree stem emissions from the Upper elevation zone still offset 42 the Upper zone  $CH_4$  soil sink capacity by ~51% during dry conditions. Water table height 43 was the strongest driver of tree stem  $CH_4$  fluxes, however tree emissions peaked once the soil 44 was inundated and did not increase with further water depth. This study highlights the 45 importance of quantifying the wetland tree stem  $CH_4$  emissions pathway as an important and 46 seasonally oscillating component of wetland CH<sub>4</sub> budgets.

47

48

#### 49 **Plain language summary**

50 Wetland tree stems were recently shown to emit the potent greenhouse gas – methane (CH<sub>4</sub>), 51 which is ~45 more powerful than carbon dioxide at warming the Earth's atmosphere. With 52 very few studies ever published on this 'treethane' phenomenon, it is still largely unknown as 53 to why, when and how much methane wetland trees may contribute to the natural emissions 54 from wetland ecosystems. This is important to understand in the context of global methane 55 budgets, climate change and future atmospheric models. Our study measured some of the 56 first-ever wetland tree stem methane emissions spanning an annual cycle, accounting for the 57 seasonal changes in water level of an ephemeral forested wetland - dominated by Melaleuca 58 quinquenervia trees. Under the wettest conditions, we found that tree stems emitted the most

methane, and accounted for the majority of the total wetland flux (compared to methane 59 emissions from the wetland water surface). We hypothesize that the methane is largely 60 61 coming from the low-oxygen wetland soils, and is being transported upwards through the tree 62 roots, transpiration stream and bark layers. The tree stem methane emissions were less important during dry periods, when soil methane emissions were dominant. Overall, tree 63 stems contributed 28-68 % of the annual methane emissions from the wetland forest, 64 65 highlighting the importance of accounting for tree stem methane emissions within wetland 66 methane budgets.

#### 68 **1.0 Introduction**

Methane (CH<sub>4</sub>) is a greenhouse gas ~45 times more potent than carbon dioxide, and 69 70 responsible for about one third of current atmospheric radiative forcing (Masson-Delmotte et 71 al., 2021; Neubauer & Megonigal, 2015). Atmospheric CH<sub>4</sub> concentrations are rising rapidly 72 (Peng et al., 2022; Saunois et al., 2016) and a thorough understanding of all CH<sub>4</sub> sources 73 (both natural and anthropogenic) is important for climate change management and mitigation 74 strategies. Currently,  $\sim 60$  % of the global annual CH<sub>4</sub> emissions are attributed to 75 anthropogenic sources such as fossil fuel use, transportation and agricultural sectors, whereas 76 tropical wetlands ( $< 30^{\circ}$  latitude) represent the largest natural source of CH<sub>4</sub> (Saunois et al., 77 2020).

78 Wetland CH<sub>4</sub> is largely produced within reduced anaerobic soils, then emitted to the 79 atmosphere via ebullition, diffusion and herbaceous plant-mediated pathways (Bartlett & 80 Harriss, 1993; Boon & Sorrell, 1995; Chanton et al., 1989; Jeffrey et al., 2019a). Only 81 recently was woody wetland vegetation (i.e., tree stems) recognized as a potentially important 82 wetland CH<sub>4</sub> source within global wetland CH<sub>4</sub> budgets (Masson-Delmotte et al., 2021; 83 Saunois et al., 2020), but due to a lack of measurements, tree stems are currently not 84 considered as a distinct emission category. The poorly constrained contribution of wetland tree stem CH<sub>4</sub> emissions to the total wetland CH<sub>4</sub> budgets may explain the large discrepancies 85 86 between bottom-up and top-down estimates, and may also help explain large uncertainties surrounding global wetland CH<sub>4</sub> emissions (Masson-Delmotte et al., 2021; Pangala et al., 87 88 2017; Saunois et al., 2020).

89 Research on tree stem CH<sub>4</sub> emissions has been gaining rapid momentum having recently 90 been coined a 'new frontier of the global carbon cycle' (Barba et al., 2019a; Covey & 91 Megonigal, 2019). Two-thirds of all tree  $CH_4$  literature was published within the last three 92 years. Tree stem CH<sub>4</sub> emissions have now been reported from various ecosystems including 93 upland forests (Barba et al., 2019b; Machacova et al., 2016; Machacova et al., 2023; Pitz & 94 Megonigal, 2017; Wang et al., 2016), mangrove forests (Gao et al., 2021; Jeffrey et al., 95 2019b; Zhang et al., 2022), riparian forests (Flanagan et al., 2021; Gauci et al., 2022) and 96 standing deadwood, snags or ghost forests (Carmichael & Smith, 2016; Martinez & Ardon, 97 2021; Warner et al., 2017). The highest tree stem  $CH_4$  emissions, however, are exclusively 98 attributed to forested wetland ecosystems, also known as lowland forests (Gauci et al., 2010; 99 Jeffrey et al., 2021b; Pangala et al., 2013; Terazawa et al., 2007). For example, in the Amazon floodplain, tree stem CH<sub>4</sub> emissions were estimated to contribute half of all CH<sub>4</sub> emissions from the Amazonian wetlands (Pangala et al., 2017) and up to 30% of the net ecosystem CH<sub>4</sub> emissions of Panamanian neotropical peatlands (Sjögersten et al., 2020). Similar in magnitude, in subtropical Australian freshwater wetland forests, flooded tree stem CH<sub>4</sub> fluxes were a significant CH<sub>4</sub> source to the atmosphere (Jeffrey et al., 2020a). However, none of these previous studies accounted for bi-monthly-scale variability in CH<sub>4</sub> fluxes over an annual cycle.

The origins and drivers of tree stem CH<sub>4</sub> emissions are complex. Sources of CH<sub>4</sub> have been 107 108 attributed to a combination of microbial production within wet or rotting heartwood (Wang et 109 al., 2021; Yip et al., 2019; Zeikus & Ward, 1974), saprotrophic fungi (Lenhart et al., 2012) 110 and/or from soil methanogenesis where trees provide a conduit for CH<sub>4</sub> emissions (Jeffrey et 111 al., 2021b). In wetland forests, this is particularly important, as soil CH<sub>4</sub> is transported 112 upwards either passively via diffusion, or actively via plant tissues and the transpiration 113 stream, and eventually egressed via tree stems. Studies on the microbial drivers of tree stem CH4 have also revealed methanogenic communities living within heartwood and living 114 115 tissues (Feng et al., 2022; Smits et al., 2021; Yip et al., 2019) and also methanotrophic 116 communities within the phyllosphere i.e. stems, bark and leaves (Feng et al., 2022; Jeffrey et 117 al., 2021a; Putkinen et al., 2021). Thus, it is clear that methane fluxes from trees can come from diverse sources. 118

119 The use of natural and labelled isotopic tracers investigating connectivity between the soil -120 tree stem - atmospheric continuum, have provided compelling evidence for a soil microbial 121 source of tree stem CH<sub>4</sub>, due to overlapping isotopic signatures and correlations with soil 122 CH<sub>4</sub> fluxes (Jeffrey et al., 2021b; Megonigal et al., 2019; Pangala et al., 2017; Plain & Epron, 123 2021). Increased soil moisture (favouring anaerobic soil conditions and methanogenesis) has also been well-documented as a positive driver of wetland tree stem CH<sub>4</sub> fluxes (Jeffrey et 124 125 al., 2020a; Pangala et al., 2014; Pitz et al., 2018; Terazawa et al., 2021). Furthermore, the 126 typically logarithmic decay in vertical CH<sub>4</sub> emission rates with stem height distance from 127 soil, also suggests a below-ground CH<sub>4</sub> source in wetland forests (Jeffrey et al., 2020b; Sjögersten et al., 2020). Ephemeral forested wetlands undergoing dynamic seasonal and 128 129 hydrological oscillations in water table height, soil moisture and soil redox potentials are an ideal location to monitor both drivers of wetland tree stem CH<sub>4</sub> emissions and to also 130 131 document potential seasonal changes in the relative contribution of trees to the net annual 132 wetland CH<sub>4</sub> flux.

Along the east-coast of Australia, many ephemeral wetland forests are dominated by 133 134 Melaleuca quinquenervia (Cav.) S.T. Blake, colloquially known as the 'broad-leaved 135 paperbark'. These forests have a high carbon storage capacity and have recently been 136 incorporated into Australian blue carbon accounting (Lovelock et al., 2022). M. 137 quinquenervia generally grow as mono-specific stands and have adapted to withstand 138 brackish to freshwater conditions, acidic soils, heavy clays, moderate bushfires and can 139 tolerate semi-permanent inundation once established (McJannet, 2008). The stems feature a 140 bark that is distinctly unique and comprised of thick, spongy, peeling and paper-like layers 141 (Chiang & Wang, 1984). Due to their hardy and invasive nature, M. quinquenervia can 142 readily colonize pasture, and can form dense stands in seasonal wetlands and flooded 143 environments (Johnston et al., 2003). The species has also been introduced to tropical and 144 subtropical lowlands around the world as a fast-growing forestry alternative, promote water 145 table draw-down and/or for exotic aesthetic reasons (CABI, 2023). As such, M. 146 quinquenervia are found in at least 57 countries including coastal Asia, the Middle East, 147 Africa and Northern, Central and Southern Americas. Outside of Australia, M. quinquenervia 148 is broadly classified as an invasive species, particularly in the Everglades National Park, Florida (USA) where they now occupy ~200,000 ha (Center et al., 2012). 149

150 Although *M. quinquenervia* have been previously shown to emit high rates of  $CH_4$  from their stems under flooded conditions (Iram et al., 2022; Jeffrey et al., 2020a; Jeffrey et al., 2020b; 151 152 Jeffrey et al., 2021b), no study has captured the transitions between inundated and dry conditions to evaluate their contribution tree stem CH<sub>4</sub> emissions to net annual wetland CH<sub>4</sub> 153 154 budgets. This study aimed to quantify both the annual and seasonal changes to tree stem  $CH_4$ 155 emissions along a forest hydro-topo-gradient and to determine the drivers of tree stem CH<sub>4</sub> fluxes. We hypothesize that *M. quinquenervia* tree stems are a major source of the net 156 157 wetland CH<sub>4</sub> emissions, and this is related to soil CH<sub>4</sub> production that is moderated by site hydrological conditions. 158

159

## 160 **2.0 METHODS**

#### 161 **2.1 Site and elevations**

162 The coastal freshwater wetland investigated here is located near Bogangar in subtropical 163 NSW, Australia (Fig. 1). The site was originally cleared during the 1970's, however by the 164 mid-1980s, fringing trees started to recolonize the site. Within two decades, the wetland became dominated by a dense monoculture stand of *M. quinquenervia*. The wetland is located within a coastal hind-dune system with soils that are primarily Pleistocene aeolian sands, with a shallow organic-rich surface horizon. During periods of heavy rainfall, surface water within the ephemeral wetland can persist for several months and reach depths of up to  $\sim 2$  m in lower parts of the wetland before completely receding during dry seasons (Fig. 1). The subtropical climate experiences a summer-dominated mean rainfall of 1812 mm per year, with generally dry conditions in winter between July to September (BOM, 2023a).

172

173

Figure 1. Map of study site in the upper panel showing locations of sampled *Melaleuca* trees (red, yellow and green dots), the location of water level loggers (white dots). The lower panel shows hydro-topological zones and tree base elevational differences relative to the lowest location in the wetland forest (black squares).

179 Based on a topographic gradient from east to west, our study design split the forest into three 180 distinct hydro-topo-gradient areas, from herein classified as 'Upper', 'Transitional' and 181 'Lower' zones (Fig. 1). In the Upper zone, *M. quinquenervia* were interspersed with other 182 coastal heath species (Banksia integrefolia, Casuarina glauca) and grasses (Lomandra 183 hysterix) and generally sit above the soil water logging threshold. Thus, this zone can be 184 considered a largely non-wetland ecotone and used as a comparative control for the wetland 185 forest. The Transitional and Lower zones consisted of a dense monoculture stands of M. 186 quinquenervia with no understory vegetation. Within each zone, 10 mature trees of various 187 stem sizes (diameter at breast height (DBH) ranging from 12 to 42 cm) were randomly 188 selected and labelled for the duration of the study. Eight field campaigns were conducted 189 over a 12-month period. Sampling for campaigns 1, 2, 6, 7 and 8 were mostly conducted from 190 a small boat as the water depth in the forest was >1 m. Data analysis were sub-grouped 191 (below) to compare the wetland hydrological campaigns featuring surface waters called 192 'Wet' (campaigns 1, 2, 6, 7 and 8) vs campaigns featuring exposed soil surfaces called 'Dry' 193 (campaigns 3, 4 and 5).

194

#### **2.2** Soil and aquatic physicochemical parameters and CH<sub>4</sub> concentrations

196 During Wet conditions (campaigns 6 and 7), triplicate surface water samples within the forest 197 were measured at various depths for pH, temperature (°C), EC and redox potential (mV) 198 directly from the side of the boat using pre-calibrated multiprobes (HQ40d, Hach). During Dry conditions (campaigns 4 and 5), porewater was collected from various subsurface depths 199 200 using an extendable push point piezometer (Sonlist), transferred via gas tubing (Bev-A-Line IV). The soil volumetric water content (VWC %) was measured in duplicate at 10 cm soil 201 202 depth (north and south side) for each tree (Hydro Sense II, Campbell Scientific, detection 203 limit up to 50 % VWC) when the water was below the surface.

To measure dissolved  $CH_4$  concentrations of surface water and porewater, duplicate water samples were collected (as described above) using tubing and 150 mL syringes and from various depths below the water surface (Wet campaigns 6 and 7) or below the soil surface (Dry campaigns 4 and 5). A 40 mL sample of the collected water was equilibrated in the syringe with 110 mL of atmospheric air headspace via vigorous shaking for four minutes (Borges et al., 2015; Roberts & Shiller, 2015). The CH<sub>4</sub> equilibrated headspace was then added to 1 L foil gas bag (Cali-5-bond, Calibrated Instruments) and diluted with 750 mL atmospheric air. The gas bags (i.e., now containing 900 mL gas sample) were connected to a field portable cavity ring-down spectrometer CH<sub>4</sub> analyzer (CRDS, G4301 Gas Scouter, Picarro) and the mean CH<sub>4</sub> concentration was recorded (ppm). The initial concentrations were then back-calculated as dissolved CH<sub>4</sub> ( $\mu$ M) to account for dilution with ambient air (CH<sub>4</sub> concentration measured *in situ* with the CRDS) and corrected for the temperaturedependant CH<sub>4</sub> solubility coefficient (Wiesenburg & Guinasso Jr, 1979).

217

## 218 2.3 Tree, soil and aquatic CH<sub>4</sub> flux measurements

219 Tree stem CH<sub>4</sub> fluxes were measured using a 30 cm tall by 40 cm wide semi-rigid wrappable 220 chamber carefully attached to each tree using straps, as described by Siegenthaler et al. 221 (2016). The chamber was connected to the CRDS (listed above) via gas tubing (Bev-A-Line 222 IV) passing through a drying desiccant (Drierite) via a closed loop. The CRDS was factory 223 calibrated and features a precision of  $\pm 0.3$  ppb and lower detection limit of 0.9 ppb. During 224 each campaign, CH<sub>4</sub> tree fluxes were measured from four stem heights on 30 individual trees 225 at 10-40 cm, 40-70 cm, 70-100 cm and 100-130 cm above the soil or water level. Once 226 chambers were sealed to the tree stems, the concentration was recorded until a clear linear 227 flux rate was observed for 150 seconds (median value) on high CH<sub>4</sub> fluxing trees and up to 228 15 minutes on low CH<sub>4</sub> fluxing trees.

229 Soil CH<sub>4</sub> fluxes were measured during dry campaigns within a 1 m radius of each sampled tree, using a 26 cm diameter x 15 cm high circular PVC chamber, that was first gently 230 231 inserted ~2 cm into the soil to create a circular groove on the soil surface. The chamber was 232 then immediately removed and flushed with ambient air, before being gently replaced back 233 onto the same soil surface location. Care was taken not to apply downward pressure or step close to the chamber, ensuring no gas efflux enhancement, which was confirmed by real-time 234 235 observation of the linearity of the fluxes. The fluxes were recorded using similar closed-loop 236 methods and the same CRDS equipment as the tree stem measurements. The soil CH<sub>4</sub> flux 237 was recorded for 300 seconds (median), but up to 14 minutes during low CH<sub>4</sub> fluxing 238 conditions.

Aquatic  $CH_4$  fluxes were measured during flooded wetland campaigns within a 1 m radius of each sampled tree using a 28 cm wide x 25 cm high floating chamber. All measurements were performed from a small boat so as not to disturb the wetland sediments. Any chambers

- featuring non-linear trends in CH<sub>4</sub> were disregarded and repeated. The flux was measured for
- 243 300 seconds (median), but as long as 13 minutes during low CH<sub>4</sub> flux measurements.

# 245 2.4 CH<sub>4</sub> flux calculations and linear flux thresholds

246 The  $CH_4$  fluxes (F) for trees, soil and water were calculated using the equation:

$$F = (s(V/RT_{air}A))t$$

where s is the regression slope for each chamber incubation deployment (ppm sec<sup>-1</sup>), V is the 248 chamber volume (m<sup>3</sup>), R is the universal gas constant (8.205 x  $10^{-5}$  m<sup>3</sup>.atm<sup>-1</sup>.K<sup>-1</sup>.mol<sup>-1</sup>),  $T_{air}$  is 249 the mean air temperature recorded inside the chamber in degrees Kelvin (°K), A is the surface 250 area of each chamber  $(m^2)$  and t is the conversion factor from seconds to day, and to mmol of 251 CH<sub>4</sub>. The s and  $T_{air}$  terms were extracted in R studio (version 3.5.1) using a modified 252 'GasFlux' package of Fuss (2019). The V term (i.e. total volume of the closed loop including 253 254 chamber, 4 m length of gas tubing, desiccant canister and internal volume of CRDS) was 255 calculated as described by Jeffrey et al. (2020b).

(1)

Linear flux  $r^2$  value thresholds were dependent upon measurement type and location. Any 256 low  $r^2$  values <0.70 were manually and visually reviewed using the 'GasFlux' package of 257 258 Fuss (2019) that generates plots of each individual incubation flux. The average aquatic flux  $r^2$  was 0.96 ± 0.01 (n=85, where ± is SE herein) and the average soil flux  $r^2$  value was 0.95 ± 259 0.01 (n=100). The overall average tree stem CH<sub>4</sub> flux  $r^2$  of 0.88 ± 0.01 (n=890) was lower 260 than the aquatic and soil  $r^2$  values, due to several low CH<sub>4</sub> fluxing upper tree stem 261 measurements and Upper zone trees, particularly during dry campaigns (i.e. trees of slight 262  $CH_4$  emission or slight uptake). The median  $r^2$  for linear regression of Lower, Transitional 263 and Upper zone tree stem fluxes was 0.99, 0.99 and 0.87, respectively. The simultaneously 264 recorded linear tree stem CO<sub>2</sub> fluxes were used as a proxy for assessing air-tight chamber 265 seals, particularly on low CH<sub>4</sub> fluxing trees. Occasionally, white potting clay was used to fill 266 267 any gaps between the chambers and tree stems, on trees featuring cracks, fissures, anomalies 268 or splits in the bark.

269

#### 270 **2.5 Up-scaling tree stem CH<sub>4</sub> fluxes**

Individual stem circumferences of the 30 trees were measured during the driest campaign at 10 cm increments from 0 cm (basal area) up to 200 cm stem height above the soil with a tape measure. The forest density (trees ha<sup>-1</sup>), DBH of all trees (cm) and mean tree height was estimated using a LiDAR enabled smartphone (iPhone 12 Pro, Apple) and forestry scanning app (Arboreal Forest, Arboreal AB). Tree density and size was scanned and calculated within triplicate 50 m<sup>2</sup> plots within each zone.

To upscale the stem  $CH_4$  fluxes measured at various heights into emissions from individual trees, we assumed a simple non-branching tree with a single cylindrical inward tapering stem to a height of 1.3 m above soil or water. During the highest water period, we assumed tree stem circumference did not change above the 2 m high circumference measurement (as mentioned above). The stem surface area was sectioned into radial bands and the  $CH_4$  fluxes at the corresponding band heights were applied and integrated according to Jeffrey et al. (2020b) and similar to Pangala et al. (2017) using the equation:

284 
$$F_t = \int_{0.1}^{1.3} (c.h.F)$$
(2)

where  $F_t$  is the flux per tree (mmol per tree d<sup>-1</sup>), *c* is the tree circumference (m) for each flux measurement location (adjusted for each campaign depending upon the water height above the soil), *h* is the height (m) for each tree segment (i.e. 30 cm as limited by chamber height) and *F* is the measured CH<sub>4</sub> flux rate for that height (mmol m<sup>-2</sup> d<sup>-1</sup>). The upscaled ecosystem tree stem flux was first calculated using a tree area-weighted flux rate ( $F_{taw}$  in mol CH<sub>4</sub> ha<sup>-1</sup> d<sup>-1</sup>) for each hydro-topo-gradient zone and during each campaign using:

$$F_{taw} = \bar{x}F_{t.}d\tag{3}$$

where  $\bar{x}$  is the mean and d is the tree density (trees ha<sup>-1</sup>). Because the mean flux from the 292 selected mature-sized trees may have positively biased the upscaling calculation, a second 293 294 conservative upscaling approach was compared that accounted for the broad range of tree stem sizes in the forest (range 4.7 - 33.5 cm), as measured in density plots (methods 295 described above). First, the average *M. quinquenervia* bark surface area of tree stems to 1.3 m 296 297 stem height was estimated by multiplying  $\pi$  by the average DBH (m) of all trees measured within the triplicate forest density plots (Lower zone n=101 trees, Transitional zone n=67298 299 trees, Upper zone n=52 trees) by a height of 1.3 m. This assumes a cylindrical stem shape (i.e. conservative stem area that does not account for larger basal area). This was then 300

upscaled to estimate bark area  $(B_a)$  per hectare  $(m^2 ha^{-1})$  by multiplying by *d* (as above) for each zone:

$$B_a = d.\bar{x} \text{DBH}.\pi.1.3 \text{m}$$
(4)

Then for each campaign, the sum of sampled tree emissions per day to 1.3 m stem height (i.e. 304  $\sum F_t$  in eq. 2) within each zone was divided by the  $\sum$  of bark surface area to 1.3 m (in m<sup>2</sup>) of 305 same trees, thus estimating the average CH<sub>4</sub> flux rate (mmol m<sup>-2</sup> of bark d<sup>-1</sup>) from each zone 306 and campaign. This was then multiplied by  $B_a$  ha<sup>-1</sup> (m<sup>2</sup> ha<sup>-1</sup>) as the second estimate for 307 upscaled tree CH<sub>4</sub> flux (mol ha<sup>-1</sup> d<sup>-1</sup>). This approach reduced our tree emissions estimates by 308 an average of  $35.7 \pm 4.5$  % from the first approach (Eq. 3). The soil and aquatic CH<sub>4</sub> fluxes 309 were upscaled by first deducting the tree basal surface area per hectare (m<sup>2</sup> ha<sup>-1</sup>) from the 310 311 forest floor from within each hydro-topological zone, then multiplying the remaining 312 soil/aquatic surface area by the average CH<sub>4</sub> flux rate.

For each campaign, the net ecosystem flux from trees (NEF, %) was calculated by dividing 313 the upscaled tree CH<sub>4</sub> flux (mol ha<sup>-1</sup> d<sup>-1</sup>) by the sum of CH<sub>4</sub> emissions per hectare (i.e., net 314 315 tree  $CH_4$  and soil/aquatic flux combined). To estimate the NEF of  $CH_4$  from the wetland over 316 an annual cycle, the results of the eight campaigns were upscaled equally (i.e., 6.5 weeks per campaign). Subsequently, the total CH<sub>4</sub> emission from tree stems (mol ha<sup>-1</sup> yr<sup>-1</sup>) was divided 317 318 by the total CH<sub>4</sub> emission/uptake from soil and water plus the total tree emissions (i.e., the total wetland emissions in mol ha<sup>-1</sup> yr<sup>-1</sup>), to determine the NEF from trees (%) over the annual 319 320 cycle. This was also sub-calculated to specifically compare the contrasting wetland hydrological periods featuring surface waters ('Wet' - campaigns 1, 2, 6, 7, 8) vs exposed 321 soil surfaces ('Dry' - campaigns 3, 4, 5). 322

323

#### 324 **2.6** Water table heights and site elevations

The water table was measured *in situ* at two locations (Fig. 1) using a temperature/pressure logger (Diver, Van Essen) recorded at hourly intervals, along with a barometric logger to correct for atmospheric pressure changes over the annual period. The loggers were deployed 1 m below the soil surface within a PVC slotted pipe. During dry campaign, the elevation of each tree relative to the lowest diver logger was surveyed using an optical level (Leica) to correct for the water table vs stem height across the Lower, Transitional and Upper zones.

#### **332 2.7 Statistical tests**

333 The correlations between two parameters were tested using linear regressions and p values 334 using t-Test: paired two sampling for mean (where p < 0.05). To test the hypothesis about 335 differences between fluxes from trees within each zone and between wet vs dry conditions, 336 and for soil vs water fluxes within each zone and between wet vs dry conditions, the non-337 parametric data was analyzed using Kruskal-Wallis one way analysis of variance (ANOVA) 338 on ranks Statistically significant difference was set at p < 0.001 and was determined using the 339 Dunn's method for multiple pairwise comparisons. Spearman's rank correlation  $(r_s)$ 340 coefficients were also used to measure the strength of association between two variables of 341 non-parametric data, for lower tree stem  $CH_4$  fluxes vs VWC (%) and vs soil  $CH_4$  flux.

342

#### 343 **3.0 Results**

#### 344 **3.1 Seasonal rainfall and hydrology**

345 The eight campaigns occurred between June 2021 and May 2022 spanning winter through to 346 the following late autumn and an annual temperature and solar cycle (Fig. 2). This also 347 occurred during two consecutive years of La Niña weather events, characterized by above 348 average rainfall (BOM, 2023b). During the first five campaigns from June 2021 onwards, the 349 wetland water table declined from +48 cm (i.e., above soil surface) to -69 cm (i.e., below the 350 soil surface) within the Lower zone forest. The water table was below ground for campaigns 351 3-5 during Spring 2021. Summer rainfalls during December 2021 through to February 2022 352 restored and maintained a shallow standing surface water ( $\sim 20$  cm for campaign 6). Two 353 large rainfall events occurring during Autumn in March (351 mm) and April 2022 (343 mm) greatly increased the wetland water table depth, peaking during campaign 7 at 185 cm within 354 355 the Lower zone forest, 161 cm in the Transitional zone forest and also 18 cm deep in the centre of the Upper zone trees (Figs. 1 & 2). 356

Figure 2. Summary of environmental conditions during the eight study campaigns showing seasonal changes in the Lower zone wetland water table (cm), daily rainfall totals (mm), maximum and minimum air temperature (°C) and photosynthetically available radiation (PAR in lum m<sup>-2</sup>). Note: Dry campaigns are highlighted in grey.

## 364 3.2 Ecosystem parameters, tree size, density and surface area

The sampled *M. quinquenervia* stem diameter at breast height (DBH) ranged from 4.6 - 27.8cm, 4.7 - 23.8 cm and 5.6 - 33.5 cm from the Lower to Upper zones respectively (Table S1). The average *M. quinquenervia* DBH increased from the Lower to Upper zones and were 11.9  $\pm 0.6$  cm,  $12.2 \pm 0.7$  cm and  $15.0 \pm 1.0$  cm respectively. The average canopy height was 14.1  $\pm 0.7$  m and the tree density was 5049, 4600 and 3466 trees per hectare for the Lower, Transitional and Upper zones respectively (Table S1). Overall, the tree bases only accounted for 2.03 - 2.14 % of the surface area compared to soil/ water surface (i.e., tree base area ha<sup>-1</sup>).

372

#### 373 **3.3** Aquatic physicochemical and CH<sub>4</sub> variability

Porewater and surface water  $CH_4$  concentrations ( $\mu M$ ) increased with sample depth (Fig. 3, Table S2). The highest porewater  $CH_4$  concentrations were found at -100 cm soil depths which ranged from  $54.3 \pm 57.7$  to  $172.2 \pm 48.3 \ \mu\text{M}$  and shallow porewater CH<sub>4</sub> at -30 cm ranged from  $0.33 \pm 0.43$  to  $23.4 \pm 12.9 \ \mu\text{M}$ . Surface water CH<sub>4</sub> trends were less pronounced vs depth, but CH<sub>4</sub> concentrations were less than porewater and ranged from  $2.4 \pm 0.02$  to  $11.0 \pm 9.7 \ \mu\text{M}$ .

380

Figure 3. Depth profiles for porewater and surface water  $CH_4$  concentrations ( $\mu$ M) during campaigns 4-7 for each wetland zone. Note: Different x-axis scales used. The brown shaded area represents the soil and blue area is surface water and dashed line is the top of water table. Error bars are SE.

#### 387 3.4 Soil and aquatic CH<sub>4</sub> fluxes

388 Aquatic CH<sub>4</sub> fluxes were highly variable in the Lower and Transitional zones and the campaign averages ranged from  $0.96 \pm 0.34$  to  $5.83 \pm 0.72$  mmol m<sup>-2</sup> d<sup>-1</sup> in the Lower zone, 389 and  $0.35 \pm 0.10$  to  $5.36 \pm 2.28$  mmol m<sup>-2</sup> d<sup>-1</sup> in the Transitional zone (Table 1, Fig. 4, Fig. 390 S1). The highest soil fluxes  $(26.12 \pm 34.66 \text{ mmol m}^2 \text{ d}^{-1})$  were observed in the Lower zone 391 when the water table was immediately below the surface during campaign 3. The soil in the 392 Transitional zone was a weak net CH<sub>4</sub> sink during campaign 5 (-0.02  $\pm$  0.01 mmol m<sup>-2</sup> d<sup>-1</sup>). 393 394 The Upper zone soils exhibited slight  $CH_4$  emissions during campaigns 1, 7 and 8 but 395 remained a  $CH_4$  sink for the other five campaigns (Table 1, Fig. 4). There were no significant 396 differences between aquatic CH<sub>4</sub> fluxes between Lower and Transitional zones (p < 0.05, 397 Table S3, Fig. S2). There were significant differences between soil and aquatic  $CH_4$  fluxes in 398 the Lower zone between each campaign but not in the Upper zone, and there were significant 399 differences between Lower and Upper zones for both soil and aquatic fluxes (Table S3, Fig. 400 S2).

401

4(

**Figure 4.** Stacked plots indicating the changing water table within each zone, average  $CH_4$ flux per tree (mmol tree<sup>-1</sup> d<sup>-1</sup>) and average  $CH_4$  flux from water or soil (mmol m<sup>-2</sup> d<sup>-1</sup>). Note: Different y-axis scales, shaded campaigns are where surface water was present, the horizontal dashed line is soil surface, the horizontal solid line separates  $CH_4$  sink and source in Upper zone. Error bars are SE.

## 412 **3.5 Tree stem CH<sub>4</sub> fluxes**

413 Tree stem CH<sub>4</sub> flux rates varied greatly between trees, stem heights, hydrological conditions, campaigns and topography, and ranged from CH<sub>4</sub> uptake to CH<sub>4</sub> fluxes of 203.1 mmol m<sup>-2</sup> d<sup>-</sup> 414 415 <sup>1</sup>, spanning several orders of magnitude (n=890, Table 1, Fig. S3). The largest tree stem CH<sub>4</sub> 416 fluxes occurred during Wet campaigns and occurred within the Transitional and Lower zones. The highest tree stem CH<sub>4</sub> fluxes were almost always from the lower stem 417 418 measurement heights (Fig. 5). Tree stems fluxes between Wet and Dry campaigns and within 419 each zone were significantly different (p < 0.05, Table S4, Fig. S2). There were no obvious 420 patterns suggesting that the same trees always emitted the highest or lowest fluxes (Fig. S3). 421 A large proportion of the Upper zone tree stems exhibited CH<sub>4</sub> uptake (31% of all 422 measurements, n=81 of 180) during the dry campaigns. Importantly, during Dry campaigns 4 and 5, the tree stem CH<sub>4</sub> fluxes (mmol per tree d<sup>-1</sup>) were of the same order of magnitude 423 424 between all site locations (and not significantly different between Lower and Upper zone 425 trees (Table S4, Fig. S3), but were two orders of magnitude different during the during Wet 426 campaigns.

Figure 5. Contour plots showing average tree stem  $CH_4$  flux rates (mmol m<sup>-2</sup> d<sup>-1</sup>) at each stem height, from each campaign and within each hydro-topographic zone. Note: log scale of CH<sub>4</sub> flux rates (mmol m<sup>-2</sup> d<sup>-1</sup>) and water table is from the Lower zone and the dashed line is the soil surface.

427

#### 433 **3.6 Drivers of CH<sub>4</sub> fluxes**

434 There were significant negative trends between both porewater  $CH_4$  ( $\mu M$ ) vs the porewater redox potential (SHE) ( $r^2=0.21$ , p<0.001, n=21) and between dissolved CH<sub>4</sub> vs water table 435 depth ( $r^2=0.22$ , p<0.05, n=31) (Fig. S4). There were no apparent trends between porewater 436 CH<sub>4</sub> (µM) at the same depth interval and tree stem fluxes (Fig. S5). During campaigns 3-5, 437 438 there were significant positive trends between adjacent surface soil moisture (% VWC) and tree stem CH<sub>4</sub> fluxes, ( $r^2$ =0.36, p<0.001, n=90) (Fig. 6). During dry conditions, there was 439 also a significant positive relationship between the soil CH<sub>4</sub> fluxes vs lower tree stem CH<sub>4</sub> 440 fluxes ( $r^2=0.53$ , p<0.001, n=61) (Fig. 7a). However, during inundated conditions, there was 441 442 no correlation between tree  $CH_4$  flux vs aquatic  $CH_4$  flux (Fig. 7b). In the Upper zone, there 443 were no trends between either soil moisture and soil CH<sub>4</sub> flux, vs tree stem CH<sub>4</sub> flux.

Figure 6. Positive significant correlations between soil WVC% and lower (10-40 cm) tree stem CH<sub>4</sub> fluxes during the three Dry campaigns. Note: log scale y-axis, Spearman's Rho ( $r_s$ ), grey areas show 99 % confidence interval and 50% VWC is the upper volumetric water content range of the probe.

Figure 7. Correlations between lower (10-40 cm) tree stem  $CH_4$  fluxes and a) soil  $CH_4$  fluxes (Dry campaigns) and b) aquatic  $CH_4$  fluxes (Wet campaigns) within the Lower and Transitional hydro-topological zones. Note: Spearman's Rho ( $r_s$ ) and grey areas show 99 % confidence interval.

450

When combining all data in the study, there were no apparent trends between tree stem CH<sub>4</sub> flux vs stem height above the soil (Fig. S6). However, when Wet and Dry data campaigns were separated, a positive significant logarithmic trend was observed between Dry campaign tree stem CH<sub>4</sub> flux in relation to the distance to the below-ground water table ( $r^2$ =0.55, p<0.005, n=369, Fig. 8a). No trend with the distance above soil height during Wet campaigns was found (Fig 8b), but a decrease in CH<sub>4</sub> flux vs stem height > water was observed (Fig. 8b).

464

Figure 8. Correlations for all positive tree stem CH<sub>4</sub> flux data vs (a) chamber height distance
from water table during Dry campaigns, and (b) chamber heights above soil surface during

467 Wet campaigns. Note: Log transformed data on y-axis. Yellow lines are 95 % confidence

468 intervals and dashed lines are 95 % prediction intervals.

469

#### 470 **3.7** The net ecosystem flux (NEF) of CH<sub>4</sub> from tree stems

471 The role of tree stem CH<sub>4</sub> fluxes to the total wetland NEF varied greatly during the study. In 472 the Lower and Transitional zones, the tree stem CH<sub>4</sub> fluxes were substantial contributors to the NEF, particularly during Wet conditions (Fig. 9). The contribution of tree stems to the 473 NEF ranged from 25-93 % during Wet campaigns and were > 6 times higher emitters per 474 475 hectare than the soil uptake rate during the Dry campaigns. During campaign 3 in the Lower 476 zone, an anomalously large soil CH<sub>4</sub> release occurred when the water table was very near at 477 the soil surface and hence the soil  $CH_4$  flux pathway was the largest contributor to the Lower zone CH<sub>4</sub> emissions during this campaign (Fig. 9). 478

In the Upper zone, tree stem fluxes were minimal yet somewhat dynamic, as tree emissions offset a portion of the soil  $CH_4$  uptake during campaigns 2, 4 and 6, and tree emissions were equal to soil uptake in campaign 5. During campaign 3, the tree stem  $CH_4$  uptake further enhanced the soil  $CH_4$  sink by ~31 %. During the wettest conditions (Campaigns 1, 7 and 8),

- the Upper zone trees were the dominant  $CH_4$  emission pathway ranging from 52-96 % of the
- 484 NEF (Fig. 9).

486

**Figure 9.** Upscaled wetland CH<sub>4</sub> NEF differentiating the CH<sub>4</sub> flux from tree stems, water and soils from each hydro-topological zone and campaign (mol ha<sup>-1</sup> d<sup>-1</sup>). The values above bar plots indicate the tree CH<sub>4</sub> contribution to: (1) the NEF % (black text); (2) offsetting soil CH<sub>4</sub> uptake (blue text), and (3) enhancing soil uptake (red text). Note: different y-axis scales.

491

## 492 4.0 Discussion

## 493 **4.1 Large variability in tree stem CH<sub>4</sub> emissions**

There were significant differences between the tree stem  $CH_4$  fluxes, both between the Wet and Dry seasons, and along the hydro-topo-gradient. The tree stem  $CH_4$  emissions varied by more than six orders of magnitude, ranging from slight  $CH_4$  uptake in the Upper zones during dry conditions, to large  $CH_4$  fluxes up to 203.1 mmol m<sup>-2</sup> d<sup>-1</sup> during flooded conditions 498 (Table 1). Tree stem  $CH_4$  fluxes also varied greatly depending upon which location of the 499 wetland they were measured in, the hydrological conditions under which they were measured 500 and the height on the tree stem at which the fluxes were measured (Fig. 8b).

501 The largest tree stem CH<sub>4</sub> emissions always occurred during Wet campaigns where the 502 wetland soils were completely inundated in the Lower and Transitional zones (Table 1) and 503 generally from the lowest measurement location on each tree stem (Fig. 5). During periods of 504 flooding, the saturated soils and/or internal tree stem tissues would likely be anaerobic, 505 promoting conditions more suitable for soil and/or internal tree stem methanogenesis to 506 occur, with very little opportunity for aerobic methanotrophy. The lower stem locations are 507 also in closest proximity to any potential soil and porewater CH<sub>4</sub> sources (Jeffrey et al., 508 2021b; Megonigal et al., 2019). Under these conditions, the saturated bark and tree stems can 509 act like a preferential conduit between the soil and the atmosphere, assisting soil-derived  $CH_4$ 510 in bypassing  $CH_4$  oxidation processes in either the wetland water column or under-lying soil 511 column.

In the Lower and Transitional zones, we found that on average,  $56 \pm 2.0$  % of the total tree 512 513 stem CH<sub>4</sub> emissions came from the 10-40 cm of stem height measurements, and  $83 \pm 1.3$  % 514 from 10-70 cm of the stem height (Table S5). Interestingly, this ratio did not change between 515 Wet and Dry campaigns (Table S5). The incremental reduction in tree stem CH<sub>4</sub> emissions 516 versus tree stem heights (Fig. 5, 8b) are likely due to a combination of  $CH_4$  being degassed to 517 the atmosphere via the bark during the upwards transport of soil derived CH<sub>4</sub>, and losses from bark-dwelling CH<sub>4</sub> oxidizing bacteria (MOB) (Jeffrey et al., 2021a). Although CH<sub>4</sub> oxidation 518 519 rates by bark-dwelling MOB were not quantified during this study, our previous work using various isotopic and MOB inhibitor approaches, estimated  $CH_4$  oxidation rates of ~33 to 36 520 521 % in these same wetland tree species (Jeffrey et al., 2021a; Jeffrey et al., 2021b).

522 The smallest tree stem CH<sub>4</sub> emissions and sometimes CH<sub>4</sub> uptake, occurred within the Upper 523 zone trees, during the driest conditions and mainly from the upper stem heights (Table 1, Fig. 524 5). As mentioned above, the  $CH_4$  uptake measured on the tree stems is likely due to the presence of bark-dwelling MOB. The low rates of tree stem CH<sub>4</sub> emission from the Upper 525 526 zone trees are also likely due to the far deeper water table 1-2 m below the soil surface (Fig. 4). These more 'upland forest' soil conditions are generally unsuitable for significant soil 527 528 methanogenesis to occur and create conditions favourable for the oxidation of deeper 529 groundwater and soil CH<sub>4</sub>, prior to entering the tree stems and soil surface.

530 If the bark-associated methanotrophy and oxidation rates throughout all campaigns are 531 similar to our two previous estimates in M. quinquenervia forests (Jeffrey et al., 2021a; 532 Jeffrey et al., 2021b), the large  $CH_4$  emissions reported in the Lower and Transitional zones 533 for this study would likely be substantially greater, if not for bark-dwelling methanotrophic 534 communities mitigating a proportion of the  $CH_4$  egress from the wetland trees. This suggests 535 that whilst *M. quinquenervia* can emit significant quantities  $CH_4$  via their stems, they may 536 also help attenuate soil CH<sub>4</sub> by creating a suitable microbial habitat for methanotrophy (and 537 potentially other microbial metabolic processes) to occur (Bringel & Couée, 2015; Van Stan 538 et al., 2021). Seasonal measurements of bark-associated methanotrophy, however would be 539 required to better constrain this process.

540

#### 541 4.2 Dynamic wetland CH<sub>4</sub> emissions from soil and aquatic surfaces

542 The patterns of the wetland soil and aquatic CH<sub>4</sub> emissions were highly dynamic, but 543 generally concomitant with the water table depth. For example, the highest CH<sub>4</sub> fluxes from 544 the wetland occurred when the soils were inundated, whilst the lowest  $CH_4$  emissions and 545 CH<sub>4</sub> uptake occurred when the water table receded deep below the soil surface (Fig. 4, Fig. 546 S2). This pattern with the water table depth was evident in the Upper zone soils that were a 547 net CH<sub>4</sub> sink during five of the eight campaigns (Fig. 4). This is common for upland forest 548 soils, which are recognized as the largest biological sink for atmospheric CH<sub>4</sub> due to soil 549 associated methanotrophy (Kirschke et al., 2013; Saunois et al., 2020).

550 In the Lower zone, even during the driest campaigns, the wetland soil always remained a net CH<sub>4</sub> source as the water table was never lower than ~55 cm below the soil surface. During 551 campaign three, a large soil CH<sub>4</sub> release was observed when the water table was within  $\leq 14$ 552 553 cm of the soil surface, but was generally water-logged around the base of most trees (Figs. 4, 9). During this time, the water table had just receded after several months of inundation and 554 555 the Lower soils were still highly saturated leading to a likely low redox potential (as indicated 556 by soil moisture content (%) near or greater than 50 %, Fig. 6). Under these conditions, there is little potential for aerobic soil CH<sub>4</sub> oxidation to occur, and this most likely explains the 557 highest rates soil CH<sub>4</sub> fluxes reported in this study (26.1 mmol  $m^{-2} d^{-1}$ ). Although the soil 558 CH<sub>4</sub> flux rates during campaign 3 greatly skewed the annual soil CH<sub>4</sub> emission estimates for 559 560 the Lower zone (Table 1), we do not consider these as outliers (Fig. S2) as they likely

captured a genuine temporal "hot spot" and pulse release of soil  $CH_4$ . Observations such as this short-term pulse serve to reinforce the importance of temporal monitoring  $CH_4$  fluxes from natural ecosystems undergoing dynamic hydrological oscillations and changing redox conditions, where significant episodic emissions can take place over short timescales.

565 Although the Transitional zone soil and aquatic surfaces were net CH<sub>4</sub> sources over the annual cycle, once the water table dropped to  $\sim$ 75 cm below the soil surface (Campaign 5, 566 567 Fig 4), the Transitional zone soils switched to a net CH<sub>4</sub> sink (Fig. 4). This soil CH<sub>4</sub> sink occurred despite the Transitional zone tree stems continuing to emit  $CH_4$  (Fig. 4). 568 Importantly, at this time, the tree stem fluxes  $(1.1 \text{ mol ha}^{-1} \text{ d}^{-1})$  offset the adjacent soil uptake 569  $(-0.17 \text{ mol } ha^{-1} d^{-1})$  by ~6.5 times (Fig. 9, Table 1). This suggests that somewhere between 570 571 these two water table depths (-55 cm in Lower zone as mentioned above, and -75 cm in the 572 Transitional zone), soil-associated methanotrophy may completely oxidize CH<sub>4</sub> during 573 upward transport through the soil column before CH<sub>4</sub> can escape to the atmosphere (Barbosa 574 et al., 2018). This depth is likely to be influenced by soil type and is therefore site dependent. 575 In our case, it also shows that soil-derived CH<sub>4</sub> can effectively bypass soil CH<sub>4</sub> oxidation if 576 transported via the tree stems to the atmosphere.

The dynamic range in  $CH_4$  flux and intra-site variability highlights the importance of measuring wetland tree stem  $CH_4$  fluxes along hydro-topo-gradients, whilst capturing multiple tree stem heights and over multiple campaigns to accurately constrain the annual contributions of tree stem fluxes to forested wetland  $CH_4$  budgets. This study also captured a large variability in the  $CH_4$  fluxes from each tree within each zone, reiterating the importance of replicate measurements.

583

#### 584 **4.3 Drivers of tree stem CH<sub>4</sub> emissions**

Trends with upland forest tree stem  $CH_4$  emissions and soil  $CH_4$  can be complex, as trees can act as  $CH_4$  sources, whilst the well aerated soils represent net  $CH_4$  sinks (Barba et al., 2019b; Machacova et al., 2023; Wang et al., 2016). Within the Upper zone stand, during most of the campaigns, the drivers were also unclear, with the tree stem  $CH_4$  fluxes often shifting between slight  $CH_4$  sources and sinks, between various stem heights and campaigns (Figs. 4,9, Table 1). As such, no clear trends were found with adjacent soil moisture, soil fluxes (mostly uptake) or water table height. Therefore, the Upper zone drivers of  $CH_4$  flux likely 592 differ and/or the smaller signal is masked by higher noise – when compared to wetland trees 593 in the Lower and Transitional zones. Several explanations for upland tree stem CH<sub>4</sub> 594 emissions may include: 1) internal heartwood rot and stem moisture niches occupied by 595 methanogens (Feng et al., 2022; Yip et al., 2019); (2) termite-associated CH<sub>4</sub> emissions 596 (Carmichael et al., 2014); (3) CH<sub>4</sub> production by saprotrophic fungi (Lenhart et al., 2012); 597 and/or (4) the transpiration of dissolved CH<sub>4</sub> from deeper groundwater sources from below 598 our measurement locations (Barba et al., 2019a; Covey & Megonigal, 2019).

599 Drivers were clearer in the Lower and Transitional zones, where we found positive 600 significant correlations between tree stem CH<sub>4</sub> fluxes, and both soil moisture content and soil 601  $CH_4$  fluxes (Figs. 6, 7). These soils were also the locations of the highest porewater  $CH_4$ 602 concentrations (Fig. 3) and were inundated for the longest time periods over the study period 603 (Fig. 1). This suggests that soil moisture, reducing soil conditions and high porewater  $CH_4$ 604 concentrations (Fig. S4) were the major drivers of tree stem CH<sub>4</sub> emissions. This agrees with 605 previous studies showing similar trends along soil moisture gradients (Daniel et al., 2023; 606 Jeffrey et al., 2020a; Moldaschl et al., 2021; Pitz et al., 2018), via artificial flooding events 607 (Pangala et al., 2014; Terazawa et al., 2021) and with seasonal changes in the forest water table heights (Gauci et al., 2022; Sjögersten et al., 2020). In the same M. quinquenervia forest 608 as our present study ~two years prior, the soil and tree stem  $\delta^{13}$ C-CH<sub>4</sub> (‰) isotopic 609 signatures were shown to overlap (Jeffrey et al., 2021b), further suggesting that most M. 610 611 quinquenervia tree stem CH<sub>4</sub> egress originates from the soil methanogenesis zone.

612 In the Lower and Transitional zones, a strong correlation between soil and tree stem CH<sub>4</sub> flux 613 was observed (Fig. 7a), however, no relationship was found between aquatic CH<sub>4</sub> flux and 614 tree stem CH<sub>4</sub> flux (Fig. 7b). If indeed the soil methanogenesis zone was the major driver of tree stem CH<sub>4</sub>, we would anticipate a correlation between soil wetted area (i.e., the total 615 methanogenesis zone in the rhizosphere below the soil surface) and the volume of tree roots 616 617 and tree stem embedded within this zone. For example, with a low water table, a smaller 618 proportion of tree roots would sit within the saturated methanogenesis zone (compared to a 619 high-water table), whilst CH<sub>4</sub> oxidation within the upper rhizosphere would be greatest, 620 and/or the pathway from the soil methanogenesis zone to the tree stem would be longest. 621 Under a scenario of complete inundation (i.e., water table at or above the surface), all of the 622 tree roots would be in the saturated soil methanogenesis zone, and there would be a much 623 shorter pathway for root-entrained CH<sub>4</sub> to tree stem CH<sub>4</sub> egress, as well as decreased CH<sub>4</sub> oxidation potential in the rhizosphere. Such a trend was observed when plotting lower tree 624
625 stem CH<sub>4</sub> fluxes of the Lower and Transition zones vs the water table height (Fig. 10). The 626 regression in Fig. 10 estimates that for every 30 cm of water table increase below the ground 627 surface (i.e., Dry campaigns), the lower stem tree  $CH_4$  flux rates increased by approximately an order of magnitude, up to a maximum of  $\sim 0.27$  mmol m<sup>-2</sup> d<sup>-1</sup> when the water table was at 628 the surface (Fig. 10). Interestingly, once the water table exceeded the soil surface (Wet 629 630 campaigns), the tree stem  $CH_4$  flux rates did not continue to rise and reached a  $CH_4$  egress 631 maxima. This process was first proposed by Gauci et al. (2022), who found a remarkedly 632 similar trend in tree stem  $CH_4$  fluxes within an Amazon riparian forest subject to  $\sim 12$  m 633 amplitude fluctuations in the water table height. Overall, this shows a significant correlation 634 between the depth of the water table below-ground and the root-entrained CH<sub>4</sub> tree stem 635 emissions, whereas tree CH<sub>4</sub> fluxes essentially become de-coupled from the water table 636 dynamics when water levels are above the soil surface (Fig. 10).

637

638

Figure 10. Regression of lower stem tree stem fluxes (10 and 40 cm) vs water table height
below the soil surface (Dry campaigns) and above the soil surface (Wet campaigns). Note:
Log scale and data for Lower and Transitional zones only. The grey shaded area is the 99 %
confidence interval.

643

645 The importance of tree stem  $CH_4$  fluxes to the total wetland  $CH_4$  flux or NEF (%) was highly 646 variable and dynamic over the annual cycle. During the Dry campaigns, although soils were 647 the most important pathway for CH<sub>4</sub> emissions, the wetland trees still contributed  $\sim$ 3 to 28 % 648 of CH<sub>4</sub> emissions for the Lower and Transitional zones respectively (Fig. 11). As mentioned 649 previously, a large soil pulse release of CH<sub>4</sub> in the Lower zone (Campaign 3) greatly skewed 650 these upscaled CH<sub>4</sub> emissions and NEF estimates. During Dry conditions in the Upper zone, 651 tree stem emissions were 13-fold lower than Lower zone, however, the tree stems accounted for 100% of the Upper zone NEF as Upper soils were a net CH<sub>4</sub> sink (-0.06 mmol  $m^{-2} d^{-1}$ , 652 653 Table 1). This is important to consider in future upland forest CH<sub>4</sub> budgets which are 654 conventionally considered as net CH<sub>4</sub> sinks.

655

656

**Figure 11.** Conceptual summary diagram of the net ecosystem CH<sub>4</sub> flux from trees (NEF, %) during Wet campaigns (n=5), Dry campaigns (n=3) and annual emissions (n=8). The average CH<sub>4</sub> flux rates for each pathway (mmol  $m^{-2} d^{-1}$ ) are shown with arrow size depicting the scale of emissions.

661

During Wet campaigns, tree stem  $CH_4$  fluxes were equal to, and the most important pathway, of the total wetland efflux, accounting for 50-70 % of the NEF of the Lower and Transitional zones respectively (Figs. 9, 11). This is similar to the range of estimates for other lowland forest studies, including ~50 % of the NEF in flooded forests of the Amazon basin (Pangala et al., 2017), 62-87 % in tropical wetlands (Pangala et al., 2013) and 30 % in neotropical peatland forest (Sjögersten et al., 2020). It should be noted that we did not account for the aquatic CH<sub>4</sub> ebullition pathway in our study design, though very little ebullition was observed from the sandy sediments during inundated campaigns. However, in some wetland systems, ebullition can represent a major component of wetland CH<sub>4</sub> budgets (Aben et al., 2017; DelSontro et al., 2016; Jeffrey et al., 2019a).

672 To the best of our knowledge, no other studies have captured forested wetland CH<sub>4</sub> emissions 673 at monthly/bi-monthly sampling temporal resolution over an annual cycle. During the entire 674 study, we calculate that the subtropical M. quinquenervia tree stems contributed  $\sim 27.8 - 68.3$ 675 % of the NEF from the Lower and Transitional zones of the wetland respectively (Fig. 11). 676 This study provides clear evidence that tree stems are a significant and often missing 677 component of many previous wetland CH<sub>4</sub> budgets, where they have been largely overlooked (Barba et al., 2019a; Covey & Megonigal, 2019). The CH<sub>4</sub> flux rates and upscaled rates from 678 679 the subtropical *M. quinquenervia* trees (per hectare) were at the upper range of other reported tree stem fluxes from the literature (Fig. 12). Generally, the lowest ecosystem tree  $CH_4$ 680 681 emissions per hectare come from temperate upland forests and mangrove forests, whereas 682 peatland and wetland forests can be up to five orders of magnitude higher (Fig.12). Our upscaled results (1187 to 37,803 mmol ha<sup>-1</sup> d<sup>-1</sup>) were higher, yet similar in range, to the 683 tropical flooded forests of the Amazon (2937 to 28,493 mmol ha<sup>-1</sup> d<sup>-1</sup>; Pangala et al., 2017) 684 and neotropical peatland (2999 to 21,745 mmol ha<sup>-1</sup> d<sup>-1</sup>; Sjögersten et al., 2020) (Fig. 12), 685 higher than seasonally flooded tropical forest in French Guiana (-101 to 183 mmol ha<sup>-1</sup> d<sup>-1</sup>; 686 Daniel et al., 2023) and tropical SE Asian peat forest (419 to 1878 mmol ha<sup>-1</sup> d<sup>-1</sup>; Pangala et 687 688 al., 2013).

689

690

**Figure 12.** Comparison of previously reported tree stem ecosystem CH4 flux rates spanning

various forest types (Covey & Megonigal, 2019; Jeffrey et al., 2020a; Jeffrey et al., 2019b;

693 Sjögersten et al., 2020) compared to the average, Wet and Dry tree CH4 emissions of our

694 study. Note: The log scale on the y-axis.

695

696 It is important to note that the up-scaling approach used can greatly influence the 697 interpretation of results, both here and for future studies. For example, if using Eq. 3 for 698 upscaling (i.e., the average  $CH_4$  flux per tree multiplied by forest density – a common 699 upscaling approach), our upscaled tree stem  $CH_4$  emissions per hectare would have been on 700 average  $\sim 35.7 \pm 4.5$  % greater than we reported. The approach we applied here considers the 701 individual surface areas of all tree stems per hectare (i.e., integrating Eq. 4) and integrates 702 this into the upscaling to ecosystem level. This approach is likely more realistic as we better 703 account for the large variability in stem sizes of the dense stands of M. quinquenervia. This 704 approach may be less important in forests and stands featuring more uniformity in tree size. 705 Furthermore, we did not account for any tree stem CH<sub>4</sub> emissions below a 10 cm stem height 706 (near the location of highest CH<sub>4</sub> emissions, Table S5). For example, the lower 30 cm of stem was previously shown to account for > 90 % of stem  $CH_4$  efflux in *M. quinquenervia* forest 707 708 (Jeffrey et al., 2020b). We also did not account for multiple trunked or branched tree stems 709 (i.e., we only measured and/or counted all as single stems). We also did not project any CH4 710 emissions beyond the 130 cm stem height that were measured - therefore, our upscaled 711 results should be considered as a conservative estimate.

712

## 713 4.5 Conclusion and future directions

714 Overall, our study highlights the significant role of trees, and the importance of accounting 715 for tree stem CH<sub>4</sub> emissions from (sub)tropical forested wetlands, to better estimate total 716 wetland CH<sub>4</sub> budgets. We also highlighted the extremely large range in tree stem CH<sub>4</sub> flux 717 variability both within a site, across seasons and at individual tree stem heights. Tree stem 718 CH<sub>4</sub> emissions appear to be mainly driven by water table height, which moderated the soil 719 methanogenesis zone and porewater redox potentials. The CH<sub>4</sub> flux rates and upscaled 720 emissions from M. quinquenervia forests presented here are at the higher end of reported 721 literature values. This may be due to the wetland soil carbon and waterlogging conditions, 722 (sub)tropical climate driving microbial metabolism, tree species-specific physiological adaptations (including the unique layered bark structure allowing for rapid CH<sub>4</sub> transport from the soils to the atmosphere), and/or high forest density (up to 5049 trees ha<sup>-1</sup>) typical of *M. quinquenervia* stands. This study also provides important baseline readings for the southern hemisphere and Australian wetland forests, which typically experience highly dynamic rainfall and large soil redox oscillations between flooding and drought conditions.

728 Future research in forested wetlands should consider all atmospheric pathways for CH<sub>4</sub> by 729 including aquatic ebullition and the importance of episodic pulses of emissions under ideal 730 conditions for methanogenesis. To account for diurnal variability in M. quinquenervia tree 731 CH<sub>4</sub> emissions (Jeffrey et al., 2020a; Jeffrey et al., 2021b), which were not measured during 732 this study, future studies should also consider auto-sampler approaches to tree stem CH<sub>4</sub> flux 733 measurements capturing high resolution temporal variability (Barba et al., 2019b; Brechet et 734 al., 2021; Sakabe et al., 2021). Lastly the role of upper stems and branches (recently shown to 735 emit CH4 in certain upland trees) (Gorgolewski et al., 2022), phyllosphere microbial CH4 736 oxidation (Putkinen et al., 2021), cryptograms and stem-associated microbial CH<sub>4</sub> oxidation (Feng et al., 2022; Jeffrey et al., 2021a; Jeffrey et al., 2021b; Machacova et al., 2021) and the 737 738 net canopy exchange of CH<sub>4</sub> (Takahashi et al., 2021) should also be taken into account, in 739 any mass balance and net ecosystem CH<sub>4</sub> flux estimates.

740 Currently, there is far less data available from the (sub)tropical ecosystems (hotspots for 741 wetland CH<sub>4</sub> emissions), compared to lowland forests of higher latitudes. In the context of local and national greenhouse gas budgets, climate change mitigation and re-forestation 742 743 efforts, constraining the role of tree stem CH<sub>4</sub> emissions from these important ecosystems 744 requires considerable further research. Although recently identified as a knowledge and data 745 gap that may potentially help explain the large uncertainties in the global CH<sub>4</sub> budget wetland term (Pachauri et al., 2014; Saunois et al., 2020), tree stem CH<sub>4</sub> emissions do not yet have a 746 747 distinct emission category, nor are they used in bottom-up scaling and modelling efforts. As 748 the drivers of tree stem CH<sub>4</sub> are highly dynamic and variable across ecosystem types and 749 individual tree species, future modelling efforts will need to consider these complexities in 750 any up-scaling approaches.

**Figure 1.** Map of study site in the upper panel showing locations of sampled *Melaleuca* trees (red, yellow and green dots), the location of water level loggers (white dots). The lower panel shows hydro-topological zones and tree base elevational differences relative to the lowest location in the wetland forest (black squares).

Figure 2. Summary of environmental conditions during the eight study campaigns showing
seasonal changes in the Lower zone wetland water table (cm), daily rainfall totals (mm),
maximum and minimum air temperature (°C) and photosynthetically available radiation
(PAR in lum m<sup>-2</sup>). Note: Dry campaigns are highlighted in grey.

1013

1014 **Figure 3.** Depth profiles for porewater and surface water  $CH_4$  concentrations ( $\mu$ M) during 1015 campaigns 4-7 for each wetland zone. Note: Different x-axis scales used. The brown shaded 1016 area represents the soil and blue area is surface water and dashed line is the top of water 1017 table. Error bars are SE.

1018

**Figure 4.** Stacked plots indicating the changing water table within each zone, average CH<sub>4</sub> flux per tree (mmol tree<sup>-1</sup> d<sup>-1</sup>) and average CH<sub>4</sub> flux from water or soil (mmol m<sup>-2</sup> d<sup>-1</sup>). Note: Different y-axis scales, shaded campaigns are where surface water was present, the horizontal dashed line is soil surface, the horizontal solid line separates CH<sub>4</sub> sink and source in Upper zone. Error bars are SE.

1024

**Figure 5.** Contour plots showing average tree stem CH<sub>4</sub> flux rates (mmol  $m^{-2} d^{-1}$ ) at each stem height, from each campaign and within each hydro-topographic zone. Note: log scale of CH<sub>4</sub> flux rates (mmol  $m^{-2} d^{-1}$ ) and water table is from the Lower zone and the dashed line is the soil surface.

## **List of Figures**

Figure 6. Positive significant correlations between soil WVC% and lower (10-40 cm) tree stem CH<sub>4</sub> fluxes during the three Dry campaigns. Note: log scale y-axis, Spearman's Rho ( $r_s$ ), grey areas show 99 % confidence interval and 50% VWC is the upper volumetric water content range of the probe.

1034

**Figure 7.** Correlations between lower (10-40 cm) tree stem  $CH_4$  fluxes and a) soil  $CH_4$  fluxes (Dry campaigns) and b) aquatic  $CH_4$  fluxes (Wet campaigns) within the Lower and Transitional hydro-topological zones. Note: Spearman's Rho ( $r_s$ ) and grey areas show 99 % confidence interval.

1039

Figure 8. Correlations for all positive tree stem CH<sub>4</sub> flux data vs (a) chamber height distance
from water table during Dry campaigns, and (b) chamber heights above soil surface during
Wet campaigns. Note: Log transformed data on y-axis. Yellow lines are 95 % confidence
intervals and dashed lines are 95 % prediction intervals.

1044

**Figure 9.** Upscaled wetland  $CH_4$  NEF differentiating the  $CH_4$  flux from tree stems, water and soils from each hydro-topological zone and campaign (mol ha<sup>-1</sup> d<sup>-1</sup>). The values above bar plots indicate the tree  $CH_4$  contribution to: (1) the NEF % (black text); (2) offsetting soil  $CH_4$ uptake (blue text), and (3) enhancing soil uptake (red text). Note: different y-axis scales.

1049

Figure 10. Regression of lower stem tree stem fluxes (10 and 40 cm) vs water table height
below the soil surface (Dry campaigns) and above the soil surface (Wet campaigns). Note:
Log scale and data for Lower and Transitional zones only. The grey shaded area is the 99 %
confidence interval.

1054

**Figure 11.** Conceptual summary diagram of the net ecosystem CH<sub>4</sub> flux from trees (NEF, %) during Wet campaigns (n=5), Dry campaigns (n=3) and annual emissions (n=8). The average CH<sub>4</sub> flux rates for each pathway (mmol m<sup>-2</sup> d<sup>-1</sup>) are shown with arrow size depicting the scale of emissions.

- **Figure 12.** Comparison of previously reported tree stem ecosystem CH<sub>4</sub> flux rates spanning
- 1060 various forest types (Covey & Megonigal, 2019; Jeffrey et al., 2020a; Jeffrey et al., 2019b;
- 1061 Sjögersten et al., 2020) compared to the average, Wet and Dry tree CH<sub>4</sub> emissions of our
- 1062 study. Note: The log scale on the y-axis.

Figures S1 to S6 Tables S1 to S5

**Figure S1.** Seasonal variation in soil (white areas) and aquatic (blue areas) CH<sub>4</sub> emissions (mmol m<sup>-2</sup> d<sup>-1</sup>). Note: Different y-axis. White circles indicate where no data was measured or removed due to low *r*<sup>2</sup> linear fluxes.

**Figure S2.** Box plots showing CH<sub>4</sub> fluxes from Wet (grey shaded areas) vs Dry (white areas) campaigns showing soil/water CH<sub>4</sub> fluxes at top; and tree stem CH<sub>4</sub> fluxes at bottom, for each zone. Dots are the outliers and solid lines the mean.

**Figure S3.** Seasonal variation in tree stem CH<sub>4</sub> emissions from each tree up to to 1.3 m stem height (mmol per tree d<sup>-1</sup>). Note: Different y-axis. White circles indicate where no data was measured and blue areas represent inundated tree stems.

**Figure S4.** Correlations between changes in water table depth vs pH, temp and dissolved CH<sub>4</sub> (top) and correlations with dissolved CH<sub>4</sub> vs physicochemical parameters (bottom). Note: The log scale y-axis for bottom plots.

**Figure S5.** Negative but non-significant trends with wetland porewater and mean tree stem CH<sub>4</sub> fluxes.

**Figure S6.** Positive tree stem CH<sub>4</sub> fluxes (mmol m<sup>-2</sup> d<sup>-1</sup>) vs height above soil surface (cm) for all campaigns. Note: The log scale of y-axis.

### **Table S2.** Average aquatic and porewater physicochemical data and CH<sub>4</sub> concentrations.

Table S3. Pairwise Multiple Comparison Procedures (Dunn's Method) for soil vs aquatic CH4

Soil vs water Comparison	Diff of Ranks	Q	Р	P<0.050
Wet Lower vs Dry Upper	105.921	10.021	<0.001	Yes
Wet Lower vs Wet Upper	80.114	3.931	0.001	Yes
Wet Lower vs Dry Trans	49.535	3.532	0.006	Yes
Wet Lower vs Dry Lower	45.68	3.458	0.008	Yes
Wet Lower vs Wet Trans	23.942	1.937	0.791	No
Wet Trans vs Dry Upper	81.979	7.302	<0.001	Yes
Wet Trans vs Wet Upper	56.172	2.71	0.101	No
Wet Trans vs Dry Trans	25.593	1.762	1	Do Not Test
Wet Trans vs Dry Lower	21.738	1.582	1	Do Not Test
Dry Lower vs Dry Upper	60.242	4.955	<0.001	Yes
Dry Lower vs Wet Upper	34.435	1.621	1	Do Not Test
Dry Lower vs Dry Trans	3.856	0.253	1	Do Not Test
Dry Trans vs Dry Upper	56.386	4.325	<0.001	Yes
Dry Trans vs Wet Upper	30.579	1.405	1	Do Not Test
Wet Upper vs Dry Upper	25.807	1.309	1	No

Table S4. Pairwise Multiple Comparison Procedures (Dunn's Method) for tree CH4 fluxes for each zone between flooded vs dry wetland conditions.

Tree flux Comparison	Diff of Ranks	0	Р	P<0.050
Wet Trans vs Dry Upper	127.362	9.964	<0.001	Yes
Wet Trans vs Dry Trans	111.644	7.579	<0.001	Yes
Wet Trans vs Dry Lower	85.911	5.832	<0.001	Yes
Wet Trans vs Wet Upper	51.578	2.768	0.085	No
Wet Trans vs Wet Lower	9.533	0.724	1	Do Not Test
Wet Lower vs Dry Upper	117.829	9.218	<0.001	Yes
Wet Lower vs Dry Trans	102.111	6.932	<0.001	Yes
Wet Lower vs Dry Lower	76.378	5.185	<0.001	Yes
Wet Lower vs Wet Upper	42.044	2.256	0.361	Do Not Test
Wet Upper vs Dry Upper	75.784	4.128	<0.001	Yes
Wet Upper vs Dry Trans	60.067	3.039	0.036	Yes
Wet Upper vs Dry Lower	34.333	1.737	1	No
Dry Lower vs Dry Upper	41.451	2.883	0.059	No
Dry Lower vs Dry Trans	25.733	1.595	1	Do Not Test
Dry Trans vs Dry Upper	15.718	1.093	1	Do Not Test

fluxes for each zone.

	Tree Stem height			
Campaigns	10-40 cm 10-70 cm			
Wet	54.2% ±	2.5%	83.7% ±	1.5%
Dry	57.2% ±	3.2%	81.4% ±	2.4%
All	55.5% ±	2.0%	82.8% ±	1.3%

**Table S5.** Proportion of lower stem height tree CH<sub>4</sub> emissions (mmol per tree d<sup>-1</sup>) to total tree stem CH<sub>4</sub> emissions of the Lower and Transitional zones ± SE.
