Abstract

Shifts in Southern Ocean (SO, \$40 - 85^{o}S\$) shortwave cloud feedback (SW_{FB}) toward more positive values are the dominant contributor to higher effective climate sensitivity (ECS) in Coupled Model Intercomparison Project phase 6 (CMIP6) models. To provide an observational constraint on the SO SW_{FB} , we use a simplified physical model to connect SO SW_{FB} with the response of column-integrated liquid water mass (LWP) to warming and the susceptibility of albedo to LWP in 50 CMIP5 and CMIP6 GCMs. In turn, we predict the responses of SO LWP using a cloud-controlling factor (CCF) model. The combination of the CCF model and radiative susceptibility explains about 50% of the variance in the GCM-simulated SW_{FB} in the SO. Observations of SW radiation fluxes, LWP, and CCFs from reanalysis are used to constrain the SO SW_{FB} . The response of SO LWP to warming is constrained to 2.76 - 4.19% $g^{-2} K^{-1}$ %, relative to a GCM prior of 0.64 - 9.33% $g^{-2} K^{-1}$ %. The susceptibility of albedo to LWP is constrained to be 0.43 - 0.90% (kg\ m^{-2})^{-1}%, relative to 0.30 - 3.91% (kg\ m^{-2})^{-1}%. The overall constraint on the contribution of SO to global mean SW_{FB} is 0.168 - 0.051% $W m^{-2} K^{-1}$ %. The overall constraint on the contribution of SO to global mean SSW_{FB} is 0.168 - 0.051% $W m^{-2} K^{-1}$ %. The overall constraint on the contribution of SO to global mean SSW_{FB} is 0.168 - 0.051% $W m^{-2} K^{-1}$ %. In summary, observations suggest SO SSW_{FB} % is less likely to be as extremely positive as predicted by some CMIP6 GCMs, but more likely to range from moderate negative to weakly positive.

15 Abstract

Shifts in Southern Ocean (SO, $40 - 85^{\circ}S$) shortwave cloud feedback (SW_{FB}) toward 16 more positive values are the dominant contributor to higher effective climate sensitiv-17 ity (ECS) in Coupled Model Intercomparison Project phase 6 (CMIP6) models. To pro-18 vide an observational constraint on the SO SW_{FB} , we use a simplified physical model 19 to connect SO SW_{FB} with the response of column-integrated liquid water mass (LWP) 20 to warming and the susceptibility of albedo to LWP in 50 CMIP5 and CMIP6 GCMs. 21 In turn, we predict the responses of SO LWP using a cloud-controlling factor (CCF) model. 22 The combination of the CCF model and radiative susceptibility explains about 50% of 23 the variance in the GCM-simulated SW_{FB} in the SO. Observations of SW radiation fluxes, 24 LWP, and CCFs from reanalysis are used to constrain the SO SW_{FB} . The response of 25 SO LWP to warming is constrained to $2.76 - 4.19 \text{ g } m^{-2} \text{ } K^{-1}$, relative to a GCM prior 26 of 0.64 - 9.33 $g m^{-2} K^{-1}$. The susceptibility of albedo to LWP is constrained to be 27 $0.43 - 0.90 \ (kg \ m^{-2})^{-1}$, relative to $0.30 - 3.91 \ (kg \ m^{-2})^{-1}$. The overall constraint 28 on the contribution of SO to global mean SW_{FB} is $-0.168 - 0.051 W m^{-2} K^{-1}$, rel-29 ative to $-0.277 - 0.270 Wm^{-2}K^{-1}$. In summary, observations suggest SO SW_{FB} is 30 less likely to be as extremely positive as predicted by some CMIP6 GCMs, but more likely 31 to range from moderate negative to weakly positive. 32

³³ Plain Language Summary

Previous studies suggest that SO clouds reflect more sunlight in response to global 34 warming and more strongly cool the planet - a negative shortwave cloud feedback (SW_{FB}) . 35 The SO SW_{FB} in the latest generation of global climate models (GCMs) participating 36 in the Coupled Model Intercomparison Project phase 6 (CMIP6) has shifted toward more 37 positive values, leading to the larger predicted temperature responses to greenhouse gas 38 increases in these GCMs. In this study, we examine if this more positive SW_{FB} is con-39 sistent with observations. We connect the effect of SO clouds on reflected sunlight with 40 the predicted response of cloud liquid content to global warming. The linkage between 41 cloud liquid water content and large-scale meteorology is applied to predict this cloud 42 liquid response. Satellite observations of reflected sunlight, cloud liquid, and observa-43 tions of large-scale meteorology are applied to constrain the SO SW_{FB} for 50 CMIP5 44 and CMIP6 GCMs. The results suggest that SO cloud liquid will increase with warm-45 ing around the average of predictions of 50 GCMs. Satellite records suggest that the sen-46 sitivity of reflected sunlight to cloud liquid is weak compared to GCMs. In combination, 47 our results suggest SO clouds most likely reflect more sunlight back to space and fur-48 ther cool our planet. 49

50 1 Introduction

Quantifying the surface temperature response to a doubling in atmospheric CO_2 51 concentration, commonly referred to as climate sensitivity, is a fundamental goal of cli-52 mate science (Houghton & el., 2001; Boucher & el., 2014; Forster & el., 2023). Climate 53 feedback processes such as changes in lapse rate, water vapor, and cloud may dampen 54 or amplify the temperature response to greenhouse gas increase and are critical for es-55 timating climate sensitivity (Bony et al., 2006). Global climate models (GCMs) provide 56 the most direct way to estimate climate sensitivity since they attempt to simulate all rel-57 evant processes, including climate feedback (Andrews et al., 2012; Zelinka, Myers, Mc-58 Coy, Po-Chedley, et al., 2020). Shortwave cloud feedback (SW_{FB}) , the shortwave (SW) 59 radiative impact of cloud responses to a surface temperature perturbation, is the largest 60 uncertainty in GCMs' estimate of net climate feedback and by extension, climate sen-61 sitivity (Zelinka, Myers, McCoy, Po-Chedley, et al., 2020; Sherwood et al., 2020). The 62 uncertainty in estimating SW_{FB} is strongly driven by difficulties in representing subgrid-63

scale cloud processes in GCMs (Storelvmo et al., 2015; Webb et al., 2015; Sherwood et al., 2014; Zhao, 2014).

Despite the large intermodel spread in global-mean SW_{FB} , robust regional features 66 have emerged from previous generations of GCMs. For example, positive SW_{FB} in the 67 subtropics has emerged, likely due to decreased cloud coverage with negative SW_{FB} in 68 the middle-to-high latitudes likely attributed to increased cloud optical depth (Zelinka 69 et al., 2012; Ceppi, McCoy, & Hartmann, 2016). Considerable progress has been made 70 on narrowing the possible ranges of tropical and subtropical SW_{FB} using observational 71 constraints (Myers et al., 2021; G. V. Cesana & Del Genio, 2021; G. Cesana et al., 2019; 72 Scott et al., 2020; Klein et al., 2017). 73

Recent GCMs have suggested a weaker negative Southern Ocean (SO, $40-85^{\circ}S$) 74 SW_{FB} . The ensemble mean SO SW_{FB} of GCMs participating in the sixth phase of the 75 Coupled Model Intercomparison Project (CMIP6) has shifted toward a more positive value 76 relative to CMIP5, leading to the emergence of several GCMs with high effective climate 77 sensitivity (ECS) (ECS ≥ 4.5 K) (Zelinka, Myers, McCoy, Po-Chedley, et al., 2020; Bodas-78 Salcedo et al., 2019). Much effort has been made to understand this change within the 79 context of GCM cloud physics (Bjordal et al., 2020; Bodas-Salcedo et al., 2019; Gettel-80 man et al., 2019; Zhang et al., 2019). The uncertainty in ECS owing to SO SW_{FB} is still 81 largely unconstrained by observations (Sherwood et al., 2020), with only a few studies 82 explicitly focusing on evaluating SO SW_{FB} using the observational records of clouds, 83 radiation, and meteorology (Terai et al., 2019, 2016; Ceppi, McCoy, & Hartmann, 2016; 84 Gordon & Klein, 2014; Tan et al., 2019; Norris et al., 2016). 85

Many mechanisms have been proposed to explain the origins of negative SO SW_{FB} 86 (Terai et al., 2019; Sherwood et al., 2020). One potential explanation is increasing liq-87 uid water content (LWC) from the warmer moist adiabat (Betts & Harshvardhan, 1987; 88 Terai et al., 2019; Frazer & Ming, 2022). Shifts in the moist adiabat as the atmosphere 89 warms will increase cloud LWC if the geometric height of clouds is preserved. As cloud 90 temperature increases, the change in LWC per degree of warming decreases rapidly, so 91 this mechanism is only salient in the high latitudes (Terai et al., 2019). Another poten-92 tial mechanism is the increase in cloud LWC driven by shifts in the cloud phase (Senior 93 & Mitchell, 1993; Tan et al., 2019, 2016; McCoy et al., 2014). As the atmospheric tem-94 perature rises, cloud condensates shifts from ice to liquid in the mixed-phased cloud re-95 gions. The total water content may also increase because liquid precipitates less efficiently 96 than ice (Ceppi, Hartmann, & Webb, 2016; Frazer & Ming, 2022). In recent literature, 97 a mechanism based on the connection between hydrological response and cloudiness change has been proposed to explain the increased LWC in extratropics (McCoy et al., 2022; 99 McCoy, Field, Bodas-Salcedo, et al., 2020; McCoy et al., 2019). All aforementioned mech-100 anisms may contribute to an increase in in-cloud LWC, which results in a negative cloud 101 optical depth feedback (Stephens, 1978). Other mechanisms may contribute to changes 102 in cloud coverage in the SO. These processes are restricted to boundary layer (BL) clouds. 103 When the capping inversion at the top of BL increases with warming, the cloud top en-104 trainment will be suppressed and lead to an increase in BL cloudiness (Bretherton et al.. 105 2013; Myers & Norris, 2013; Qu et al., 2015). However, the cloud top entrainment may 106 also increase with warming because of the increased vertical humidity gradient between 107 BL and free troposphere (Bretherton et al., 2013; Frey & Kay, 2018; Rieck et al., 2012). 108 This will reduce the BL cloudiness. The decoupling in the BL may increase with warm-109 ing, preventing moisture transports from the surface into the cloud layer and also de-110 creasing the low-cloud amount (Bretherton & Wyant, 1997; Bretherton et al., 2013; Zheng 111 et al., 2020). All these hypothesized mechanisms may contribute to SO SW_{FB} and are 112 entangled with each other, making process-level constraint of the SO SW_{FB} difficult (Terai 113 et al., 2019; Frazer & Ming, 2022). 114

Here, we seek to provide a constraint on the GCM ensemble SO SW_{FB} using observed cloud properties and their covariability with meteorological state. The existing

research has examined various cloud properties such as shortwave cloud radiative effect 117 (SWCRE), albedo, cloud optical depth, and cloud fraction to provide observational con-118 straints on the extratropical SW_{FB} (Gordon & Klein, 2014; Qu et al., 2015; Ceppi, Mc-119 Coy, & Hartmann, 2016; Norris et al., 2016; Terai et al., 2016; Myers et al., 2021; Mc-120 Coy et al., 2022). They generally support a positive SW_{FB} related to BL clouds and a 121 negative SW_{FB} related to upper level clouds, and an overall negative extratropical SW_{FB} . 122 Many of these studies have had to contend with the availability of GCM data and the 123 challenges in characterizing SO clouds using visible radiation. GCM cloud fraction and 124 cloud optical depth have to be processed with satellite simulators to enable direct com-125 parison between model output and satellite retrievals (Bodas-Salcedo et al., 2011). The 126 number of models that provide these outputs is very restricted, which limits evaluation 127 of the shift in SO SW_{FB} spanning a large number of GCMs across CMIP5 and CMIP6 128 (Gordon & Klein, 2014; Ceppi, McCoy, & Hartmann, 2016). The SO also presents an 129 observational challenge. Satellite retrievals of low-topped cloud properties like low-cloud 130 fraction are difficult because of the multilayered structure of SO clouds (Qu et al., 2015; 131 Haynes et al., 2011; Marchand et al., 2009; Sourdeval et al., 2016). Top-of-atmosphere 132 (TOA) radiative flux derived quantities like SWCRE and albedo are more directly com-133 parable to GCM output(Loeb et al., 2020), but they combine the effects of radiative pro-134 cesses as well as the response of clouds to meteorology. This makes it difficult to unpick 135 how variations in TOA radiation are related to large-scale meteorology (Myers et al., 2021). 136

Area-mean column-integrated liquid water mass (LWP) is an advantageous cloud 137 property for constraining SO cloud variability because the comparison between CMIP 138 GCM output and low-frequency microwave radiometers is relatively straightforward. The 139 LWP reported by GCMs and microwave observations is averaged over cloudy and cloud-140 free scenes and variability in LWP combines variability in cloud coverage and in-cloud 141 LWC. LWP is a standard model output for all CMIP5/6 GCMs and can be directly com-142 pared to microwave observations without a satellite simulator as long as attention is paid 143 to separating precipitating and non-precipitating liquid. Microwave LWP retrieval is not 144 sensitive to multi-layered clouds, making it optimal for constraining SO cloud variabil-145 ity without partitioning by cloud top pressure regimes and accounting for overlap (McCoy 146 et al., 2014). The response of area-mean LWP to warming is anti-correlated with SW_{FB} 147 in the SO (Stephens, 1978; McCoy et al., 2022). For the above reasons, we choose to con-148 strain the SO SW_{FB} across CMIP5 and CMIP6 models by constraining the response of 149 LWP to warming. 150

We predict SO LWP response by the linkage between clouds and large-scale me-151 teorology (so-called cloud-controlling factor (CCF) analysis, Stevens and Brenguier (2009)). 152 Observations of clouds and their environment can be used to infer the response of clouds 153 to long-term warming by assuming the relationships between clouds and large-scale me-154 teorology are invariant from shorter observed periods (days - years) to climate change 155 time-scale (years - century) (Klein et al., 2017). Surface temperature, stability, and large-156 scale subsidence have been widely used as environmental factors to predict cloud responses 157 (Grise & Medeiros, 2016; Frey & Kay, 2018; McCoy, Field, Gordon, et al., 2020; McCoy, 158 Field, Bodas-Salcedo, et al., 2020; Myers et al., 2021). In addition to these quantities, 159 our CCF analysis considers large-scale moisture convergence. As shown in Held and So-160 den (2006), column-integrated water vapor increases with warming following Clausius-161 Clapeyron (C-C) scaling. Two direct consequences of increased humidity are increased 162 horizontal transport of water vapor and enhanced existing patterns of moisture conver-163 gence and divergence. The latter change also satisfies the C-C scaling, albeit with spa-164 tial adjustments such as poleward expansion of the drying region (Siler et al., 2018; Bo-165 nan et al., 2023). Local precipitation and evaporation in the extratropics increase with 166 warming but at a slower rate than C-C scaling owing to the energetic constraints (Allen 167 & Ingram, 2002; Lorenz & DeWeaver, 2007; Stephens & Ellis, 2008; Trenberth, 2011; Yet-168 tella & Kay, 2017). The effects of a strengthening hydrological cycle in response to warm-169 ing is consistent with how SO LWP responds to warming (McCoy et al., 2019). Because 170

the conversion of water vapor to precipitation happens in clouds, increases in both the source and sink of clouds should guarantee an increase in cloudiness. In this work, we evaluate the linkage between the hydrological cycle and SO SW_{FB} by using moisture convergence as one of the large-scale meteorology factors to predict the SO LWP response (McCoy, Field, Bodas-Salcedo, et al., 2020; McCoy et al., 2022).

In addition to constraining the cloud response to meteorology, it is necessary to con-176 strain the interactions between clouds and the radiation to constrain SW_{FB} . Previous 177 work has shown that GCMs differ substantially in their simulation of how increasing cloudi-178 ness affects TOA upwelling SW flux (Bender et al., 2017). The intermodel differences 179 in the radiative susceptibility of TOA SW flux to LWP contribute strongly to the inter-180 model difference in the SO SW_{FB} (McCoy et al., 2022). Model biases in simulating cloudi-181 ness changes in a perturbed climate are likely being compensated by the biases in the 182 optical properties of simulated clouds. The so-called 'Too few, Too bright' bias has been 183 diagnosed in previous generations of GCMs in the tropics (Nam et al., 2012; Konsta et 184 al., 2022). 185

The goal of this paper it to use observations to constrain the SO SW_{FB} across 50 186 CMIP5 and CMIP6 GCMs (Table S1). A simplified physical model is developed to pre-187 dict GCM SW_{FB} calculated from radiative kernels (Zelinka, Myers, McCoy, Po-Chedley, 188 et al., 2020) by using the responses of LWP to warming combined with the susceptibil-189 ity of radiation to liquid. Then, we constrain the LWP response to warming of GCMs 190 by the observed covariability between LWP and large-scale meteorology, focusing on the 191 role of hydrological response on SO SW_{FB} . Following this, we use satellite observations 192 to calculate the susceptibility of radiation to liquid. Combining the constraints on LWP 193 194 response and radiative susceptibility, we produce a constraint on the SO SW_{FB} . The paper is organized as follows. Section 2 describes the GCMs and observations, the sim-195 plified physical model, and how observations are used to constrain GCM SW_{FB} . In sec-196 tion 3, we conduct step-by-step constraints on the LWP response, radiative susceptibil-197 ity, and the SO SW_{FB} of GCMs. Section 4 presents conclusions of this study and sug-198 gestions for future work on constraining extratropical SW_{FB} . 199

200 2 Data and Methodology

2.1 Data

201

We use 50 GCMs participating in CMIP5 (20) and CMIP6 (30) to provide the prior 202 distribution of SO SW_{FB} . GCMs and their SO (40-85°S) SW_{FB} are listed in Table 203 S1. The SW_{FB} for all GCMs are provided by Zelinka, Myers, McCoy, Po-Chedley, et al. (2020). For each GCM, Zelinka, Myers, McCoy, Po-Chedley, et al. (2020) calculate the 205 response of SWCRE (clear-sky minus all-sky upwelling SW flux at TOA) to warming in 206 the fully coupled 150-year CO_2 quadrupling ($abrupt4xCO_2$) simulation. SW_{FB} is ob-207 tained by adjusting the SWCRE response for non-cloud influences. This was completed by employing all- and clear-sky radiative kernels to discern the change in SWCRE due 209 to clouds from other perturbations (e.g., water vapor, surface albedo, and external forc-210 ing) (Huang et al., 2017; Soden et al., 2008; Shell et al., 2008). The SW_{FB} output is spatially-211 resolved (1° gridded) the region $90^{\circ}S - 90^{\circ}N$. 212

We use monthly-mean LWP, global-mean near-surface temperature (GMT), large-213 scale meteorology, and TOA SW flux from fully-coupled preindustrial control (*piControl*) 214 and $abrupt4xCO_2$ GCM simulations to construct a simplified physical model linking vari-215 ability in LWP to SW_{FB} . Using monthly-mean output instead of higher temporal res-216 olution output allowed us to survey nearly all CMIP5 and CMIP6 GCMs. LWP is the 217 column-integrated liquid water mass averaged over cloudy and cloud-free portions of the 218 model gridbox, which can be related to in-cloud LWP and cloud fraction since LWP \approx 219 cloud fraction \times in-cloud LWP. LWP is computed as the difference between CMIP vari-220

ables *clwvi* (total condensed water path) and *clivi* (ice water path, IWP). We calculate 221 the change in GMT (tas) in each GCM to normalize the change in LWP for consistency 222 with the calculation of SW_{FB} (Zelinka, Myers, McCoy, Po-Chedley, et al., 2020). Four 223 descriptors of large-scale meteorology are used to predict the SO LWP: surface skin tem-224 perature (T_s ; labeled ts in CMIP output); precipitation minus evaporation (P-E; pr 225 and hfls), a proxy for moisture convergence; lower-tropospheric stability (LTS; calcu-226 lated from ta at 700 mb, ps, and ts) (Klein & Hartmann, 1993), and subsidence at 500 227 mb (ω_{500} ; wap). Note that T_s refers to the skin temperature of Earth's surface, which 228 differs from the near-surface air temperature used to calculate GMT (output from CMIP 229 as tas). For the open ocean, T_s is the sea surface temperature. GCM radiative suscep-230 tibility is calculated from the TOA albedo (α calculated from the CMIP outputs rsut/rsdt), 231 LWP, and clear-sky albedo ($\alpha_{cs} = rsutcs/rsdt$) (section 2.2.4). Anomalies (between 232 abrupt CO2 quadrupling and pre-industrial control) are computed as the difference be-233 tween the mean of years 121-140 of $abrupt4xCO_2$ and the average of *piControl* simu-234 lations following Bjordal et al. (2020); Myers et al. (2021). 235

Satellite observations and reanalysis are used to constrain the LWP covariance with 236 meteorology and the radiative covariance with LWP. Monthly-mean LWP is provided 237 by the Multisensor Advanced Climatology of Liquid Water Path (MAC-LWP) (Elsaesser 238 et al., 2017b). MAC synthesizes passive microwave observations of cloud LWP from mul-239 tiple satellites. It provides 1° gridded total LWP output averaged over cloudy and cloud-240 free scenes, which makes it directly comparable to GCM LWP. However, microwave re-241 trievals are only available over open water, which limits our ability to constrain the LWP 242 response over sea ice. 243

Monthly-mean GMT and large-scale meteorology are described by Modern-Era Ret-244 rospective analysis for Research and Applications, Version 2 (MERRA-2) reanalysis (Gelaro, 245 McCarty, Suárez, et al., 2017). LWP, GMT, and large-scale meteorology observations 246 from 1992 to 2016 are used to test whether the chosen large-scale meteorology can pre-247 dict observed LWP (section 3.1.1). The observed covariance between LWP and mete-248 orology is used to constrain the GCM LWP response (section 3.1.2). Monthly-mean TOA 249 SW fluxes are provided by the Clouds and the Earth's Radiant Energy System (CERES) 250 Energy Balanced and Filled (EBAF) Edition 4.1 product (Loeb et al., 2018b). The ob-251 served clear-sky flux in Edition 4.1 is adjusted to be consistent with the definition of GCM 252 clear-sky flux (Loeb et al., 2020). The TOA SW fluxes and LWP from 2003 to 2016 are 253 used to constrain the GCM radiative susceptibility (section 3.2) based on the availabil-254 ity of CERES and MAC-LWP data. 255

2.2.1 Simplified Physical Model for Predicting SW Cloud Feedback

In this work we seek to understand drivers of SW_{FB} . To this end, we develop a 258 simplified physical model to predict the SO SW_{FB} . To give context to and motivate this 259 analysis we provide a brief survey of the cloud and radiation response to warming in CMIP5 260 and CMIP6 GCMs. Figure 1a shows the SW_{FB} and LWP responses to increases in GMT 261 for the GCMs surveyed in this study (written as $\Delta LWP/\Delta GMT$). Across GCMs, the 262 263 LWP response is anti-correlated with model SW_{FB} and reproduces the dipole pattern of feedback in the SO (Figure 1b). GCMs with a larger increase in LWP in response to 264 rising GMT tend to have more strongly negative SW_{FB} . While LWP generally increases 265 with GMT, there are a few GCMs reporting decreasing LWP after the first few degrees 266 of warming (Figure 1b). One goal of this study is to understand why these models be-267 have differently from the majority of GCMs where LWP increases in step with GMT (sec-268 tion 3.1.3). This correspondence between LWP response to warming and SW_{FB} in the 269 SO suggests that LWP can be used to describe how cloud macrophysical state drives cloud 270 feedback in this region, consistent with previous studies (McCoy et al., 2022). 271

A simplified, but physical, model can be built to predict SW_{FB} based on the link-272 age between the change in liquid cloudiness and its effect on TOA radiative flux. SW_{FB} 273 is the change in upwelling SW flux at TOA (ΔSW_{\uparrow}) due to the adjustment of cloud prop-274 erties, normalized by the change in GMT ($\Delta SW_{\uparrow C}/\Delta GMT$) (Zelinka, Myers, McCoy, 275 Po-Chedley, et al., 2020). Because the downwelling SW flux at TOA (SW_{\perp}) is only a func-276 tion of months and latitudes, local SW_{FB} at a given month is proportional to the cloud-277 induced change in TOA albedo ($\alpha = SW_{\uparrow}/SW_{\downarrow}$) and normalized by GMT ($\Delta \alpha_C/\Delta GMT$). 278 In turn, the response of α to warming can be approximated as the product of the sus-279 ceptibility of α to liquid $(\partial \alpha / \partial LWP)$ and the response of cloud liquid to warming $(\Delta LWP / \Delta GMT)$, 280 as follows 281

282

$$SW_{FB} = -\frac{\Delta SW_{\uparrow C}}{\Delta GMT} \propto -\frac{\Delta \alpha_C}{\Delta GMT} \sim -\frac{\partial \alpha}{\partial LWP} \cdot \frac{\Delta LWP}{\Delta GMT}$$
(1)

This model derives from previous work (McCoy et al., 2022). Equation 1 is used to predict GCM SW_{FB} calculated from radiative kernels (Zelinka, Myers, McCoy, Po-Chedley, et al., 2020). Equation 1 makes several simplifications based on the limitations of GCMs and observational data. Two simplifications central to the formulation of equation 1 are detailed below.

First, SW_{FB} is proportional to $\Delta \alpha_C / \Delta GMT$ for a given latitude and time. As mentioned in section 2.1, LWP observations are only available over open water, so we can not provide apples-to-apples observational constraints on the $\Delta LWP / \Delta GMT$ and $\partial \alpha / \partial LWP$ for high latitudes. We average $\Delta LWP / \Delta GMT$ and $\partial \alpha / \partial LWP$ to allow regional constraints.

Second, we neglect changes in albedo $(\Delta \alpha_C)$ driven by changes in ice cloud in re-293 sponse to warming. We make this approximation for two reasons. First, there is no equiv-294 alent observational data set to MAC-LWP for IWP, making it difficult to offer an effec-295 tive observational constraint on the response of IWP to global warming. Second, IWP 296 response (ΔIWP) to warming contributes minimally to a GCM SW_{FB} in this region 297 (McCoy et al., 2022). This is due to a combination of the smaller magnitude of $\Delta IWP/\Delta GMT$ 298 compared to $\Delta LWP/\Delta GMT$ in the SO (McCoy et al., 2016) and the weaker scatter-299 ing of SW radiation per unit mass of ice compared to liquid due to the smaller size of 300 typical liquid droplets relative to ice crystals (Liou, 2002; McCoy et al., 2014). Section 301 3.3 evaluates the effect of neglecting ice on the results of this study. 302

As with any approximate model, the predictive ability of our model is degraded 303 by the simplifications. The model in Equation 1 is balance between simplicity and ac-304 curacy. Uncertainty introduced by the simplifications will be reflected in the statistical 305 uncertainty in the equation 1 prediction of GCM-derived SW_{FB} . This is similar to other studies seeking to develop a simplified, but interpretable, model that can explain vari-307 ability in the Earth system (Held & Soden, 2006; Qu et al., 2015). We constrain the SO 308 SW_{FB} by providing constraints on the GCM LWP response ($\Delta LWP / \Delta GMT$) and the 309 radiative susceptibility $(\partial \alpha / \partial LWP)$ separately. Constraint methods are discussed in the 310 following sections. 311

312

2.2.2 Prediction of LWP using Cloud-Controlling Factor Analysis

In this section we examine the linkage between LWP and large-scale meteorology. The large-scale environmental factors affecting local cloud properties are referred to as cloud-controlling factors (Stevens & Brenguier, 2009). CCF analysis is based on the idea that the response of cloud properties to global warming can be expressed by a first-order Taylor expansion in CCFs (Klein et al., 2017). One application of this framework in the literature is to use observations to constrain LWP response to GCM-predicted changes in CCFs (Qu et al., 2015; Klein et al., 2017). Following Qu et al. (2015), we predict the response of LWP to GMT as

321

$$\frac{\Delta LWP}{\Delta GMT} = \sum_{i} \frac{\partial LWP}{\partial X_i} \frac{\Delta X_i}{\Delta GMT} + Res$$
(2)

where X_i are CCFs. Equation 2 decomposes LWP response to GMT into the LWP re-322 sponses to CCFs and a residual term. LWP response to GMT induced by each CCF is 323 a product of the sensitivity of LWP to each CCF $(\partial LWP / \partial X_i)$ and the response of that 324 CCF to GMT ($\Delta X_i / \Delta GMT$). The CCF model shown in equation 2 is trained on *piControl* 325 simulations of each GCM to calculate $\partial LWP/\partial X_i$. The $\Delta X_i/\Delta GMT$ term is given by 326 the differences between piControl and $abrupt4xCO_2$ simulations of each GCM. Com-327 pared to clouds, CCFs suffer from less parametric uncertainty in GCMs because they 328 are aspects of the resolved large-scale processes (Qu et al., 2015; Klein et al., 2017). Us-329 ing equation 2, we can provide a constraint on the LWP response to GMT by replacing 330 the $\partial LWP/\partial X$ derived from *piControl* simulations of GCMs with the values derived 331 from observations and using GCM estimates of $\Delta X_i / \Delta GMT$. As discussed in the in-332 troduction, an important assumption underlying CCF analysis is that the relationships 333 between clouds and CCFs are time-scale invariant (Qu et al., 2015; Klein et al., 2017). 334 We test this assumption in section 3.1. 335

The CCFs (X_i) considered in this study are surface skin temperature (T_s) , precipitation minus evaporation (P-E), lower tropospheric stability (LTS) (Klein & Hartmann, 1993; Slingo, 1980), and 500 mb subsidence (ω_{500}) . These CCFs are consistent with previous studies of covariance between extratropical clouds and meteorology (McCoy, Field, Bodas-Salcedo, et al., 2020; McCoy et al., 2022; Zelinka, Myers, McCoy, Po-Chedley, et al., 2020; Zelinka et al., 2018).

We use P-E as a proxy for moisture convergence because moisture convergence 342 is not output from GCMs participating in CMIP5 and CMIP6. These two terms differ 343 by the change in moisture storage over time (Seager & Henderson, 2013). To demonstrate 344 that these quantities are nearly identical for our study, we examine the fifth generation 345 European Centre for Medium-Range Weather Forecasts (ECMWF; ERA5) for both vari-346 ables, P - E is a close approximation of moisture convergence in $40 - 85^{\circ}S$ when we 347 averaged them in $5^{\circ} \ge 5^{\circ}$ gridbox of monthly output (Figure S1 in the supplementary 348 information). The discrepancy between these two variables in GCMs should be smaller 349 than in reanalysis because of the absence of an analysis increment in GCMs (Seager & 350 Henderson, 2013). For these reasons, we will average GCM LWPs and CCFs as well as 351 observations over $5^{\circ} \ge 5^{\circ}$ gridboxes within $40-85^{\circ}S$ to conduct the CCF analysis. The 352 LWP response is predicted by the CCF model (Equation 2) in each $5^{\circ} \ge 5^{\circ}$ gridbox in 353 the SO. 354

P-E is consistently positive in $40-85^{\circ}S$ across all GCMs in the mean state cli-355 mate (*piControl* simulation) (gray lines in Figure S2). In $abrupt4xCO_2$ simulations, P-356 E reduces in the $40 - 50^{\circ}S$ region and enhances across the $50 - 85^{\circ}S$ region (colored 357 lines in Figure S2). This is consistent with a poleward expansion of subtropical drying 358 region under global warming (Siler et al., 2018; Bonan et al., 2023) and a robust moist-359 ening of latitudes poleward of $50^{\circ}S$ (Held & Soden, 2006). Comparing moisture conver-360 gence response to warming and SW_{FB} suggests that $50^{\circ}S$ may act as a demarcation be-361 tween positive SW_{FB} (negative $\Delta LWP/\Delta GMT$) and negative SW_{FB} (positive $\Delta LWP/\Delta GMT$) 362 estimated from $abrupt4xCO_2$ simulations of CMIP5 and CMIP6 GCMs (Figure 1a) due 363 to changes in moisture convergence regime. This is consistent with the notion that the hydrological response to warming (Held & Soden, 2006) sets some of the pattern of SW 365 cloud feedback in the SO (McCoy et al., 2022). To characterize this feature, we present 366 our analysis separately for the $40-50^{\circ}S$ and $50-85^{\circ}S$ regions (sections 3.1.2 and 3.3). 367

We use monthly-mean data to examine the covariance between LWP and P - E. 368 This enables averaging across the synoptic systems that drive extratropical moisture con-369 vergence (Field & Wood, 2007). This approach is not particularly new and many pre-370 vious studies have leveraged monthly mean CCFs to predict extratropical cloudiness (Zelinka, 371 Myers, McCoy, Po-Chedley, et al., 2020; Zelinka et al., 2018; Ceppi, McCoy, & Hartmann, 372 2016). We believe this averaging doesn't substantially degrade our results based on pre-373 vious studies relating LWP in extratropical cyclones to moisture convergence (McCoy 374 et al., 2019; McCoy, Field, Bodas-Salcedo, et al., 2020). We don't expect that monthly 375 averages will strongly degrade the predictive capacity of our CCF model since previous 376 studies examining daily means suggest fairly linear dependence of LWP on CCFs (McCoy 377 et al., 2018; McCov, Field, Bodas-Salcedo, et al., 2020). We test whether performing our 378 analysis on monthly means degrades the predictive ability of our model using two out-379 of-sample tests. 380

381

2.2.3 Cloud Regime Temperature-dependence

CCF analysis has been used in numerous studies to predict the response of clouds 382 to warming in the tropics and subtropics (Qu et al., 2015; Zhai et al., 2015; Myers & Nor-383 ris, 2016; Brient & Schneider, 2016; McCoy et al., 2017; Myers et al., 2021; Wall et al., 384 2022) as well as the extratropics (Ceppi, McCoy, & Hartmann, 2016; Zelinka, Myers, Mc-385 Coy, Po-Chedley, et al., 2020; Zelinka et al., 2018). The SO region present a challenge 386 to a CCF model that lumps together all clouds into a single set of sensitivities between clouds and CCFs (i.e, equation 2). From $40 - 85^{\circ}S$, T_s varies from 210 K in the aus-388 tral winter over the Antarctic continent to around 290 K in the summer subtropics. The 389 temperature of the atmosphere and clouds varies along with T_s . The wide range of cloud 390 temperatures results in a combination of mixed-phase clouds and liquid-only clouds in 391 the SO (Tan et al., 2016). 392

The formation and removal processes governing liquid and mixed-phase clouds are 393 very different (Morrison et al., 2012). Precipitation efficiency is higher in mixed-phase 394 clouds than in liquid-only clouds due to the rapid growth of ice crystals at the expense 395 of liquid drops (Storelvmo & Tan, 2015). The higher precipitation efficiency of mixed-396 phase clouds results in the majority of mid-latitude precipitation events originating as 397 snow (Field & Heymsfield, 2015). Previous studies suggest that mixed-phase and liquid-398 only clouds will respond differently to global warming (Tan et al., 2016). GCM low cloud 399 optical depth increases with warming for cold clouds and decreases with warming for warm clouds (Gordon & Klein, 2014; Terai et al., 2016). This behavior is also found in in-situ 401 observations (Terai et al., 2019). 402

Because of the differing cloud physics and potential cloud feedback processes aris-403 ing due to cold (mixed-phase) and warm (liquid-only) clouds, we split our CCF model 404 over temperature. The intent of splitting our CCF model over temperature is to sepa-405 rate the SO into regions that are only mixed-phase and only liquid-only clouds, which is not really possible in the context of climate model output at monthly resolution, but 407 to separate the SO into regimes that are dominated by different processes and therefore 408 LWP covaries with CCFs differently. We count a $5^{o} \ge 5^{o}$ gridbox in $40-85^{o}S$ as a cold 409 (warm) regime gridbox if the mean T_s of gridbox is lower than (larger or equal to) a thresh-410 old T_s (TR_{T_s}) . This results in a CCF model split over TR_{T_s} : 411

$$\frac{\Delta LWP}{\Delta GMT}|_{Cold} = \sum_{i} \left(\frac{\partial LWP}{\partial X_{i}}|_{Cold} \cdot \frac{\Delta X_{i}}{\Delta GMT}|_{Cold}\right) + Res_{1}$$

$$T_{s} < TR_{T_{s}}$$

$$\frac{\Delta LWP}{\Delta GMT}|_{Warm} = \sum_{i} \left(\frac{\partial LWP}{\partial X_{i}}|_{Warm} \cdot \frac{\Delta X_{i}}{\Delta GMT}|_{Warm}\right) + Res_{2}$$

$$T_{s} > TR_{T}$$
(3)

412

440

445

We have two goals in our methodology for determining TR_{T_s} for each GCM. First, 413 we want to make the determination of TR_{T_s} objective for each GCM. Second, we want 414 to make the determination of TR_{T_s} in a way that allows an analogous calculation for ob-415 servations. For each GCM, TR_{T_s} is defined as the threshold T_s that maximizes the ex-416 plained variance in mean-state (piControl) LWP by the CCF model in equation 3. For 417 each GCM we iterate through possible TR_{T_s} values within the entire range of T_s within 418 the SO latitudes and calculate the coefficient of determination (R^2) of equation 3 when 419 predicting *piControl* LWP (Figure S3 in the supplementary information). Equation 3 420 explains more than 70 % of the variance of *piControl* LWP across GCMs. One question 421 is whether TR_{T_s} is time scale invariant. In Figure S4 of the supplementary information, 422 we calculate TR_{T_s} using $abrupt4xCO_2$ data instead of piControl. The TR_{T_s} trained 423 using $abrupt4xCO_2$ simulations correlates with TR_{T_s} trained from *piControl* simulations, 424 supporting that TR_{T_s} is time-scale invariant. We use the TR_{T_s} trained on *piControl* sim-425 ulations to predict the LWP response to warming in $abrupt4xCO_2$ simulations (section 426 3.1.2). The TR_{T_s} for most GCMs is around 270 K (Figure S3), which generally sepa-427 rates the clouds over cold ice or land surfaces from the open ocean. Komurcu et al. (2014) 428 shows that the supercooled liquid fraction in GCMs dramatically drops when cloud tem-429 perature is lower than 255 K. Assuming a typical extratropical environment with cloud 430 base height of $2-3 \ km$ and lapse rate of 6.5 K/km, its T_s would be close to 270 K. This 431 is consistent with the idea that mixed-phased and liquid-only clouds have different cloud 432 physics and response behaviors to their environments. 433

Because microwave radiometers do not retrieve LWP over ice (Elsaesser et al., 2017b), we need to consider sampling differences between GCMs and observations when providing observational constraints. The region for which valid data is available from MAC is very similar to GCM warm regimes (Figure S5). In the remainder of this study observational constraint is only available for the warm regime of equation 3 and all the cold regime observations are treated missing due to lack of observations.

2.2.4 Radiative Susceptibility

In equation 1, the response of LWP to GMT is connected to its SW radiative effect through a radiative susceptibility term $(\partial \alpha / \partial LWP)$. This term describes how a change in LWP affects α while keeping other factors fixed. Following McCoy et al. (2022), the radiative susceptibility is estimated by training the multi-linear regression model

 $\alpha = c_1 * LWP + c_2 * \alpha_{clear-sky} + c_3 \tag{4}$

where c_1 is $\partial \alpha / \partial LWP$. The regression model is trained on *piControl* GCM simulations 446 and observations to obtain radiative susceptibilities for GCMs and observations. Train-447 ing is performed at the native spatial resolution of the data. TOA albedo α is a func-448 tion of clear-sky albedo (α_{cs}) and LWP, while LWP is in turn affected by cloud areal ex-449 tent (Bender et al., 2017) and cloud optical depth (Gordon & Klein, 2014). By includ-450 ing α_{cs} as a predictor we seek to separate the change in α contributed by changes in clouds 451 from non-cloud perturbations (e.g., surface conditions). This is consistent with calcu-452 lating SW_{FB} by adjusting the SWCRE response for non-cloud influences using radia-453 tive kernels (Zelinka, Myers, McCoy, Po-Chedley, et al., 2020; Soden et al., 2008). 454

One way to think of equation 4 is a very simple radiative kernel. To enable the use 455 of equation 4 we subset our training data to remove cases where surface albedo or near 456 surface sun angle strongly affect TOA albedo. The sensitivity of TOA upwelling SW flux 457 to changes in cloudiness over a bright surface is low because of the high surface albedo. 458 Consequently SW_{FB} is nearly zero over surface ice (i.e. the Antarctic continent) (Shell 459 et al., 2008). We train equation 4 over open water to minimize the effect of extremely 460 bright surfaces on the calculation of $\partial \alpha / \partial LWP$. We subset training data using a clear-461 sky albedo threshold $(TR_{\alpha_{cs}})$. We evaluate the sensitivity of $\partial \alpha / \partial LWP$ to the value of 462 $TR_{\alpha_{cs}}$ in section 3.2. Increasing solar zenith angle increases albedo (McCoy et al., 2018). 463 Compounding this effect, LWP decreases in winter while solar zenith angle increases. Data 464 from a single month is used to calculate the radiative susceptibility $\partial \alpha / \partial LWP$ to reduce 465 the effects of spurious covariation between solar zenith angle and LWP. We choose Jan-466 uary because austral summer is the time that the change in LWP contributes the most 467 to SW_{FB} when insolation is strong. 468

469 **3 Results**

3.1 Predicting LWP

The first step to providing an observational constraint on SW_{FB} using equation 471 1 is to constrain the response of SO LWP to warming using observed covariability be-472 tween CCFs and LWP. To understand the uncertainty in our CCF-based constraint of 473 LWP response we need to evaluate whether the relationships between LWP and CCFs 474 are invariant across time scales (Klein et al., 2017). Two out-of-sample tests are performed 475 to test time scale invariance, and more broadly, to test the predictive skill of the CCF 476 model. First, we train a CCF model (equation 2) on monthly-mean observations for a 477 short period and use it to predict the interannual variability of LWP back to 1992. This 478 is shown in section 3.1.1. Second, we train the regression model in equation 3 on monthly-479 mean piControl simulations and use it to predict the GCM-simulated response of LWP 480 to CO_2 quadrupling. This is discussed in section 3.1.2. Following these tests, we use the 481 LWP-CCF relationships obtained from observations to constrain the LWP responses in 482 GCMs in section 3.1.2. In section 3.1.3, we discuss GCM LWP responses by apportion-483 ing $\Delta LWP / \Delta GMT$ among the CCFs. 484

485

470

3.1.1 Predicting Historical Trends in LWP

Observations of LWP are available from 1992-2016. We this period into a train-486 ing period (2012-2016) and a validation period (1992-2011). Equation 2 is trained on 2012-487 2016 to calculate $\partial LWP/\partial X_i$. Equation 2 is used to predict the interannual variation 488 of LWP 1992-2011. MAC-LWP observes an increase in SO LWP over the past two decades, 489 consistent with Manaster et al. (2017) and Norris et al. (2016) (Figure 2a). The predicted 490 LWP from equation 2 broadly reproduces the positive trend of LWP during the period 491 from 1996 onward (Figure 2a). Before 1996, the LWP trend predicted by the CCF model is negative. This may be because the CCFs predicted by MERRA-2 are reliant on the 493 observations being ingested into the reanalysis. Many fewer observations of precipita-494 tion are available before the mid-1990s (Gelaro, McCarty, Suárez, et al., 2017). The lack 495 of observational input to reanalysis may lead to the disagreement between the LWP pre-496 dicted by the CCF model and LWP observations in the early 1990s. During the period 497 where numerous observations were available to the MERRA-2 reanalysis, the ability of 498 CCF model in equation 2 to reproduce the decadal-scale trend and interannual variabil-100 ity of LWP in an out-of-sample test supports the time-scale invariance of $\partial LWP/\partial X_i$. 500 The ability of the CCF model to reproduce the observed trend in LWP is not sensitive 501 to the choice of training and validation periods (Figure S6). 502

Equation 2 can be used to decompose the predicted trend into contributions from individual CCFs. The positive decadal trend in SO LWP can be largely explained by the increase in P-E (Figure 2b). Increases in T_s explain only a small fraction of the LWP trend. Stability and large-scale subsidence have negligible effects on the SO LWP on a decadal scale. Increased P-E is related to the increased moisture content in the extratropical atmosphere (Held & Soden, 2006). This result suggests that the hydrological cycle has played an important role in the response of SO LWP to increased GMT over the past two decades (Norris et al., 2016; Manaster et al., 2017).

511

3.1.2 Predicting LWP response to CO₂ Quadrupling

Following our evaluation of time-scale invariance of $\partial LWP/\partial X_i$ in observations, 512 we evaluate whether the $\partial LWP/\partial X_i$ trained using *piControl* GCM data can be used 513 to predict the LWP response in $abrupt4xCO_2$ simulations. Figure 3 shows the changes 514 in LWP in response to warming $(\Delta LWP/\Delta GMT)$ between the average of *piControl* and 515 the mean of years 121-140 of $abrupt 4x CO_2$ simulations (Myers et al., 2021; Bjordal et 516 al., 2020). Predicted LWP responses are shown in three latitude bands: $40-85^{\circ}S$ (Fig-517 ure 3 left); $40-50^{\circ}S$ (Figure 3 middle); and $50-85^{\circ}S$ (Figure 3 right). The CCF model 518 (equation 3) predicts 70% of GCM variance in $\Delta LWP/\Delta GMT$ in the latitude band en-519 compassing the SO (Figure 3b). This supports the time-scale invariance of $\partial LWP/\partial X_i$. 520 The explained variance in the $40-50^{\circ}S$ latitude band is 60% (Figure 3d). This decrease 521 in explained variance relative to the entire SO may be related to the hydrological response 522 in this region. While moisture is converged into $40 - 50^{\circ}S$ in the mean-state climate, 523 the convergence pattern becomes less robust at the end of $abrupt4xCO_2$ simulations. Some 524 GCMs display drying and some display moistening in $40-50^{\circ}S$ (Figure S2). In the lat-525 itude band where warming simulations consistently predict moistening $(50-85^{\circ}S)$, the 526 explained variance in $\Delta LWP / \Delta GMT$ is 86% (Figure 3f). 527

Because observational constraint from MAC-LWP is only available in the warm regime, we separate the predictions of CCF model into warm and cold regimes for each latitude band. The LWP response to GMT in the warm regime predicts the majority of total LWP response across latitude bands (Figure 3ace). Only the warm regime exists in the 40– $50^{\circ}S$ region, so $r^2 = 1$ (Figure 3c). The explained variance in $\Delta LWP/\Delta GMT$ by warm regime is still high in the $50 - 85^{\circ}S$ region ($r^2 = 0.64$, Figure 3e).

We calculate how observations in the warm regime in each latitude band constrain 534 overall $\Delta LWP / \Delta GMT$. The $\partial LWP / \partial X_i$ for each GCM in the warm regime is replaced 535 with the $\partial LWP/\partial X_i$ computed from observations yielding a constraint on $\Delta LWP/\Delta GMT$ 536 in the warm regime. This constraint is propagated from the warm regime to the aggre-537 gate of both regimes. Uncertainty in the best fit line fit relating the CCF prediction of 538 the warm regime to the CCF prediction of both regimes is estimated by Jackknife re-539 sampling (Tukey, 1958). We intersect the shaded regions on the x-axis in Figure 3ace 540 with the best-fit lines and their uncertainties to propagate the warm regime constraint 541 to both regimes for each latitude band. The observational constraint on $\Delta LWP/\Delta GMT$ 542 for each latitude band is then propagated through the uncertainty from the CCF model. 543 In Figure 3bdf, the constrained ranges from the y-axis of Figure 3ace are denoted via 544 intersection of the brown shading with the x-axis. The best fit lines and uncertainty in 545 Figure 3bdf are used to propagate the constraints on the CCF model predictions to the 546 GCM simulated LWP response. These constraints are used in section 3.3 to constrain 547 SW_{FB} . Once propagated, observational constraints on the warm regime point towards 548 a moderate $\Delta LWP / \Delta GMT$ across the SO. 549

Potential systematic biases in the passive microwave observations of LWP can be propagated to uncertainty in our constraint on $\Delta LWP/\Delta GMT$. Observational biases in LWP impact constraints on $\Delta LWP/\Delta GMT$ by affecting the observed sensitivities of LWP to CCFs ($\partial LWP/\partial X$). Potential systematic biases in microwave LWP observations are estimated following Greenwald et al. (2018). The net bias of LWP in the SO (poleward to $40^{\circ}S$) should be smaller than $+10 \ g/m^2$ and is relatively spatially uniform (Figure 17(f) and Figure 19(a) in Greenwald et al. (2018)). The LWP percentage bias is $\pm 10.8\%$, calculated by dividing $\pm 10 \ g/m^2$ by the averaged LWP during the observational training period. We then recalculate $\partial LWP/\partial X_i$ by perturbing the observational values of LWP by $\pm 10.8\%$. Considering potential observational LWP bias slightly loosens the constraint of $40-85^{\circ}S \ \Delta LWP/\Delta GMT$ from [2.76, 4.19] $g \ m^2 \ K^{-1}$ to [2.60, 4.47] $g \ m^2 \ K^{-1}$. The effect of observational bias is propagated through to the constraint on the SO SW_{FB} in section 3.3.

563

3.1.3 CCF Contributions to LWP Response to CO₂ Quadrupling

In this section we show the sensitivities of LWP to CCFs $(\partial LWP / \partial X_i)$ as well as 564 each CCF's contribution to the LWP response to warming following similar analysis in 565 previous studies (Zelinka, Myers, McCoy, Po-Chedley, et al., 2020). $\partial LWP/\partial X_i$ for each 566 GCM (Figure 4a) can be scaled by the change in each CCF between piControl and the 567 end of $abrupt4xCO_2$ simulation ($\Delta X_i/\Delta GMT$; Figure 4b) to yield the contribution of 568 each CCF to $\Delta LWP / \Delta GMT$ (Figure 4c; equation 3). Cold and warm regime predic-569 tions are shown separately. Observed $\partial LWP/\partial X$ are only available for the warm regime 570 (Figure 4a). 571

The dependence of LWP on CCFs across GCMs and observations (Figure 4a) is 572 broadly consistent with previous studies. The coefficient relating LWP and $T_s (\partial LWP / \partial T_s)$ is 573 positive across all GCMs for the cold regime. Agreement between GCMs on the sign of 574 $\partial LWP/\partial T_s$ decreases for the warm regime. This is consistent with previous studies sug-575 gesting that cold cloud optical depth increases in response to warming (Gordon & Klein, 576 2014; Terai et al., 2019), mostly due to the increased cloud water content (Betts & Harsh-577 vardhan, 1987). Terai et al. (2019) suggests that the cloud optical depth for warm clouds 578 may decrease or stay constant with increasing temperature owing to the reduced cloud 579 adiabaticity. The coefficient relating LWP to $P - E (\partial LWP / \partial P - E)$ is positive for warm 580 and cold regimes, which is consistent with previous literature (McCoy et al., 2019; Mc-581 Coy, Field, Bodas-Salcedo, et al., 2020). The coefficient relating LWP and LTS ($\partial LWP / \partial LTS$) 582 is mostly positive in the warm regime of GCMs, while the coefficient relating LWP to 583 ω_{500} ($\partial LWP/\partial\omega_{500}$) is small. This is consistent with previous work on boundary layer 584 cloudiness (Zelinka et al., 2018; Myers & Norris, 2015, 2013). Observed $\partial LWP/\partial T_s$ and 585 $\partial LWP/\partial P - E$ are positive and much larger than $\partial LWP/\partial LTS$ and $\partial LWP/\partial \omega_{500}$. 586

Both T_s and P - E increase with warming in warm and cold regimes (Figure 4b). LTS increases with warming in the warm regime but decreases in the cold regime. This pattern may be related to the poleward shift of the Hadley cell (stabilizing the warm regime lower troposphere) and the poleward shift of the Southern Hemisphere storm track (destabilizing the cold regime lower troposphere) simulated by GCMs (Barnes & Polvani, 2013; Bender et al., 2012). The variation in large-scale subsidence is relatively small compared to other CCFs.

⁵⁹⁴ Combining $\partial LWP/\partial X_i$ and the response of CCF to warming $(\Delta X_i/\Delta GMT)$ al-⁵⁹⁵ lows us to apportion $\Delta LWP/\Delta GMT$ among CCFs. In the warm regime, GCMs have ⁵⁹⁶ roughly equivalent contributions due to T_s , P-E, and LTS. In the cold regime, P-⁵⁹⁷ E and T_s changes contribute the most (Figure 4c).

Among the GCMs surveyed here (Table S1), the second Community Earth System 598 Model (CESM2), its variants (CESM2-WACCM, CESM2-FV2, CESM2-WACCM-FV2), 599 and E3SM-1-0 predict a decrease in LWP after the first few degrees of warming in $abrupt4xCO_2$ 600 simulations (Figure 1b), which is consistent with previous studies (Bjordal et al., 2020). 601 These models share a similar atmosphere component (Danabasoglu et al., 2020; Golaz 602 et al., 2019; Rasch et al., 2019). Focusing on CESM2 in Figure 4, characterizes how de-603 creases in LWP as GMT increases relate to CCFs. The prediction of CESM2's LWP re-604 sponse to warming by equation 3 trained on piControl is less skillful than the predic-605 tion for other GCMs (Figure S7), but it is improved relative to previous CCF-based pre-606

dictions (McCoy et al., 2022). While work is required to more accurately predict the CESM2 607 LWP response using a CCF model, the decreased LWP in the warm regime is captured 608 by equation 3 (Figure 4c and Figure S7). Decomposing the prediction from equation 3 609 suggests that the LTS-induced increase in CESM2 LWP in the warm regime is offset by 610 decreases related to T_s . CESM2 displays the lowest warm regime $\partial LWP/\partial P - E$ and 611 the P-E contribution to LWP response is small (Figure 4ac). Relative to observations 612 CESM2 overestimates $\partial LWP / \partial LTS$ and underestimates $\partial LWP / \partial P - E$ in the warm 613 regime. Warm regime $\partial LWP / \partial T_s$ is negative in CESM2, but is positive in observations 614 (Figure 4a). Warm regime T_s , P - E, and LTS increase in response to GMT (Figure 615 4b) and the net effect is a negative trend in LWP beyond the first degree of warming with 616 an the overall near-zero response of LWP to warming. 617

As mentioned in the introduction, the phase shift in mixed-phased clouds is one 618 of the potential mechanisms that may contribute to the increase in SO LWP that in turn 619 drives a negative SW_{FB} (Tan et al., 2016). Bjordal et al. (2020) attribute the high cli-620 mate sensitivity of CESM2 to its large mean-state supercooled liquid fraction (i.e., small 621 ice fraction) in the SO because its low-level clouds are easily shifted to being liquid-dominated 622 and the contribution of the negative cloud phase feedback reduces as GMT increases. 623 We examine this idea in the context of our analysis framework by examining the state 624 dependence of $\partial LWP/\partial T_s$. In the context of our CCF model, $\partial LWP/\partial T_s$ may indicate 625 the contribution to LWP change by shifts between ice and liquid. As with any other cor-626 relative analysis caution should be used in interpreting this metric since it may also re-627 lated to other processes such as shifts in the moist adiabat. 628

Following Bjordal et al. (2020), we calculate $\partial LWP/\partial T_s$ in 15-year chunks dur-629 ing the 150 years of $abrupt4xCO_2$ simulations to contrast how this sensitivity evolves 630 with warming across GCMs (Text S1). We find that CESM2 is an outlier among the GCMs 631 surveyed here in regards to how $\partial LWP/\partial T_s$ changes with time (Figure S8 in the sup-632 plementary information). $\partial LWP / \partial T_s$ shifts toward more negative values as warming 633 continues. This behavior is not displayed in other GCMs. This is consistent with the anal-634 ysis of CESM2 in Bjordal et al. (2020). For GCMs like CESM2 that have large super-635 cooled liquid fractions, as the climate warms the ice available for transition to liquid is 636 decreased and the phase shift-related changes in LWP are reduced. This may explain the 637 non-monotonic response of LWP to warming that is displayed in CESM2. 638

639

3.2 Radiative Susceptibility

Following equation 1, we argue that SW_{FB} can be approximated as proportional 640 to the product of change in LWP and the sensitivity of albedo to LWP. Across GCMs, 641 $\partial \alpha / \partial LWP$ vary by nearly a factor of seven. One emergent behavior in GCMs is an in-642 verse relationship between $\partial \alpha / \partial LWP$ and mean-state LWP. This is consistent with pre-643 vious studies (McCoy et al., 2022). TOA albedo and cloud fraction (areal coverage of 644 clouds) are approximately linearly related until the scene becomes overcast (Bender et al., 2017). The effect of in-cloud LWP on albedo saturates at high in-cloud LWP (Lacis 646 & Hansen, 1974). The SO mean-state LWP is a function of cloud fraction and in-cloud 647 LWP. A GCM that simulates high mean-state LWP has fewer clear-sky pixels that can 648 be filled and is closer to radiative saturation. As LWP increases with warming, additional 649 liquid affects α less efficiently by only increasing the in-cloud liquid rather than increas-650 ing cloud coverage. 651

Radiative susceptibility calculated from CERES and MAC-LWP observations is low relative to GCMs (Figure 5). This result suggests that the too-bright and too-homogeneous bias of tropical clouds in CMIP6 GCMs (Konsta et al., 2022) may also exist in the simulation of extratropical clouds. One potential uncertainty in estimating $\partial \alpha / \partial LWP$ is the clear-sky albedo threshold ($TR_{\alpha_{cs}}$) applied before training the regression model in equation 4. We include this uncertainty in the SW_{FB} constraint by calculating $\partial \alpha / \partial LWP$ varying $TR_{\alpha_{cs}}$ from 0.11 to 0.30 (0.105 is lowest clear-sky albedo for some GCMs). This uncertainty range is compounded by potential systematic uncertainty in observed LWP as discussed above. When both sources of uncertainty are included, the range of observed susceptibility widens from [0.43, 0.90] (kg m⁻²)⁻¹ to [0.39, 1.01] (kg m⁻²)⁻¹.

One intriguing feature of GCMs is that GCMs where SO LWP is more sensitive 662 to the hydrological cycle (large $\partial LWP/\partial P - E$) tend to have a weaker radiative response 663 (small $\partial \alpha / \partial LWP$). This results in a buffering between macrophysical cloud response 664 to GMT and radiative response to GMT. We examine how radiative and macrophysi-665 cal factors are linked through mean-state LWP. $\partial LWP/\partial P - E$ positively correlates with 666 mean-state LWP in both cold and warm regimes (Figure 5). This relationship can be 667 explained in the context of sources and sinks of cloud liquid content (McCoy, Field, Bodas-668 Salcedo, et al., 2020; McCoy et al., 2022). Source and sink rates of clouds can be writ-669 ten as 670

$$K_{source} = e_{source} \cdot r_{water \ vapor}$$

$$K_{sink} = e_{sink} \cdot r_{LWP}$$
(5)

with rates being the product of bulk efficiency coefficients for sources (e_{source}) and sinks (e_{sink}) and their respective reservoir terms. The reservoir that liquid draws from is water vapor $(r_{water \ vapor})$ while the sink reservoir (precipitation) is cloud liquid (r_{LWP}) . In the mean-state climate, sources and sinks are balanced $(K_{source} = K_{sink})$ and

$$\frac{e_{source}}{e_{sink}} = \frac{r_{LWP}}{r_{water \ vapor}}.$$
(6)

Following this conceptual model, mean-state LWP is proportional to the relative strength 677 of source and sink efficiencies (i.e., e_{source}/e_{sink}). If we assume the same water vapor 678 $(r_{water \ vapor})$ in the mean-state climates of GCMs, the diversity in model mean-state LWP 679 can be traced back to the subgrid-scale parameterization of cloud source and sink pro-680 cesses. Similarity in water vapor climatologies is an assumption, since free-running mod-681 els without a fixed SST will yield slightly different mean-state water vapor paths (Jiang 682 et al., 2012). In this conceptual model $\partial LWP/\partial P - E$ trained using the GCM mean-683 state climate may act as a proxy for the relative strength of source to sink efficiencies 684 $(e_{source}/e_{sink} \propto \partial LWP/\partial P - E).$ 685

The steady-state framework outlined here provides insight into why the slope of $\partial LWP/\partial P - E$ for the cold regime is larger than the slope for the warm regime (Figure 5). In this framework, differences in slope could arise due to a stronger source efficiency for cold regime clouds due to the larger moist adiabat (Betts & Harshvardhan, 1987), even though the sink efficiency for cold regime clouds may be larger as well (Field & Heymsfield, 2015)

⁶⁹² How does the steady-state framework outlined above inform us of the diversity in ⁶⁹³ the GCM LWP responses to warming? The moisture content ($r_{water \ vapor}$) in the ex-⁶⁹⁴ tratropics increases with GMT. If we assume the relative strength of source-to-sink ef-⁶⁹⁵ ficiency (e_{source}/e_{sink}) is fixed under climate change, a model with larger mean-state sen-⁶⁹⁶ sitivity of LWP to P - E would simulate a larger increase in LWP. This is consistent ⁶⁹⁷ with GCM behavior and warm regime $\partial LWP/\partial P - E$ and $\Delta LWP/\Delta GMT$ covary across ⁶⁹⁸ GCMs (Figure S9 in the supplementary information) with a correlation of r = 0.78.

699

676

3.3 Constraints on Southern Ocean SW Cloud Feedback

In the proceeding sections we examine the response of SO LWP to GMT predicted by CCFs and the response of α to LWP. Combining these terms in equation 1 we evaluate whether our simplified model of SW_{FB} has skill in predicting GCM SW_{FB} . In Figure 6, we use the $\Delta LWP/\Delta GMT$ and $\partial \alpha / \partial LWP$ calculated from GCMs to predict their SW_{FB} calculated using radiative kernels as presented in Zelinka, Myers, McCoy, Po-Chedley, et al. (2020). The ability of the simple model in equation 1 to reproduce SW_{FB} is evaluated in the $40 - 50^{\circ}S$ and $50 - 85^{\circ}S$ latitude bands (Figure 6). Equation 1 explains 54 % of the variance in GCM SW_{FB} averaged over $40 - 50^{\circ}S$ and and 40 % averaged over $50 - 85^{\circ}S$.

Based on the observational constraints on $\Delta LWP/\Delta GMT$ (Figure 3) and the ob-709 servational estimate of $\partial \alpha / \partial LWP$ (Figure 5), we provide observational constraints on 710 SW_{FB} . Observational constraints on the right-hand side of equation 1 predict the con-711 tributions of $40 - 50^{\circ}S$ and $50 - 85^{\circ}S$ regions' clouds to global mean cloud feedback 712 to be 0.00-0.06 $W m^{-2} K^{-1}$ and -0.15-0.01 $W m^{-2} K^{-1}$. These ranges are calcu-713 lated by taking the shaded y-ranges in Figure 6 and scaling them by the ratio of the area 714 in the latitude band to global surface area. The constraint on $50-85^{\circ}S$ SW_{FB} is con-715 sistent with the constraint $-0.10-0.0 W m^{-2} K^{-1}$ calculated by McCoy et al. (2022). 716 The uncertainties in $40-50^{\circ}S$ and $50-85^{\circ}S$ SW_{FB} constraints are calculated by com-717 bining uncertainties in $\Delta LWP / \Delta GMT$ constraints and the uncertainty in the estimate 718 of $\partial \alpha / \partial LWP$. Uncertainties in the constraints on $\Delta LWP / \Delta GMT$ are due to the in-719 termodel spread in $\Delta X / \Delta GMT$ and the uncertainties propagated from the warm regime 720 to latitude bands including both cold and warm regimes (section 3.1.2). The uncertainty 721 in $\partial \alpha / \partial LWP$ is given by varying the clear-sky albedo threshold (section 3.2). The con-722 straint on $40-50^{\circ}S$ SW_{FB} is tighter than for $50-85^{\circ}S$ because an observational con-723 straint on $\Delta LWP/\Delta GMT$ is only available in the warm regime, and the $40-50^{\circ}S$ re-724 gion is entirely within the warm regime. 725

To evaluate the extent to which neglecting ice water path (IWP) changes impact 726 our prediction of GCM SW_{FB} , we examined the relative contributions of LWP and IWP 727 changes to SW_{FB} in GCMs. We first calculate the changes in IWP with GMT ($\Delta IWP / \Delta GMT$) 728 between the mean of years 121-140 of $abrupt 4x CO_2$ and the average of piControl sim-729 ulations for all GCMs in this study following the same procedure used in the calculation 730 of $\Delta LWP/\Delta GMT$. The median $\Delta LWP/\Delta GMT$ in 40–85°S is around 10 times larger 731 than $\Delta IWP/\Delta GMT$ across GCMs (Figure S10a). To compare the sensitivity of albedo 732 to LWP $(\partial \alpha / \partial LWP)$ with IWP $(\partial \alpha / \partial IWP)$, we first partition the TOA albedo (α) into 733 50 LWP/IWP bins. Then we follow the method for calculating radiative susceptibility 734 (section 2.2.4) to compute the sensitivities of albedo to liquid versus ice by keeping the 735 other variable fixed (Text S2). The product of $\partial \alpha / \partial LWP$ ($\partial \alpha / \partial IWP$) and $\Delta LWP / \Delta GMT$ 736 $(\Delta IWP/\Delta GMT)$ is a measure of the contribution of LWP (IWP) changes to the response 737 of α to per degree warming $(\Delta \alpha / \Delta GMT)$, which is proportional to their contributions 738 to SW_{FB} (equation 1). Among the GCMs surveyed here, the median contribution to an 739 α response from changes in LWP is inferred to be a factor of 14 larger than that aris-740 ing from changes in IWP (Figure S10b). This result is consistent with the approxima-741 tion in equation 1 that the SO SW_{FB} is dominated by LWP changes and the ability of 742 equation 1 to predict the full radiative kernel calculation of SW_{FB} . 743

We combine our constraints on SW_{FB} for $40 - 50^{\circ}S$ and $50 - 85^{\circ}S$ to compute 744 the constraint on $40-85^{\circ}S SW_{FB}$. We take the sum of the area-weighted latitudinal 745 constraints in $40-50^{\circ}S$ and $50-85^{\circ}S$ and propagate their standard errors to estimate 746 $40-85^{\circ}S$ SW_{FB}. The contribution of the SO clouds to the global mean SW_{FB} is con-747 strained to $-0.168 - 0.051 W m^{-2} K^{-1}$ with a 95% confidence interval (Figure 7). 748 Considering potential systematic error in observations of LWP shifts the constraint on 749 $40-85^{\circ}S SW_{FB}$ to $-0.192 - 0.047 W m^{-2} K^{-1}$. The constrained range of SO SW_{FB} 750 is a bit wider than the range reported by McCoy et al. (2022), but we have added a new 751 constraint from the $40-50^{\circ}S$ latitude band and have taken into account the uncertainty 752 in radiative susceptibility arising from different α_{cs} thresholds and potential systematic 753 uncertainties in observed LWP. Our constraint suggests that $40 - 85^{\circ}S SW_{FB}$ is less 754 likely to be extremely negative or positive, as simulated by some CMIP6 GCMs. The 755 most likely range of the SO SW_{FB} is from moderately negative to weakly positive. 756

4 Conclusions 757

801

In this work we built a CCF regression model to predict the response of the SO (40-758 $85^{\circ}S$) LWP to global warming. The CCFs considered in the regression model were sur-759 face skin temperature, precipitation minus evaporation (approximately the moisture con-760 vergence), lower-tropospheric stability, and 500 mb subsidence. Warm and cold clouds 761 are regulated by very different microphysical processes and have different responses to 762 warming. To allow our CCF regression model to adapt to this, we partitioned the SO 763 into cold and warm regimes. This new method increases the robustness of the CCF model 764 prediction compared to previous work (McCoy et al., 2022). We used two out-of-sample 765 tests to evaluate the predictive ability of our CCF regression model: the ability of our 766 CCF model trained on observations to replicate the observed decadal trend in SO LWP 767 (section 3.1.1; Figure 2) and the ability of our CCF model trained on the mean-state out-768 put of GCMs to predict their response to CO_2 quadrupling (section 3.1.2; Figure 3). Us-769 ing the CCF regression model trained on observations combined with the GCM simu-770 lated changes in CCFs in response to CO_2 quadrupling, we were able to provide an ob-771 servational constraint on the change in LWP in response to GMT ($\Delta LWP/\Delta GMT$) of 772 2.76 - 4.19 $gm^{-2}K^{-1}$ (Figure 3b). 773

Ultimately, the quantity we care about in relation to Earth's radiation budget is 774 not cloudiness, but radiative flux. We define a radiative susceptibility to liquid cloud $(\partial \alpha / \partial LWP)$ 775 that we can use to scale the LWP changes in response to warming. We compute $\partial \alpha / \partial LWP$ 776 from satellite observations and GCM output. The observational constraint suggests that 777 most of the GCMs overestimate $\partial \alpha / \partial LWP$ (Figure 5), which is consistent with recent 778 studies of tropical clouds (Konsta et al., 2022). Satellite observations estimate $\partial \alpha / \partial LWP$ 779 to be 0.43 - 0.90 $(kq m^{-2})^{-1}$. 780

GCMs with higher mean-state LWP tend to have lower $\partial \alpha / \partial LWP$ (Figure 5)- re-781 sulting in compensation between macrophysical changes in cloud and radiative impact. 782 This feature can be connected to the sensitivity of LWP to moisture convergence $(\partial LWP/\partial P - E)$. 783 GCMs with higher $\partial LWP/\partial P - E$ simulate higher mean-state LWP. These GCMs tend 784 to predict a larger LWP response ($\Delta LWP / \Delta GMT$) but have a lower $\partial \alpha / \partial LWP$ due 785 to radiative saturation. 786

Approximating SO SW_{FB} as the product of $\partial \alpha / \partial LWP$ and $\Delta LWP / \Delta GMT$ pre-787 dicts roughly 50% of the variance in SO SW_{FB} across 50 CMIP5 and CMIP6 GCMs (Ta-788 ble S1) calculated from radiative kernels (Zelinka, Myers, McCoy, Po-Chedley, et al., 2020) (Figure 6). Observational constraints on $\Delta LWP/\Delta GMT$ and $\partial \alpha/\partial LWP$ produce a con-790 strained range on SO SW_{FB} of -0.168 to $0.051 Wm^{-2}K^{-1}$ (95% confidence interval) 791 (Figure 7), which suggests a moderate negative to weakly positive SO SW_{FB} . This is 792 consistent with previous work (McCoy et al., 2022), but expands the constraint region 793 to the entire SO as opposed to just constraining the region where GCMs consistently moisten 794 and more fully accounts for observational uncertainty. 795

Our analysis suggests some directions of future studies seeking to constrain extra-796 tropical SW_{FB} : 797

- 1. Our analysis identified increased moisture convergence into the SO as a key driver 798 of increased LWP. This mechanism ultimately links the global circulation and hy-799 drological cycle to the extratropical SW_{FB} . To better understand this linkage, it 800 would be useful to understand how Hadley cell expansion and transient eddies (i.e. atmospheric rivers) contribute to long-term variability of the SO moisture bud-802 get. 803
- 2. Due to the lack of microwave observations of LWP over ice, we cannot provide an 804 observationally-constrained CCF model for the cold regime. In this study, the GCM 805 relationship between the warm regime LWP response and the response averaged 806 over the latitude band including both cold and warm regimes provides an estimate 807

808	including uncertainty related to the cold regime. Ground-based LWP observations
809	in high latitude SO, such as those taken during the Atmospheric Radiation Mea-
810	surement (ARM) West Antarctic Radiation Experiment (AWARE, Lubin et al.
811	(2020)), may be able to provide an observational constraint on the cold regime LWP
812	response.
813	3. We found that $\partial \alpha / \partial LWP$ varied dramatically across GCMs and strongly mod-
814	ulated the effect of changes in LWP on radiation. We also found that observations
815	suggested that GCMs tended to have a $\partial \alpha / \partial LWP$ that was too large. One pos-

sibility is that this is due to clouds that are too uniform and radiatively efficient (Konsta et al., 2022; Nam et al., 2012). Determining the origin of this behavior might be helpful in identifying a potential source of GCM bias in SW_{FB} .

⁸¹⁹ 5 Open Research

GCM outputs used in this study are available from Earth System Grid Federation 820 (ESGF) esgf-node.llnl.gov (Cinquini et al., 2014)[Data]. The code for calculating the full 821 shortwave cloud feedback data from GCM output is documented and published in (Zelinka, 822 Myers, McCoy, Po-Chedley, et al., 2020) [Software] and at github.com/mzelinka. MAC-823 LWP and MERRA-2 reanalysis data are available from the Goddard Earth Sciences Data 824 and Information Services Center at disc.gsfc.nasa.gov (Elsaesser et al., 2017a; Gelaro, 825 McCarty, Suárez, et al., 2017) [Data]. CERES EBAF Edition 4.1 data is available from 826 ceres.larc.nasa.gov (Loeb et al., 2018a) [Data]. 827

828 Acknowledgments

The efforts of CT, DTM, and GSE are supported under NASA-PMMST Grant #80NSSC22K0599. 829 GSE acknowledges additional support from the NASA Modeling, Analysis and Predic-830 tion Program and APAM GISS Co-Op #80NSSC18M0133. We thank Dr. Mark Zelinka 831 for sharing his shortwave cloud feedback map data for all the GCMs included in this study. 832 We appreciate the World Climate Research Programme (WCRP) for their promoting 833 and coordinating efforts of CMIP. We also thank all modeling groups for producing and 834 publishing their model output. We thank the Earth System Grid Federation (ESGF) for 835 archiving and providing useful accessing tools to all model output, and the multiple fund-836 ing agencies that support CMIP5/6 and ESGF. We would like to acknowledge the use 837 of computational resources (doi:10.5065/D6RX99HX) at the NCAR-Wyoming Super-838 computing Center provided by the National Science Foundation and the State of Wyoming, 839 and supported by NCAR's Computational and Information Systems Laboratory. 840

Figure 1. (a) Extratropical SW cloud feedback (SW_{FB}) (top) and the response of liquid water path (LWP) to global-mean temperature (GMT) ($\Delta LWP/\Delta GMT$) in the GCMs in Table S1. Anomalies in LWP and GMT are calculated as the differences between the mean of *piControl* and year 121 - 140's mean of *abrupt4xCO*₂ simulations. Thick black lines are the multi-model mean and the shaded regions correspond to the 25th-75th percentiles of quantities. (b) Annualmean anomalies in Southern Ocean (40 - 85°S) averaged LWP versus GMT relative to *piControl* average for the first 150 years of *abrupt4xCO*₂ simulations. Lines show the second-order polynomial fit of the annual-mean LWP responses to GMT for each GCM. Lines for each GCM in (a) and (b) are colored by model effective climate sensitivity (ECS) and the 40 - 85° averaged SW_{FB} , respectively. SW cloud feedback and effective climate sensitivity (ECS) data are from Zelinka, Myers, McCoy, Po-Chedley, et al. (2020). -19-

Prediction of Observed LWP

Figure 2. (a) Observed annual-mean Southern Ocean averaged LWP from MAC-LWP (green) and LWP predicted by the CCF model (Equation 2; blue) from 1992 to 2016. The CCF model is trained on monthly-mean data from 2012 to 2016 (right side of the dashed line) and is used to predict the annual-mean LWP back to 1992. (b) The decomposition of annual-mean LWP anomalies into individual CCF contributions by equation 2.

Figure 3. Predictions of the GCM-simulated LWP response to CO_2 quadrupling $(\Delta LWP/\Delta GMT)$ by Equation 3. $\Delta LWP/\Delta GMT$ is shown averaged over (a,b) $40 - 85^{\circ}S$, (c,d) $40 - 50^{\circ}S$, and (e,f): $50 - 85^{\circ}S$. (a,c,e) Latitude-averaged $\Delta LWP/\Delta GMT$ predicted by equation 3 in warm and cold regimes versus only in the warm regime. (b,d,f) Latitude-averaged $\Delta LWP/\Delta GMT$ simulated by GCMs versus $\Delta LWP/\Delta GMT$ predicted by equation 3 in both regimes. 1-1 lines are shown using dashed gray lines and best-fit lines are shown as solid red and brown lines with their uncertainties estimated by Jackknife resampling. Observational constraints (red shading) are shown in (a,c,e). This constraint is propagated from the warm regime $\Delta LWP/\Delta GMT$ to the $\Delta LWP/\Delta GMT$ in both regimes by taking the intersection between the red shading and the best-fit line with its uncertainty (red dashed lines). Constraints on $\Delta LWP/\Delta GMT$ in both regimes are then shown in (b,d,f) using brown shading. The constrained ranges are combined with the uncertainty in the CCF model prediction by using the best-fit line between GCM and CCF model predictions to yield an observational constraint on GCM-simulated $\Delta LWP/\Delta GMT$ (brown dashed lines). Explained variance (r^2) is shown in each subplot. GCMs are denoted with the number listed in Table S1.

Decomposition on LWP Response $\left(\frac{\Delta LWP}{\Delta GMT}\right)$

Figure 4. Decomposition of $\Delta LWP/\Delta GMT$ predicted by Equation 3: (a) Sensitivities of LWP each CCF; (b) standardized change in each CCF per degree warming; (c) LWP changes due to each CCF (the product of (a) with (b)), their sum (sky blue box), and the GCM-simulated LWP response (gray box). Cold and Warm regime values are shown separately. The variance (r^2) of GCM-simulated $\Delta LWP/\Delta GMT$ explained by the CCF model predictions in each regime is shown in subplot (c). Changes in CCFs are normalized by their spatio-temporal standard deviations of each regime in the mean-state climate. We single out one GCM, CESM2, by denoting its values as orange diamonds. All other GCMs are denoted as light blue dots. Observational sensitivities are denoted as red triangles in the warm regime.

Figure 5. The radiative susceptibility $(\partial \alpha / \partial LWP$, left axis) and the sensitivity of LWP to moisture convergence $(\partial LWP / \partial P - E, \text{ right axis})$ in the warm (pink) and cold (blue) regimes as a function of regime mean-state (*piControl*) LWP. Observed $\partial LWP / \partial P - E$ and $\partial \alpha / \partial LWP$ are shown by the pink and green triangles (observational $\partial LWP / \partial P - E$ is comparable to the warm regime values of GCMs for reason discussed in sections 2.1 and 2.2.3). The linear fit between $\partial LWP / \partial P - E$ and *piControl* LWP in each regime and the power law fit between $\partial \alpha / \partial LWP$ and *piControl* LWP are shown. Uncertainty in $\partial \alpha / \partial LWP$ from varying the maximum clear-sky albedo $TR_{\alpha_{cs}}$ from 0.11 to 0.30 is shown as an uncertainty range.

Constraint on Shortwave Cloud Feedback (SW_{FB})

Figure 6. The SW cloud feedback of GCMs listed in Table S1 from Zelinka, Myers, McCoy, Po-Chedley, et al. (2020) for $40 - 50^{\circ}S$ (red) and $50 - 85^{\circ}S$ (blue) latitude bands versus predictions from the simplified physical model developed in this study (Equation 1). The observational constraints on $40 - 50^{\circ}S$ and $50 - 85^{\circ}S$ the constrained ranges on the y-axis of Figure 3 (d) and (f). The observational constraint on radiative susceptibilities ($\partial \alpha / \partial LWP$) is the error range of the green triangle in Figure 5. The combination of these two constraints yields constraints on $40 - 50^{\circ}S$ and $50 - 85^{\circ}S$ SW_{FB}, shown as shaded regions along the x-axis. Constrained $40 - 50^{\circ}S$ and $50 - 85^{\circ}S$ SW_{FB} are the extents of y-coordinate of models within the shaded regions. The linear fit between model SW_{FB} and predictions from equation 1 are shown with their 95% confidence interval.

Figure 7. The contribution of Southern Ocean (40 - 85°S) SW_{FB} to the global mean cloud feedback. The prior distribution of SW_{FB} for GCMs listed in Table S1 is shown as the blue histograms and black kernel density estimate. The dashed black line denotes the multimodel mean of SW_{FB} for 50 GCMs. Red shading shows the 95% confidence interval of the Southern Ocean (40 - 85°S) averaged SW_{FB} by combining the constrained 40 - 50°S and 50 - 85°S averaged SW_{FB} shown in Figure 6. Observational constraint suggests a moderate negative to weak positive Southern Ocean SW_{FB} .
