Abstract

Representing single or multi-layered mixed-phase clouds (MPCs) accurately in global climate models (GCMs) is critical for capturing climate sensitivity and Arctic amplification. Ice multiplication, or secondary ice production (SIP), can increase the ice crystal number concentration (ICNC) in MPCs by several orders of magnitude, affecting cloud properties and processes. Here, we propose a machine-learning approach, called Random Forest SIP (RaFSIP), to parameterize the effect of SIP on stratiform MPCs. The RaFSIP scheme uses few input variables available in models and considers rime splintering, ice-ice collisional break-up, and droplet-shattering, operating at temperatures between 0 and -25 @C. The training dataset for RaFSIP was derived from two-year pan-Arctic simulations with the Weather Research and Forecasting (WRF) model with explicit representations of SIP processes. The RaFSIP scheme was evaluated offline against WRF simulation outputs, then integrated within WRF. The parameterization exhibits stable performance over a simulation year, and reproduced predictions of ICNC with explicit microphysics to within a factor of 3. The coupled WRF-RaFSIP scheme can replicate regions of enhanced SIP and accurately map ICNCs and liquid water content, particularly at temperatures above -10 @C. Uncertainties related to the RaFSIP representation of MPCs marginally affected surface cloud radiative forcing in the Arctic, with radiative biases of lower than 3 Wm-2 compared to simulations with explicit SIP microphysics. Training from a few high-resolution model grid points did not limit the predictive skill of RaFSIP, with the approach opening up new avenues for model simplification and process description in GCMs by physics-guided machine learning algorithms.

12

Key Points:

- A random-forest parameterization for secondary ice production is developed using outputs from a high-resolution regional climate simulation.

- The scheme produces tendencies of ice multiplication comparable to the high resolution model with explicit microphysics.

- The scheme can be adjusted to coarse resolutions typical of climate models without loss of computational efficiency and numerical stability.

20

21 **Abstract**

22 Representing single or multi-layered mixed-phase clouds (MPCs) accurately in global climate
23 models (GCMs) is critical for capturing climate sensitivity and Arctic amplification. Ice
24 multiplication, or secondary ice production (SIP), can increase the ice crystal number
25 concentration (ICNC) in MPCs by several orders of magnitude, affecting cloud properties and
26 processes. Here, we propose a machine-learning approach, called Random Forest SIP (RaFSIP),
27 to parameterize the effect of SIP on stratiform MPCs. The RaFSIP scheme uses few input
28 variables available in models and considers rime splintering, ice-ice collisional break-up, and
29 droplet-shattering, operating at temperatures between 0 and -25 ˚C. The training dataset for
30 RaFSIP was derived from two-year pan-Arctic simulations with the Weather Research and
31 Forecasting (WRF) model with explicit representations of SIP processes. The RaFSIP scheme
32 was evaluated offline against WRF simulation outputs, then integrated within WRF. The
33 parameterization exhibits stable performance over a simulation year, and reproduced predictions
34 of ICNC with explicit microphysics to within a factor of 3. The coupled WRF-RaFSIP scheme
35 can replicate regions of enhanced SIP and accurately map ICNCs and liquid water content,
36 particularly at temperatures above -10 ˚C. Uncertainties related to the RaFSIP representation of
37 MPCs marginally affected surface cloud radiative forcing in the Arctic, with radiative biases of
38 lower than 3 Wm^{-2} compared to simulations with explicit SIP microphysics. Training from a few
39 high-resolution model grid points did not limit the predictive skill of RaFSIP, with the approach
40 opening up new avenues for model simplification and process description in GCMs by physics-
41 guided machine learning algorithms.

42

43 **Plain Language Summary**

44 Being able to correctly simulate the amount of ice and liquid in clouds is essential for accurate
45 predictions of the cloud radiative forcing in the climatologically-sensitive polar regions. A
46 number of collisional processes between ice and liquid particles in clouds, known as secondary
47 ice production, can significantly enhance the ice crystal number concentrations contained in
48 them. This enhancement is often accompanied by a decrease in the number and mass of liquid
49 cloud droplets, resulting in less opaque clouds to incoming solar radiation, which, in turn, can
50 cause a cloud-induced warming at the surface. Currently most global climate models are missing
51 the description of the most important secondary ice production processes, which can lead to a
52 biased radiative impact of clouds at the surface. To address this, we propose using a machine
53 learning algorithm trained on high-resolution model outputs to include the effect of ice
54 multiplication in large-scale climate models. The machine learning framework effectively
55 captures the physical processes underlying secondary ice production in stratiform clouds using
56 only a few inputs readily available in model frameworks. This approach has the potential to
57 improve model outputs and bring them closer to the observed cloud phase partitioning.

58

59 **1 Introduction**

60   In the big data and machine learning era, general circulation models (GCMs) remain an
61 indispensable tool for predicting how the Earth system will respond to rising greenhouse gas
62 concentrations (Balaji et al., 2022; Irrgang et al., 2021). GCMs typically represent atmospheric
63 processes with a horizontal grid spacing of about 50-100 km. However, at this coarse resolution,

64 small-scale processes, such as those associated with clouds, cannot often be explicitly resolved.
65 These complex subgrid scale processes interact with the resolved model scales only through
66 parameterizations tuned in a way to improve the agreement with theory or observations (Hourdin
67 et al., 2017). Parameterization schemes are a necessary but non-trivial part of climate modeling,
68 introducing uncertainties in future climate projections. These uncertainties frequently result in
69 persistent model biases, especially over climatically sensitive regions of the world, such as the
70 Arctic (Sledd & L'Ecuyer, 2021; Tan & Storelvmo, 2019) and the Southern Ocean
71 (Schuddeboom & McDonald, 2021; Vergara-Temprado et al., 2018).

72 Machine learning (ML)-based parameterizations are a promising and computationally
73 efficient approach increasingly used in climate science to replace, supplement or speed up
74 conventional parameterizations (e.g., Brenowitz & Bretherton, 2019; Gentine et al., 2018;
75 Grundner et al., 2022; Han et al., 2020; Mooers et al., 2021). ML parameterizations are
76 sometimes developed based on high-resolution three-dimensional (3D) simulations, in which
77 subgrid processes are either explicitly resolved (Brenowitz & Bretherton, 2018; Yuval et al.,
78 2021; Yuval & O'Gorman, 2020) or parameterized using conventional schemes (Grundner et al.,
79 2022; O'Gorman & Dwyer, 2018). In this approach, high-resolution data is often coarse-grained
80 to match the lower spatial resolution of the GCM grid (e.g., Brenowitz & Bretherton, 2019).
81 Advances in both computational tools and data assimilation methods have now allowed for
82 global observations to be integrated into ML training datasets (Schneider et al., 2017), yet
83 limitations concerning the limited spatiotemporal coverage of observational data still need to be
84 addressed (Irrgang et al., 2021).

85 Neural networks (NNs) and random forests (RFs) are two ML methods that have been
86 used for developing parameterizations for GCMs. RF – an ensemble learning algorithm
87 consisting of multiple decision trees – ensures the preservation of physical properties by taking
88 the average predictions of subsets of the training samples (Breiman, 2001). This conservative
89 behavior leads to more stable simulations when coupled with GCMs compared to NNs (Han et
90 al., 2020; O'Gorman & Dwyer, 2018), which can deviate from the training data pool. Notably,
91 RF parameterizations have demonstrated successful emulation of conventional convective
92 schemes in GCMs (O'Gorman & Dwyer, 2018). Yuval and O'Gorman (2020) applied RF
93 parameterization using coarse-grained, high-resolution outputs from an idealized simulation,
94 achieving effective replication of climate patterns across different grid spacings. In contrast, NN
95 parameterizations, although requiring less memory in GCMs, can introduce numerical
96 instabilities and result in model runaway or climate drift (Rasp et al., 2018; Brenowitz &
97 Bretherton, 2018, 2019). To ensure stable long-term simulations, post-prediction adjustments and
98 accurate processing of the training dataset are necessary (Rasp, 2020; Yuval et al., 2021). While
99 offline comparisons favored NN parameterizations, both RF and NN algorithms satisfied
100 physical constraints (energy conservation and non-negative surface precipitation) and
101 demonstrated comparable performance when coupled with the dynamical core of a coarse-
102 resolution aqua-planet GCM (Yuval et al., 2021). Additionally, RFs and NNs showed similar
103 performance in predicting the probability density function of surface solar irradiance under 3D
104 cumulus clouds (Gristey et al., 2020).

105 Parameterizations of cloud microphysical processes and aerosol-cloud interactions are
106 perhaps one of the most challenging aspects of climate simulations (e.g., Liu et al., 2023; Hugh
107 Morrison et al., 2020). They are also computationally expensive because they require a large
108 amount of information to be carried around in simulations (e.g., cloud microphysical and aerosol

109   quantities and their interactions) and the parameterizations themselves also may require
110   considerable computational effort. Few studies to date try to simplify cloud microphysical
111   processes using ML-based approaches, focusing on warm cloud microphysical processes. For
112   instance, Seifert & Rasp (2020) employed a Monte Carlo superdroplet simulation to train neural
113   network (NN) models for parameterizing autoconversion, accretion, and self-collection rates in
114   two-moment schemes. Chiu et al. (2021) developed NN-based parameterizations for
115   autoconversion and accretion rates, incorporating in-situ observations of droplet size
116   distributions and employing the stochastic collection equation with bin microphysics to
117   separately account for cloud and drizzle water contents. Although these ML approaches were
118   evaluated offline, Gettelman et al. (2021) successfully replaced the computationally expensive
119   bin microphysical scheme used in a GCM with ML emulators to predict autoconversion and
120   accretion tendencies, achieving comparable accuracy with reduced computational costs.
121   However, there remains a research gap regarding ML parameterizations specifically tailored to
122   represent cold cloud microphysics.

123   This study focuses on developing an RF-based approach for parameterizing secondary ice
124   production (SIP) in stratiform mixed-phase clouds (MPCs) which are prevalent in polar regions
125   (de Boer et al., 2009; Shupe et al., 2006), sustained by a complex interplay of microphysics,
126   dynamics, radiatively-driven turbulence, as well as surface heat and moisture fluxes (Morrison et
127   al., 2012). Misrepresentation of the mid- and high-latitude MPCs in GCMs has been shown to
128   increase the spread of predicted cloud feedbacks in the recent Climate Model Intercomparison
129   Project (phase 6 – CMIP6; Murray et al., 2021; Zelinka et al., 2020). Furthermore, the ice and
130   liquid phase partitioning in GCMs can significantly impact Arctic amplification, highlighting the
131   necessity of revisiting the microphysical parameterizations associated with Arctic MPCs (Tan &
132   Storelvmo, 2019).

133   Ice multiplication, also known as SIP, can be an important source of ice particles in
134   MPCs, as it can rapidly increase the pre-existing ice crystal number concentrations (ICNCs)
135   through a number of collisional processes (Field et al., 2017; Korolev & Leisner, 2020). The
136   most frequently acknowledged SIP mechanism is the Hallett-Mossop (HM; Choularton et al.,
137   1980; Hallett & Mossop, 1974), ice-ice collisional break-up (BR; Takahashi et al., 1995;
138   Vardiman, 1978) and droplet-shattering (DS; Choularton et al., 1980; James et al., 2021;
139   Kleinheins et al., 2021). Observations of MPCs in the Arctic region have shown high
140   concentration of ICNCs that greatly surpass ice nucleating particle (INP) concentrations (Wex et
141   al., 2019), particularly at temperatures above -25 ˚C (Luke et al., 2021; Pasquier et al., 2022;
142   Rangno & Hobbs, 2001; Schwarzenboeck et al., 2009). This suggests that SIP must be a
143   prevalent process in the moderately cold polar conditions.

144   Along with observations, modeling studies across scales have also emphasized the
145   significance of incorporating SIP parameterizations in regional and global climate model
146   simulations for an accurate representation of the phase partitioning and radiative properties of
147   Arctic MPCs (e.g., Fridlind & Ackerman, 2019; Sotiropoulou et al. 2020; 2021; Zhao et al. 2021;
148   Zhao and Liu 2021; 2022). Recent physically-based SIP parameterizations tested in GCMs were
149   developed by pooling experimental observations and further considering the physics of collisions
150   or applying correction factors to account for the simplified laboratory setups (Phillips et al.,
151   2017; 2018). These advanced SIP formulations require that the host model explicitly describes a
152   number of ice (cloud ice, snow and graupel) and liquid species (cloud droplets and raindrops) as
153   well as interactions among them (i.e., aggregation, collection and riming). Zhao et al. (2021) and

154 Zhao & Liu (2022) developed a hybrid-bin framework for improved representation of SIP, but
155 this approach can be computationally expensive (Sotiropoulou et al., 2022).

156   Here we propose a new approach towards parameterizing SIP in stratiform MPCs, which
157 we call the RaFSIP (Random Forest SIP) parameterization. RaFSIP is derived from
158 comprehensive model output from mesoscale model simulations that account for all three SIP
159 processes: HM, BR and DS. Following this, the effect of SIP is expressed either directly by
160 predicting the corresponding SIP rates or through the use of the ice-enhancement factor (IEF),
161 which is a multiplication factor applied to primary ice crystals. To account for the effects of SIP
162 for a wide range of stratiform conditions, the RaFSIP parameterization is trained using key
163 thermodynamic and microphysical variables to facilitate its implementation in most models with
164 double-moment representations of ice hydrometeors.

165

2 Data and Methods

167   The reference simulation used to develop the RF framework is derived from the
168 mesoscale Weather Research and Forecasting (WRF) model. The WRF outputs from the target
169 simulation were used to train two different versions of the RaFSIP parameterization: the first
170 version of the parameterization predicts the effect of SIP through the use of a multiplication
171 factor applied to the primary ice production rates (hereafter denoted as RaFSIPv1), while the
172 second version is trained to predict directly the production rates of secondarily formed ice
173 particles (hereafter referred to as RaFSIPv2). The workflow followed to develop each
174 parameterization is summarized in Figure 1.

175   2.1 WRF regional climate simulations

176   The target simulation was generated using WRF version 4.0.1, including augmented
177 cloud microphysics that considers the effects of BR and DS mechanisms introduced by
178 Sotiropoulou, Vignon, et al. (2021) and Georgakaki et al. (2022), in addition to the default HM
179 parameterization. A regional climate configuration was employed (Abdelwares et al., 2018),
180 where a 50-km resolution parent domain covering the Arctic region contains a single-way nested
181 domain of 10-km resolution. Figure 1 shows the map of the two domains centered over Ny-
182 Ålesund using a polar-stereographic projection, that is suitable for high-latitude WRF domains.
183 The outermost domain consists of 148×148 grid points, while the innermost one contains
184 301×301 grids. In the hybrid terrain-following mass coordinate system adopted by WRF, we
185 used 40 vertical levels up to a model top of 50 hPa (i.e., ∼20 km), with the standard grid spacing
186 generated automatically by WRF.

187   The initial and lateral boundary conditions are taken from the fifth generation of the
188 European Centre for Medium-Range Weather Forecasts (ECMWF) atmospheric reanalyses
189 dataset (ERA5; Hersbach et al., 2020), with a 31-km horizontal grid spacing. The lateral forcing
190 at the edge of the parent domain was updated every 6 h. To ensure realistic synoptic dynamics in
191 the model and allow for a comparison between in situ observations and simulations, the outer
192 domain of WRF has been nudged toward ERA5 reanalysis for zonal and meridional wind speed,
193 with a relaxation time scale of 6 h. Static fields come from default WRF pre-processing system
194 datasets with a resolution of 30'' for both the topography and land use fields. The WRF physics
195 options include the Rapid Radiative Transfer Model for General Circulation Models (RRTMG)
196 radiation scheme to parameterize both the shortwave and longwave spectra, the local Mellor-

197   Yamada-Nakanishi-Niino Level 2.5 (MYNN; Nakanishi & Niino, 2006) scheme with its
198   associated surface layer scheme for the planetary boundary layer (PBL) processes representation,
199   the Noah land surface model (Noah LSM; Chen & Dudhia, 2001) for surface options, and the
200   Kain–Fritsch cumulus parameterization, which was activated in both domains.

201   Cloud microphysics is treated using the scheme of Morrison et al. (2005) (hereafter
202   M05), which represents raindrops, cloud ice, snow and graupel particles with a double-moment
203   approach. However, a single-moment approach is used for cloud droplets, which requires
204   predefining a constant number concentration. For this study, we assumed that an average cloud
205   droplet number concentration of 100 cm^{-3} is suitable for Arctic clouds (e.g., McCoy et al., 2020;
206   Young et al., 2016). Regarding ice formation processes, M05 includes parameterizations for
207   homogeneous freezing at temperatures below -40 ˚C, as well as heterogeneous ice nucleation
208   initiated below -4 ˚C. The latter accounts for immersion freezing of cloud droplets and raindrops
209   (Bigg, 1953), contact freezing (Meyers et al., 1992) and condensation/deposition freezing
210   nucleation (Cooper, 1986), all of which are dependent only on temperature.

211   In the standard M05 code there is only one SIP mechanism described – the HM process –
212   which is activated after cloud droplets or raindrops rime onto snow or graupel particles within a
213   specific temperature range between -8 and -3 ˚C (Cotton et al., 1986). The activation of this
214   process depends on preset thresholds concerning the minimum mass mixing ratios of the
215   involved ice and liquid species that are found to limit its efficiency and were removed (Atlas et
216   al., 2020; Karalis et al., 2022; Young et al., 2019).

217   A detailed description of the BR implementation in M05 is provided in Sotiropoulou,
218   Vignon, et al. (2021). The default M05 code was updated to include all possible collisional
219   interactions among the three ice hydrometeor species (see their Appendix B). The number of
220   fragments produced is parameterized as a function of the ice particle size, habit, degree of riming
221   as well as the collisional kinetic energy, following Phillips et al. (2017). Two types of collisions
222   were considered: those involving only high-density precipitating ice particles (such as graupel),
223   and those involving collisions of rimed snow or cloud ice particles with any ice species. The
224   rimed fraction and ice habit were used only in the formulation describing the latter type of
225   collisions, but they were not explicitly resolved in the M05 scheme. BR was enabled only when
226   there was a nonzero rimed mass of either raindrop or cloud droplet onto the ice particle that
227   would undergo fragmentation. A rimed fraction of 0.4 was prescribed, based on previous studies
228   that showed better agreement with observations in polar clouds (Sotiropoulou et al., 2020;
229   Sotiropoulou, Vignon, et al., 2021). Regarding the ice habit, we assumed planar ice particles, as
230   they capture a wider range of conditions in terms of temperature and particle shapes compared to
231   dendritic ice crystals. Sotiropoulou, Ickes, et al. (2021) suggested that the absence of a thorough
232   handling of ice habit and rimed fraction in most bulk microphysics schemes does not seem to
233   significantly impact the depiction of BR in polar conditions. All secondary ice fragments
234   produced by the BR mechanism are added to the cloud ice category.

235   Georgakaki et al. (2022) described the implementation of the DS mechanism in the M05
236   scheme of WRF. We considered two collision modes that can cause the freezing and subsequent
237   shattering of large raindrops, as described by Phillips et al. (2018). The first mode, or 'mode 1',
238   occurs when a supercooled raindrop collides with a less massive cloud ice particle or when an
239   INP initiates freezing in immersion mode. Freezing probability is set to unity and zero for
240   temperatures below -6°C and above -3°C, respectively, with intermediate values in between. The
241   shattering probability depends on raindrop size, being 0 for sizes smaller than 50 μm, 1 for sizes

242 larger than 60 μm, and varying for sizes in between. The second mode, or 'mode 2', involves
243 collisions between raindrops and larger ice particles such as snow or graupel (James et al., 2021),
244 producing only tiny ice fragments that are passed to the cloud ice category. Big fragments are
245 treated as either graupel, snow, or frozen drop depending on the type of collision that initiated
246 the raindrop freezing process.

247   The regional climate set-up (Figure 1) with augmented cloud microphysics was employed
248 to run a reference WRF simulation for two years from 2016 to 2017, preceded by a 1-week spin-
249 up period starting on December 25, 2015. This time frame was considered sufficient to capture
250 the possible parameter space in the atmospheric state. High-resolution three-dimensional
251 snapshots of the simulation with a 10-km resolution domain (the area bounded by the dashed
252 lines in Figure 1), were saved every 3 h. These snapshots formed the basis for developing the
253 ML parameterization, which will be described in the following section.

254

255

256 **Figure 1.** Schematic diagram of the methodology followed to develop the two versions of the
257 RaFSIP parameterization. The map on the left shows the two WRF domains used to simulate the
258 two-year period required for training the RaFSIP parameterization. The rectangular region
259 marked by the purple dashed lines delimit the 10-km resolution domain, while colors indicate
260 terrain heights (left axis) and sea ice concentration (right axis). The 4 triangles represent the
261 regions from where the training dataset is extracted. The two-year high-resolution model output
262 is split into ~85% training dataset (20 months) and ~15% testing dataset (4 months). The
263 RaFSIPv1 (RaFSIPv2) parameterization is trained to predict the IEF (SIP_{rate}) as well as the
264 transfer of mass from cloud droplets (Qc_{tr}) or raindrops (Qr_{tr}) to cloud ice due to SIP. The
265 snapshot corresponds to the monthly average of January, 2016.

266

267   2.2 Random forest (RaFSIP) parameterization development

268   RaFSIP is based on a random forest regressor (RFR) algorithm, which is a supervised
269 ML technique, consisting of an ensemble of decision trees (Breiman, 2001) trained directly from

270 the outputs of the high-resolution WRF simulation. To minimize variance, each decision tree is
271 trained on a random subset of the training data and a random subset of the inputs – also called as
272 features – of that data. The RFR prediction is calculated by averaging over the individual
273 decision trees, which reduces the risk of overfitting and improves generalization performance
274 compared to a single decision tree. RFR can capture non-linear relationships between input
275 features and output variables and is proficient at interpolation. However, it cannot extrapolate
276 due to its predictions being averages over subsamples of the training dataset. This helps ensure
277 that a RF-based parameterization will be robust when coupled with a model in an online setting,
278 such as in our case.
279

280   2.2.1 Description of the two parameterization approaches

281   Depending on the prevailing temperature and the presence of rime onto ice particles, we
282 expect different SIP processes to be activated. This is the reason why the two versions of the
283 RaFSIP parameterization consist of a number of RFR models, each one of them being
284 responsible for predicting the effect of SIP as dictated by the thermodynamic and microphysical
285 state describing every model timestep. The RFR models consisting the RaFSIPv1
286 parameterization, are trained to predict the so-called IEF, which is the ratio between the
287 production rate of secondary ice particles from each SIP process (HM_{rate}, BR_{rate} and DS_{rate}), and
288 primary ice particles via heterogeneous freezing of cloud droplets (PIP_{rate}). Hence, RaFSIPv1
289 provides 3 predictions: IEF_{HM}, IEF_{BR}, and IEF_{DS}, the contribution of which can be added to yield
290 the total IEF: IEF $= SIP_{rate}/PIP_{rate}$. The notation of IEF is frequently employed in the
291 literature as an indication of the prevalence of SIP, in both observational (e.g., Korolev et al.,
292 2022; Wieder et al., 2022) and modeling studies (e.g., Waman et al., 2022; Zhao et al., 2023).

293   In RaFSIPv2, the RFR models predict directly the three SIP rates – HM_{rate}, BR_{rate} and
294 DS_{rate} (in kg^{-1} s^{-1}), derived from the high-resolution WRF results. The three rates are combined to
295 determine the total SIP_{rate}. As the HM and DS processes move mass from the liquid to the ice
296 species when active (albeit from the rimed liquid particles in the former case), both versions of
297 the RaFSIP parameterization are trained to predict Qc_{tr} and Qr_{tr} (in kg kg^{-1} s^{-1}) corresponding to
298 the mass transferred from the cloud droplets and raindrops to the cloud ice category,
299 respectively. Therefore, the two versions of the RaFSIP parameterization can provide up to five
300 different predictions, given certain SIP conditions are met.

301   Here, we consider two main temperature regimes: -8 ≤ T< -3 °C (HM zone) and -25 ≤ T<
302 -8 °C, which is essential as the HM mechanism can only be effective within the former one. By
303 combining these temperature ranges with the presence or absence of mass production rate of
304 raindrops collected by ice particles (RIMR in kg kg^{-1} s^{-1}), we obtain 4 different RFR models that
305 are used in both versions of the RaFSIP parameterization (Table 1 and 2). Two models can be
306 activated in the HM zone, namely "forestALL" and "forestBRHM", that are replaced by the
307 "forestBRDS" and "forestBR" at lower temperatures (the suffix of the model name denotes the
308 SIP processes in action). The final selection of which forest to use in the corresponding
309 temperature range is based on the presence of a nonzero RIMR at the current timestep, which is
310 the criterion used to identify the cases where DS might be taking place. The two forests that take
311 into account the effect of DS are the forestALL and forestBRDS models.

312   Both RaFSIP parameterizations incorporate SIP through BR and DS at temperatures as
313 low as -25°C, which is supported by recent observational findings (Korolev et al., 2022; Pasquier

314   et al., 2022; Wieder et al., 2022). Approaching warmer subzero temperatures (T > -4 °C),
315   RaFSIPv1 does not predict ice enhancement, since heterogeneous freezing of cloud droplets (i.e.,
316   the denominator in the IEF expression) does not occur in the M05 scheme (Section 2.1). In
317   contrast, RaFSIPv2 can still account for the effect of SIP as it is not directly linked to the PIP_{rate}.
318   An additional RFR model called "forestBRwarm" is therefore used in RaFSIPv2 (Table 2), to
319   calculate the BR_{rate} at temperatures between -3 ≤ T ≤ 0 °C. At these warm subzero temperatures,
320   DS is also proposed to contribute to SIP through recirculation (Korolev et al., 2020), but only in
321   tropical or midlatitude frontal systems (Lauber et al., 2021) owing to strong convective turbulent
322   updrafts that are rare in polar stratiform clouds. Therefore, RaFSIPv2 considers that only the BR
323   mechanism initiated by collisions of seeding rimed ice particles can be efficient at temperatures
324   above -3 °C.
325

326   2.2.2 Features and training dataset

327   Both versions of the RaFSIP parameterization share the same input features. The ambient
328   temperature (T in K), total ice water content (IWC in kg kg^{-1}), liquid water content (LWC in kg
329   kg^{-1}), relative humidity with respect to ice (RHi) and mass production rate of cloud droplets
330   rimed onto ice particles (RIMC in kg kg^{-1} s^{-1}) are among the features that have been used in all
331   RFR models of the two versions of the parameterization. Since DS requires the presence of large
332   raindrops, RIMR is also used as input to the models accounting for its effect (i.e., forestALL and
333   forestBRDS). With these 6 inputs we seek to effectively capture all range of cloud states that can
334   initiate and drive ice multiplication. The training dataset was constrained to scenarios with
335   substantial liquid water content (LWC>10^{-5} gm^{-3}), accompanied by nonzero riming tendencies,
336   to ensure the effectiveness of SIP. The 6 inputs are chosen in a way to simplify the detailed SIP
337   formulations (e.g., Phillips et al., 2017; 2018), yet are expected to generate complex mappings
338   for training the RFR models. Here we use the instantaneous predictions of the model for all
339   individual vertical grid cells as inputs for all RFRs, rather than their vertical profiles (e.g.,
340   O'Gorman & Dwyer, 2018; Yuval & O'Gorman, 2020).

341   We generated the training dataset for all RFR models using the 3-hourly high-resolution
342   WRF results (Section 2.1), extracted from 2×2 grid cell regions (16 grid cells in total) indicated
343   by purple triangles in Figure 1. Half of these grid cells represented continental conditions, while
344   the other half were over the sea. The absence of a latitudinal preference in SIP rates between the
345   Northern and Southern hemispheres (Zhao & Liu, 2021) suggests that a limited number of grid
346   points from the 2-year high-resolution simulation of WRF is adequate for capturing the
347   thermodynamic and microphysical conditions associated with SIP events in stratiform
348   conditions. Note that horizontal and vertical coarse-graining is frequently applied when
349   developing ML parameterizations for GCMs based on high-resolution simulations (e.g.,
350   Brenowitz & Bretherton, 2019; Grundner et al., 2022; Yuval & O'Gorman, 2020). Indeed, the
351   impact of SIP can vary depending on the scale considered, with higher-resolution simulations
352   exhibiting greater SIP tendencies due to their ability to capture localized and enhanced SIP
353   events. Our goal is to investigate whether a SIP parameterization derived from a 10-km
354   resolution grid (innermost WRF domain) is effective at the coarser resolution of 50-km in the
355   parent domain of WRF, which is closer to the resolutions seen in GCMs. Given that the input
356   tendencies predicted by the coarser-resolution grids will be lower than the higher-resolution
357   ones, we expect that the resulting SIP tendencies will also be smoothed out. An important aspect
358   to consider also here is that the RFR models tend to underestimate extreme values and

359   overestimate low values (Zhang & Lu, 2012). This behavior arises from the fact that RFR
360   predictions are derived as averages of the predictions made by all decision trees within the
361   ensemble.

362   To prepare for training, each feature and output variable is normalized using the natural
363   logarithm, which is important given the range of several orders of magnitude they span (Figure
364   2). During the training process, we excluded IEF values below 10^{-1} and SIP rates below 10^{-5} kg^{-1}s^{-1}
365   (Figure 2). This was made because such values would not result in significant SIP, and we
366   aimed to reduce the range of predictions. The training dataset comprises 20 months of high-
367   resolution WRF results, representing approximately 85% of the data. The remaining 15% of the
368   data, consisting of 4 months (January, April, July, and October 2017), were used for testing the
369   offline performance of the RaFSIP parameterization (Section 3). The RandomForestRegressor
370   class from the scikit-learn package version 1.2.0 (Pedregosa et al., 2011) was used to train each
371   RFR model. All RFR models consisting the two RaFSIP parameterizations were stored as ASCII
372   files.

374   ### 2.2.3 Choice of hyperparameters

375   To improve the performance of the RFR models, different hyperparameters governing the
376   learning process can be tuned. The Mean Squared Error (MSE) resulting from the RFR
377   predictions was evaluated using 10-fold cross validation on the training dataset. We selected the
378   number of trees in each forest, the minimum samples per leaf node, and the number of training
379   samples as the three most important hyperparameters to tune. Figure S1 shows the validation
380   curves for the forestALL model (used in RaFSIPv2), which illustrate how the performance of the
381   model varies with different hyperparameter values. The final decision on hyperparameters
382   involves a trade-off between model complexity and runtime, with the latter being crucial for
383   optimizing online performance when coupled with the WRF model. We chose 10 trees in each
384   RFR, a minimum of 4 samples per leaf node, and 25,000 training samples for all RFR models, as
385   these produced comparable validation curves. Note that, for online applications of the RFR
386   models, it is common practice to use 10 decision trees to ensure computational efficiency
387   (O'Gorman & Dwyer, 2018; Yuval & O'Gorman, 2020). The offline performance of the RaFSIP
388   parameterizations will be discussed in Section 3, followed by the online performance in Section
389   4.

391   ### 2.3 Implementation of RaFSIP parameterization in WRF

392   To implement the RaFSIP parameterization in WRF, a Fortran 90 module is developed to
393   read and store the parameters for building the RFR models. The ASCII files are only read during
394   the first model timestep and all forest parameters are passed as public variables into the
395   microphysics code. Within the M05 microphysics routine, the RaFSIP parameterization replaces
396   the three detailed inline SIP parameterizations (Section 2.1), taking the fields of T, RHi, LWC,
397   IWC as well as RIMC and RIMR as inputs to make predictions. Calculations for LWC and IWC,
398   consider contributions from all liquid (cloud droplet and raindrops) and ice (cloud ice, snow and
399   graupel) species. RIMC and RIMR encompass all possible ways in which cloud droplets or
400   raindrops are collected by frozen particles in the M05 scheme: (i) droplet/raindrop-cloud ice, (ii)
401   droplet/raindrop-snow, and (iii) droplet/raindrop-graupel. At each model timestep and grid cell,

402 if certain requirements are met (discussed in Section 2.2.1), a different RFR model may be
403 activated to represent the effect of single or combined SIP processes.

404 At the end of each model timestep, the RaFSIP parameterization calculates the total
405 SIP_{rate} (in kg^{-1} s^{-1}) either directly or through the use of the IEF, depending on the chosen version.
406 In RaFSIPv1, the SIP_{rate} is obtained by multiplying the number tendency of heterogeneously
407 frozen cloud droplets (in kg^{-1} s^{-1}) by the total IEF. However, this approach has a significant
408 caveat: SIP cannot be accounted for unless a nonzero PIP_{rate} is predicted by the model.
409 Therefore, RaFSIPv1 can only be used at temperatures colder than -4 °C, where PIP is initiated
410 in the model. To ensure that the final SIP_{rate} does not exceed a certain threshold, an upper limit
411 of 100 particles kg^{-1} s^{-1} was applied, corresponding to the highest simulated value in the training
412 dataset. Although our results were not sensitive to the choice of this upper limit, it may be an
413 important consideration for the implementation of RaFSIPv1 in other microphysical schemes
414 employed by different models. The SIP_{rate} predicted by RaFSIPv1 is then added to the cloud ice
415 number concentration conservation equation. The RaFSIPv2 parameterization follows a similar
416 approach to RaFSIPv1, but does not link SIP_{rate} to the instantaneous PIP_{rate}. This direct
417 prediction is enabled by the RFR models, allowing for RaFSIPv2 to be applicable over a wider
418 temperature range from 0 °C to -25 °C, without requiring a nonzero PIP_{rate}.

419 When HM and/or DS mechanisms are active, the transported masses Qc_{tr} and Qr_{tr} are
420 subtracted from their respective cloud categories and added to the conservation equation for
421 cloud ice mass mixing ratio. It is important to note that the transferred liquid masses involved in
422 SIP were initially part of the rimed masses constituting the RIMC and RIMR quantities. Without
423 SIP, these masses would have been transported to the mass conservation equation of the
424 corresponding rimed ice particles. To avoid double-counting the transferred masses of liquid
425 water, Qc_{tr} and Qr_{tr} should also be removed from the riming tendencies of the involved ice
426 species. To account for this, we subtract the transferred masses from the term with the biggest
427 contribution; given that the terms participating in RIMC and RIMR can vary by several orders of
428 magnitude, this approach ensures that the simulations will not be subject to significant bias.

429 To evaluate the online performance of the new RaFSIP parameterizations when coupled
430 with the WRF model, we conducted a one-year simulation using the same set-up depicted in
431 Figure 1 (Section 2.1). This simulation covers the period between September 2019 and August
432 2020, which is more than 1.5 years after the training period, with one additional week of spin-up
433 starting from August 25, 2019. The testing simulation was conducted three times. First, we
434 carried out the "CONTROL" simulation, which does not take into account any SIP process.
435 Then, we performed the "ALLSIP" simulation, which includes all the detailed inline
436 parameterizations of SIP outlined in Section 2.1. Finally, the "RaFSIP" simulation refers to the
437 one where the RaFSIP parameterizations replaced the detailed SIP descriptions. By comparing
438 the results of the ALLSIP simulation with those of the RaFSIP simulation in Section 4, we seek
439 to examine the robustness of the new SIP parameterizations in terms of computational efficiency
440 and result quality.
441

3 Offline performance of RaFSIP parameterizations and feature importance

443 To evaluate the performance of both RaFSIP parameterizations, each RFR model was
444 tested on the 4-month dataset that was not used during training (Section 2.2.2). The performance
445 was assessed using two metrics summarized in Tables 1 and 2: Root-Mean-Square Error

446   (RMSE) and coefficient of determination (R^2), which were calculated based on the normalized
447   output variables. R^2 is defined as one minus the ratio of the sum of squared errors to the true
448   variance. The offline performance of the forestALL model, which is used by both RaFSIP
449   parameterizations when all conditions for SIP processes are met, is shown in Figure 2. For the
450   rest of the RFR models, the offline performance is displayed in Figures S2 to S5, in the
451   Supporting Information.
452

453

Figure 2. Normalized histograms (i.e., frequency is scaled by the total number of predictions) of
the true WRF results versus the forestALL predictions used in (top panel) RaFSIPv1
parameterization to predict the IEF due to (a) BR, (b) HM, (c) DS, and the transferred masses
from (d) cloud droplets (Qc_{tr}) and (e) raindrops (Qr_{tr}) to cloud ice, and (bottom panel) RaFSIPv2
parameterization to predict the SIP rate due to (f) BR, (g) HM, (h) DS, and the transferred
masses (i) Qc_{tr} and (j) Qr_{tr}. The black line represents the one-to-one line.

460

461   All five outputs of the forestALL model present a wide range of values (Figure 2),
462   making accurate prediction challenging. For instance, IEF_{BR} and IEF_{HM} vary from 10^{-1} to 10^{11},
463   while IEF_{DS} is confined below $\sim10^8$, with predictions more spread out along the 1:1 line,
464   especially at lower values. The RaFSIPv1 parameterization predicts an inverse relationship
465   between IEF and PIP_{rate} (not shown), primarily due to the PIP_{rate} being in the denominator of the
466   IEF expression. The competing relationship between SIP and PIP has also been highlighted in
467   previous modeling studies (e.g., Georgakaki et al., 2022; Zhao & Liu, 2022), as an outcome of
468   the enhanced ice nucleation leading to more glaciated MPCs with fewer precipitating particles
469   such as rain or graupel. Note that the predicted IEF values are higher than those frequently
470   reported in the literature (e.g., Waman et al., 2022; Zhao et al., 2023), as they are extracted from
471   the ratio of tendencies rather than integrated particle concentrations. Similar trends are observed
472   in the SIP rates predicted by RaFSIPv2 (Figure 2f, g, h), with the BR and HM processes again
473   proving more efficient at producing SIP particles compared to DS.

474   Although RaFSIPv1 and RaFSIPv2 use the same predictors, the former is limited to cases
475 where PIP_{rate} is nonzero, resulting in noticeable differences among the two approaches. To
476 evaluate the relevance of each input feature in the predictions made by the RFR models, we
477 employed the permutation importance metric (Figure S6 to S10) from the
478 RandomForestRegressor class of scikit-learn. This metric estimates feature importance by
479 randomly permuting its values and measuring the consequent decrease in model performance.
480 This approach can capture the effect of both linear and nonlinear relationships between features
481 and target variables, and can also help identify any potential overfitting issues in the RFR
482 models. Note that here we used the negative RMSE as the scoring parameter and normalized the
483 resulting variable importance by dividing by the maximum value among features.

484   The most significant features in the predictions made by all RFR models are the riming
485 tendencies and the IWC. Specifically, inside the HM zone, RIMC has the highest permutation
486 importance score for the forestALL (Figure S6) and forestBRHM (Figure S7) models employed
487 in both RaFSIP versions. The two mass tendencies, RIMC and RIMR, are explicitly used as
488 inputs in the detailed parameterized expression of HM in the default M05 scheme (Section 2.1).
489 Outside the HM zone, where BR can lead to larger IEF or SIP_{rate} compared to DS, IWC becomes
490 the more important feature for the predictions of the RFR models, particularly for forestBR
491 (Figure S9) and forestBRwarm (Figure S10), with the amount of (rimed) cloud droplets
492 becoming the second most important feature. The increase in IWC, associated with ice
493 sedimenting from higher-level clouds, is frequently found to drive the BR process (Georgakaki et
494 al., 2022; Järvinen et al., 2022; Pasquier et al., 2022; Ramelli et al., 2021; Sotiropoulou, Vignon,
495 et al., 2021).

496
497

Table 1.
Root-Mean-Square Error (RMSE) of the output variables predicted by the RaFSIPv1 parameterization, along with the corresponding coefficient of determination (R^2) values in parentheses.

RaFSIPv1 model	Conditions		Predictions				
	Temperature	RIMR	IEF_{BR}	IEF_{HM}	IEF_{DS}	Qc_{tr}	Qr_{tr}
forestALL	-8≤T<-3°C	>0	0.32 (0.97)	0.36 (0.94)	0.46 (0.86)	0.17 (0.99)	0.26 (0.93)
forestBRHM	-8≤T<-3°C	=0	0.37 (0.98)	0.12 (0.98)	–	0.09 (0.99)	–
forestBRDS	-25≤T<-8°C	>0	0.31 (0.97)	–	0.38 (0.87)	–	0.39 (0.83)
forestBR	-25≤T<-8°C	=0	0.44 (0.97)	–	–	–	–

498

499   Using the different RFR models depending on the prevailing thermodynamic and
500 microphysical conditions allowed us to evaluate the performance of the RaFSIP
501 parameterizations under various scenarios. The distribution of all RFR predictions against true
502 values, as shown in Figure 2 and Figures S2 to S5, indicates that predictions with a higher
503 relative frequency of occurrence are closer to the 1:1 line for both RaFSIP approaches. The

504 statistical metrics presented in Tables 1 and 2 can differ significantly depending on the prevailing
505 conditions and the SIP processes involved. The RMSE for RaFSIPv1 predictions varied from
506 ~10-45%, while for RaFSIPv2, it ranged between ~15-40%. The transferred masses due to SIP,
507 Qc_{tr} and Qr_{tr}, are generally well-predicted in most of the RFR models with an RMSE of less than
508 30%, despite spanning more than 10 orders of magnitude.

509 In cases where multiple SIP processes are present, the prediction error tends to be higher
510 for DS, as shown in Figures 2c and 2h and reflected in the higher RMSE values in Tables 1 and
511 2. To improve the offline accuracy of the forestALL and forestBRDS models for predicting this
512 SIP mechanism, we tested the inclusion of the size of raindrops undergoing DS as a potentially
513 important predictor. The resulting RMSE metrics showed a ~5% decrease in the forestBRDS
514 model, while the forestALL model remained unaffected (not shown). However, since the total
515 effect of SIP is cumulative and DS is the least significant mechanism compared to the other two,
516 any errors associated with its uncertain representation are not likely to significantly impact the
517 online performance of the RaFSIP parameterizations. Therefore, we argue that adding more
518 predictors may not be worth the increased model complexity.
519

Table 2.
Root-Mean-Square Error (RMSE) of the output variables predicted by the RaFSIPv2
parameterization, along with the corresponding coefficient of determination (R^2)
values in parentheses.

RaFSIPv2 model	Conditions		Predictions				
	Temperature	RIMR	IEF_{BR}	IEF_{HM}	IEF_{DS}	Qc_{tr}	Qr_{tr}
forestALL	-8≤T<-3°C	>0	0.23 (0.96)	0.22 (0.93)	0.36 (0.87)	0.16 (0.99)	0.21 (0.94)
forestBRHM	-8≤T<-3°C	=0	0.34 (0.96)	0.36 (0.90)	–	0.18 (0.99)	–
forestBRDS	-25≤T<-8°C	>0	0.17 (0.97)	–	0.27 (0.89)	–	0.27 (0.89)
forestBR	-25≤T<-8°C	=0	0.28 (0.96)	–	–	–	–
forestBRwarm	0≤T≤-3°C	=0	0.38 (0.96)	–	–	–	–

520

521 When only BR is active, either in the colder (i.e., forestBR) or warmer (i.e.,
522 forestBRwarm) temperature regime, the RMSE scores range between ~30-45% (Tables 1 and 2).
523 This could indicate and important input feature related to BR may be missing or that the
524 relationship between the input features and the target variable (IEF_{BR} or BR_{rate}) is inherently
525 difficult to model accurately due to the level of non-linearity. In the physically-based
526 parameterization by Phillips et al. (2017), the SIP fragments generated after BR depend on
527 collisional kinetic energy, which is an uncertain parameter as it is a function of the difference in
528 terminal velocities of colliding ice particles. The latter follows a fall-speed-diameter relationship,
529 the parameters of which are highly uncertain and can directly impact both the precipitation rates
530 and the SIP efficiency (Karalis et al., 2022). Therefore, we chose not to include collisional
531 kinetic energy in our set of predictors, as it would increase model complexity without necessarily

532 improving accuracy. The predictors we chose strike a good balance between model complexity
533 and accuracy, allowing us to describe SIP occurrence as a function of simplified inputs that most
534 GCMs can predict.
535

4 Coupling the RaFSIP parameterization with WRF

537 In this section, we aim to assess the performance of the parameterization when coupled
538 back with the dynamical core of the WRF model, making fast and precise predictions at runtime.
539 To facilitate the discussion, in the rest of the paper we will focus on the results of the RaFSIPv2
540 parameterization, while the corresponding RaFSIPv1 results will be available in the Supporting
541 Information. RaFSIPv2 can predict SIP rates directly, making it less coupled with the WRF
542 model on which it was trained. In contrast, the approach followed in RaFSIPv1 tends to be more
543 dependent on the PIP rates predicted by each model, implying that its good online performance
544 in WRF may not be guaranteed in other models using different PIP schemes.

545 When introducing the RaFSIP parameterization into the M05 scheme of WRF, two main
546 concerns had to be addressed in order to ensure the robustness of the approach: model stability
547 and computational efficiency. The stability of the model was tested during the one-year test
548 simulation starting from September 2019 until August 2020 (Section 2.1). The coupled WRF
549 model with the RaFSIP parameterization ran stably across a wide range of conditions. Regarding
550 computational efficiency, the new parameterization performed comparably to the inline SIP
551 parameterizations without increasing computational demands. This implies that the RaFSIP
552 scheme can be easily incorporated into existing models without significant impact on runtime,
553 being a result of carefully selecting the number of trees in the RFR models. In the following
554 discussion all results will be divided into four groups according to season.

4.1. Horizontal distribution of ice crystal number concentrations

556 Latitude-longitude snapshots of the median ICNCs obtained from the instantaneous 3-
557 hourly outputs of the CONTROL, ALLSIP, and RaFSIP experiments (Section 2.3), along with
558 the resulting R^2 between the predictions of the latter two, provide a way to assess the quality of
559 the WRF predictions when coupled with the RaFSIPv2 parameterization (Figure 3). Note that the
560 modeled ICNCs include the contribution of all three ice species (cloud ice, snow and graupel).
561 To calculate the median ICNCs presented in Figure 3 we considered only the in-cloud conditions
562 represented by ICNCs $> 10^{-5}$ L^{-1} and temperatures between -25 and 0 °C, which is the range
563 where RaFSIPv2 can be active. For calculating the median values and R^2 scores, we went
564 through each latitude and longitude reshaping the remaining two dimensions (time and height).
565 To facilitate the identification of patches where RaFSIPv2 performs favorably in terms of R^2, we
566 further coarse-grained the information from the coarse-resolution grid mesh by dividing the
567 original grid into non-overlapping 3×3 sub-grids, and computing the average value of each sub-
568 grid. Thus the R^2 map in Figure 3 is projected onto a 49×49 mesh.

569 The RaFSIPv2 parameterization coupled with WRF can skillfully predict the median
570 horizontal distribution of ICNCs, closely following the pattern produced by the ALLSIP
571 simulation with the detailed SIP descriptions. Darker blue shades are produced by ALLSIP and
572 RaFSIP indicating the higher median ICNCs compared to CONTROL. The increase in median
573 ICNCs is observed for all four seasons, even though it is more prevalent during winter and
574 spring, particularly in the sea region between Greenland and Canada to the west and extending to

575   the north of the Scandinavian Peninsula to the east. In these areas the median seasonal ICNCs
576   can exceed 10 L^{-1}, suggesting the significant role of ice multiplication processes in elevating the
577   median ICNCs by up to an order of magnitude when SIP conditions are met.

578   Despite being trained on a small subset of high-resolution WRF grid cells, the RaFSIPv2
579   parameterization can generalize and accurately predict the locations of ice enhancement in the
580   coarser resolution domain as dictated by the ALLSIP results. The R^2 maps superimposed in
581   Figure 3 reveal patches of especially high predictive skill denoted with R^2 scores exceeding 90%.
582   The accuracy of the predictions largely exceeds 80% of R^2 over localized areas of significant ice
583   enhancement, shown with darker shades on Figure 3g and 3k. This implies the ability of
584   RaFSIPv2 to reproduce the physical processes occurring in polar MPCs. However, the southeast
585   part of Greenland poses a challenge for accurate model predictions, with R^2 dropping below
586   60%, especially in winter.
587

Figure 3. Latitude-longitude maps of the median ICNC simulated by the (a, d, g, j) CONTROL,
(b, e, h, k) ALLSIP, and (c, f, i, l) RaFSIP simulations, along with the corresponding (d, h, l, p)
R^2 computed between ALLSIP and RaFSIPv2 results. Statistics are calculated for the 4 simulated
seasons: fall (top panel), winter (second panel), spring (third panel) and summer (bottom panel).

594   Compared to other seasons, the predictive skill of RaFSIPv2 is reduced during summer,
595   with R^2 dropping below 40% in very localized regions close to the edges of the WRF domain.

Higher temperatures are not likely the cause of lower R^2 values, as the RaFSIPv2 models were trained using a wide range of temperatures and temperature was not found to be among the most important input features for the predictions of the RFR models (Figures S6-S10). A possible explanation could be that during summer the expected shift towards warmer clouds may lead to increased riming tendencies, which can be associated with higher SIP rates in RaFSIPv2. Replacing the RaFSIPv2 parameterization with the RaFSIPv1 in WRF, results in a further decline in the predictive skill in all four seasons, as shown in Figure S11. The R^2 scores decrease to below 60% in most regions with significant ice enhancement, with a further drop to below 40% during the summer months. The degradation in the performance of the model is most likely because of RaFSIPv1 requiring a nonzero value of PIP_{rate} to provide ice enhancement.

Table 3 presents median statistics extracted from all three sensitivity experiments during the cold (autumn and winter) and warm (spring and summer) seasons. The latitudinal zones north of 70°N are divided into three groups, and the results are grouped into two distinct temperature ranges (-10≤T≤0˚C and -20≤T<-10˚C) where SIP effects are more prevalent. During the cold season, it is observed that the CONTROL simulation leads to higher median ICNCs in the warmer temperature regions compared to the colder one at latitudes 70-80˚N, which may seem contradictory since PIP efficiency generally increases with decreasing temperatures. This unexpected finding could potentially be explained by ice seeding from colder clouds enhancing the median ICNCs in lower-level warmer clouds at temperatures above -10˚C, or by increased efficiency of ice aggregation leading to significantly lower median ICNCs in the colder temperature range (-20≤T<-10˚C) (Barrett et al., 2019; Chellini et al., 2022).

The introduction of SIP in the WRF simulations results in a substantial increase in median ICNCs, particularly in the warmer temperature bin during the cold (warm) season, where ALLSIP and RaFSIP simulations show a factor of approximately 2-3 (3-6) higher ICNCs compared to the CONTROL simulation. On the other hand, in the colder temperature bin, the ICNC enhancement in ALLSIP and RaFSIP is relatively modest, reaching only up to ~20-25% during both examined seasons. It is worth noting that latitudes above 80°N display systematically lower ICNCs, with no significant contribution of SIP being observed at temperatures below -10°C, likely due to complete cloud glaciation. Overall, the median statistics derived from the WRF simulation coupled with the RaFSIPv2 parameterization are in good agreement with the ALLSIP simulation results during the cold and warm seasons examined here (Table 3).

To assess the agreement between our WRF results and satellite remote sensing data, we compare our median values from the 3 sensitivity experiments to the 10-year median values between 2006-2016 presented in (Papakonstantinou-Presvelou et al., 2022). Their study, which focused on low-level pure ice clouds, demonstrated that higher ICNCs are found over sea ice compared to open ocean, a finding contrary to previous expectations. To ensure comparability with Figure 1 of Papakonstantinou-Presvelou et al. (2022), we calculated the median ICNC statistics focusing on grid points over sea ice with a glaciation fraction exceeding 98% and a sea ice concentration higher than 50%. These are annotated as $ICNC_{si}$ in Table 3. The glaciation fraction was determined by calculating the ratio of modeled IWC to total water content (TWC = IWC + LWC).

In the glaciated clouds simulated between -10°C and 0°C, the contribution of SIP is crucial for bringing the modeled $ICNC_{si}$ closer to the 10-year median observed values (Figure 1 in Papakonstantinou-Presvelou et al., 2022). At these warmer subzero temperatures, both

641 ALLSIP and RaFSIP, enhance the median $ICNC_{si}$ by a factor of up to ~2 compared to the
642 CONTROL simulation of WRF during both seasons (Table 3). Note that glaciated conditions
643 prevent the effect of SIP from manifesting with higher enhancement factors. This is particularly
644 evident at temperatures below -10°C, where the efficiency of ALLSIP and RaFSIP in producing
645 SIP particles diminishes. At these temperatures, all three experiments underestimate the observed
646 median $ICNC_{si}$ levels (which reach up to ~3 or 4 L^{-1}) at all latitudes. The missing ice crystal
647 source in this temperature range may be primarily due to the representation of PIP in the model.

648
649

Table 3.
Median ICNC for different latitudinal zones, temperature ranges, and seasons, obtained from three different WRF experiments. The cold season values were extracted from September 2019 to February 2020, while the warm season values were obtained from March to August 2020. The values in all four columns represent the results from the CONTROL/ALLSIP/RaFSIP experiments. The subscript $ICNC_{si}$ indicates that the median ICNC is derived for glaciated clouds (glaciation fraction > 0.98) from model grid points over the sea-ice (sea-ice concentration > 50%).

Latitude	Temperature range (°C)	Median ICNC cold (L^{-1})	Median ICNC warm (L^{-1})	Median $ICNC_{si}$ cold (L^{-1})	Median $ICNC_{si}$ warm (L^{-1})
70-75°N	[-10,0]	1.9/4.6/4.5	0.2/0.6/0.6	4.0/7.5/7.6	3.2/5.8/5.7
	[-20,-10)	1.5/1.9/1.7	1.2/1.4/1.3	1.4/1.5/1.7	2.5/2.7/2.8
75-80°N	[-10,0]	1.8/4.1/4.2	0.1/0.5/0.6	4.0/6.2/6.5	2.9/5.0/4.9
	[-20,-10)	1.2/1.5/1.4	0.9/1.1/1.1	1.4/1.4/1.5	2.3/2.4/2.5
> 80°N	[-10,0]	0.4/1.1/1.3	0.09/0.3/0.5	2.5/3.8/4.1	2.0/4.2/4.1

650
651

652   4.2. Joint probability distributions of simulated cloud properties

653   Figure 4 illustrates the bivariate joint probability density function (PDF) of the median
654 ICNCs as a function of temperature and glaciation fraction. This figure aims to provide further
655 insight into the conditions where the RaFSIP parameterization is expected to perform better. The
656 statistics were derived using instantaneous 3-hourly results from the CONTROL, ALLSIP, and
657 RaFSIP sensitivity experiments (Section 2.3), focusing again on the in-cloud conditions
658 characterized by significant concentrations of ice crystals (ICNC > 10^{-5} L^{-1}), as well as ice and
659 liquid masses (IWC, LWC > 10^{-6} gm^{-3}).
660

661   4.2.1 Median ice crystal number concentration

662   Figure 4 reveals that the WRF model, coupled with the RaFSIPv2 parameterization, can
663   accurately capture the most prominent patterns of the median 2D-binned ICNCs in all four
664   seasons compared to the ALLSIP simulation with detailed inline microphysics. This is
665   particularly true for temperatures ranging from -8 to -3 °C and glaciation fraction below ~25-
666   30% or higher than ~80%. The turquoise bands in the lower right of the 2D-binned ICNCs
667   indicate the importance of SIP in relatively warm polar clouds. At these temperatures,
668   supercooled liquid water prevalent in simulated MPCs enhances riming tendencies (RIMC
669   and/or RIMR) and facilitates the action of SIP, resulting in modeled ICNCs up to an order of
670   magnitude higher in the ALLSIP and RaFSIP simulations, compared to the CONTROL
671   simulation. These findings align with the results of Arctic clouds presented by Sotiropoulou et al.
672   (2020), which reported a 10-20 fold increase in ice when both HM and BR were considered, with
673   the effectiveness of BR decreasing in moderately colder clouds (Sotiropoulou, Ickes, et al.,
674   2021).

675   At higher glaciation fractions (between ~25-80%) within the same temperature range, we
676   observe that the RaFSIPv2 simulation tends to overestimate the median ICNCs predicted by
677   ALLSIP. Indeed, from the normalized histograms of 2D-binned median ICNCs superimposed in
678   Figure 4, we can also infer that RaFSIPv2 predictions can be up to a factor of 3 higher than the
679   ALLSIP predictions, especially in the lower ICNC ranges (e.g., Figure 4d and 4h). In these
680   temperature conditions, only the forestALL and forestBRHM can be activated, with the latter
681   contributing presumably more due to the expected limited presence of large raindrops, which
682   prevents the frequent activation of the forestALL model. The permutation importance of
683   forestBRHM (Figure S7) suggests that RIMC and IWC are the two most important features for
684   the predictions of this model. If higher SIP rates are associated with higher IWC and, hence,
685   glaciation fraction, this could explain the slightly overestimated RaFSIPv2 predictions.

686   At temperatures below ~ -15 °C, where the relative contribution of PIP starts becoming
687   more important than SIP (Zhao et al., 2023), all three sensitivity experiments produce similar
688   ICNC patterns (Figure 4). The vertical zones of constant median ICNCs observed in all three
689   sensitivity simulations originate from the PIP scheme of WRF being dependent only on
690   temperature (Section 2.1). Nevertheless, reduced ICNCs are simulated during the summer
691   months in ALLSIP (Figure 4n) and RaFSIP (Figure 4o) simulations compared to CONTROL, for
692   clouds formed at temperatures below -18°C and glaciation fractions higher than 40% (upper right
693   part of Figures 4n and 4o). At such low temperatures, the competition between SIP and PIP may
694   limit the amount of water available or the distribution of ice crystals throughout the cloud, thus
695   limiting the ice crystals produced by SIP.

696   Focusing on the upper right corner of Figure 4, where the temperatures are between -5
697   and 0°C and the glaciation fraction exceeds 80%, we can observe higher ICNCs simulated by the
698   CONTROL simulation than the two experiments that include SIP parameterizations, especially
699   during Winter and Spring. At temperatures higher than -4°C, elevated ICNCs in the CONTROL
700   experiment can only be explained by ice sedimentation, where precipitating ice particles fall
701   from higher model grid cells. The implementation of SIP in the model can induce numerous ice
702   crystals – albeit with smaller sizes – in the overlying colder clouds or colder parts of the same
703   cloud (Georgakaki et al., 2022; Sotiropoulou et al., 2022). This shift in the ice particle size
704   distribution leads to smaller ice crystals leading to the reduced sedimentation rate of frozen
705   hydrometeors observed in the ALLSIP and RaFSIP simulations. This is further supported by the

706 joint PDF of the modeled IWC values (Figure S12), where both simulations accounting for SIP
707 result in comparable or even lower IWC values compared to the CONTROL simulation. This can
708 have important implications for the ice and liquid phase partitioning in polar MPCs, determining
709 their microphysical evolution and radiation properties (Curry et al., 1996; Tan & Storelvmo,
710 2019; Shaw et al., 2022). Overall, the RaFSIP simulation adequately reproduces the most
711 important features in the 2D-binned ICNCs (Figure 4) and IWC (Figure S12) modeled by the
712 ALLSIP simulation, indicating that the newly developed ML parameterization can replicate the
713 underlying physics of the simulation with the detailed SIP microphysics.
714

Figure 4. Bivariate joint PDF of median ICNC defined in terms of both temperature and glaciation fraction from the 50-km resolution domain results of the CONTROL (a, e, i, m), ALLSIP (b, f, j, n) and RaFSIPv2 (c, g, k, o) WRF simulations. The normalized histograms of the 2D-binned median ICNC results from the ALLSIP simulation are also plotted versus the

720   RaFSIPv2 predictions (d, h, l, p). The black line represents the one-to-one line, while the grey
721   dashed lines delimit the area where the ALLSIP values are over or under-estimated by a factor of
722   3. Statistics are calculated for the 4 simulated seasons: fall (top panel), winter (second panel),
723   spring (third panel) and summer (bottom panel).

724

725   Despite the lower R^2 scores in the horizontally averaged ICNCs (Figure S11), replacing
726   the RaFSIPv2 parameterization with RaFSIPv1 in the model leads to comparable results when
727   plotted in the joint temperature-glaciation fraction spectrum (Figure S13). However, the
728   distribution around the 1:1 line is more spread out, especially in spring and summer (Figure S13j
729   and S11p versus Figure 4j and 4p). The main difference between the two approaches is in the
730   very warm subzero temperatures (T>-4°C), where RaFSIPv1 disregards completely the effect of
731   SIP due to the zero PIP rates. As a result, the upper right part of the RaFSIPv1 ICNC distribution
732   is more comparable to the one produced by the CONTROL simulation rather than the ALLSIP
733   simulation (Figure S13).
734

735   *4.2.2 Median cloud liquid water content*

736   SIP often causes changes in modeled liquid cloud droplets due to increased number
737   concentrations of their frozen counterparts (e.g., Georgakaki et al., 2022; Zhao & Liu, 2021). In
738   addition to direct liquid-to-ice mass transitions caused through the HM and/or DS mechanisms,
739   the elevated concentrations of secondarily formed ice particles can further deplete the
740   surrounding liquid phase hydrometeors in MPCs after their initial growth through vapor
741   diffusion, through the action of the Wegener–Bergeron–Findeisen (WBF) or the riming
742   processes. It is therefore essential to investigate how SIP affects the joint PDF of LWC in the
743   ALLSIP simulation and whether the RaFSIP simulation can reproduce the results.

744   From the complex patterns of LWC produced (Figure 5), we can infer the non-linearity of
745   the microphysical interactions occurring in mixed-phase and ice clouds. The competition
746   between the two cloud phases is highlighted by the decreasing cloud LWC as the glaciation
747   fraction increases at a given temperature. The dark blue shades confined in the lower part of
748   Figure5, indicate a persistent supercooled liquid layer present in all three sensitivity simulations
749   at temperatures below ~ -4°C with a degree of glaciation below 20% in all seasons except
750   summer, where in the CONTROL simulation it extends up to almost 40% (Figure 5m). This
751   remark can be consistent with the typical structure of high-latitude MPCs, comprising single or
752   multiple stratiform layers of supercooled liquid water from which ice crystals form and
753   precipitate (e.g., Morrison et al., 2012; Shupe, 2011). Including SIP in the simulations slightly
754   restricts the extent of this liquid layer to lower glaciation fractions in both ALLSIP and RaFSIP,
755   most notably during the summer months.

756   At higher temperatures (>-4°C) and glaciation fraction (>80%), the CONTROL
757   simulation predicts higher LWC values in the region with the elevated ICNCs caused by more
758   frequent ice seeding events (i.e., upper right part of Figure 4a). The presence of more massive
759   precipitating ice particles, indicated by higher IWC values in this region (Figure S12a, e, I, m),
760   sediment quickly and constrains their ability to compete with supercooled liquid water for the
761   available water vapor. In the same region, the ALLSIP and RaFSIP simulations predict lower
762   contribution from both the liquid (Figure 5) and the ice hydrometeors (Figure 4 and S12).
763

Figure 5. Bivariate joint PDF of median LWC defined in terms of both temperature and glaciation fraction from the 50-km resolution domain results of the CONTROL (a, e, i, m), ALLSIP (b, f, j, n) and RaFSIPv2 (c, g, k, o) WRF simulations. The normalized histograms of the 2D-binned median LWC results from the ALLSIP simulation are also plotted versus the RaFSIPv2 predictions (d, h, l, p). The black line represents the one-to-one line, while the grey dashed lines delimit the area where the ALLSIP values are over or under-estimated by a factor of 3. Statistics are calculated for the 4 simulated seasons: fall (top panel), winter (second panel), spring (third panel) and summer (bottom panel).

By incorporating SIP into the WRF model, polar MPCs are produced with reduced LWC at temperatures above -15°C and glaciation fractions below 60%. In the CONTROL simulation, for instance, during fall and spring, a drop in the simulated LWC to ~10^{-4} gm^{-3} requires

777 temperatures around -8°C and glaciation fraction exceeding 60% (Figure 5a, i). However, in the
778 ALLSIP (Figure 5b, j) and RaFSIP (Figure 5c, k) simulations, such low LWC values can be
779 attained in clouds with a degree of glaciation as low as 40%. The regions of significant ice
780 enhancement in the ALLSIP and RaFSIP simulations (i.e., turquoise bands in Figure 4) do not
781 overlap with the regions of decreased LWC in Figure 5. This can be explained by the time
782 needed for small secondary ice particles to grow first through vapor diffusion until the vapor
783 pressure drops below saturation with respect to liquid water. As the glaciation fraction increases,
784 they can gain mass more efficiently at the expense of the surrounding evaporating cloud droplets
785 (WBF) or through their collection and subsequent freezing (i.e., riming). Both simulations
786 accounting for SIP show remarkable agreement in the location of the most significant ice
787 enhancement (Figure 4), followed by depletion of the mass of supercooled water (Figure 5).

788   At temperatures ≲-15°C, PIP can contribute significantly to the total ice crystal
789 production rates, leading to a further decrease in LWC through heterogeneous freezing. The
790 combination of heterogeneous freezing, WBF, riming and SIP likely controls the complex LWC
791 patterns observed between -20°C and -4°C. Despite the complexity of the simulated system, the
792 RaFSIP predictions align closely with the 1:1 line in the produced normalized histograms,
793 particularly during fall and winter (Figure 5d and 5h), indicating excellent agreement with the
794 ALLSIP simulation. These findings suggest that the RaFSIP parameterization can accurately
795 capture the cloud phase partitioning produced by the ALLSIP simulation, with an uncertainty of
796 up to a factor of 3. The LWC results from the RaFSIPv1 parameterization (Figure S14)
797 demonstrate that the use of the IEF for parameterizing the effects of SIP also has sufficient
798 predictive skill in WRF. The main difference lies again at warmer temperatures, where the
799 RaFSIPv1 results in slightly overestimated LWC compared to the ALLSIP predictions,
800 especially during fall and winter.
801

802   4.3. Cloud radiative forcing at the surface

803   The preceding discussion illustrates how SIP can significantly alter the number
804 concentration and size distribution of ice and liquid particles in polar MPCs. Such changes in the
805 macro- and microphysical properties of clouds are expected to impact the two most critical cloud
806 feedbacks associated with the polar regions: the cloud optical depth and the cloud-sea-ice
807 feedbacks (e.g., Goosse et al., 2018). For instance, changes in the albedo of MPCs resulting from
808 an increase in the amount of small liquid droplets contained in them can lead to enhanced
809 shortwave radiation reflected back to space and reduced warming at the surface (Murray et al.,
810 2021; Tan & Storelvmo, 2019). During the polar night, however, an increase in low-level cloud
811 coverage has been found to increase the longwave radiation emitted to the surface that is trapped
812 as heat due to the stable stratification conditions in the Arctic, ultimately resulting in surface
813 warming (Ebell et al., 2020; Kay et al., 2016). In this section, we aim to evaluate the
814 performance of the RaFSIP parameterization concerning the anomalies observed in the simulated
815 cloud radiative forcing at the surface (CRF_{surf}) with respect to the ALLSIP simulation (ΔCRF_{surf},
816 Figure 6). The calculations of CRF_{surf} and ΔCRF_{surf} are elaborated in supporting information of
817 Young et al. (2019), which also accounts for additional modifications in the shortwave fluxes to
818 account for the highly reflective Arctic surface (Vavrus, 2006).

819   Figure 6 illustrates the annual cycle of the cloud impact on the surface radiative energy
820 budget, with blue (red) shades indicating cloud-induced cooling (warming). The polar clouds

821 have a strong longwave greenhouse warming effect during the non-summer months, with the
822 maximum CRF_{surf} reaching up to ~40 Wm^{-2} and locally up to ~60 Wm^{-2} during fall and winter
823 (Figure 6a, b). Ground-based remote sensing observations collected at Ny-Ålesund over two
824 years (2016-2018) found positive monthly net CRF_{surf} between September and April/May, with a
825 mean longwave warming of ~50 Wm^{-2}, which is in line with our results (Ebell et al., 2020). In
826 contrast, during summer, the higher occurrence of liquid in the simulated polar clouds (Figure
827 5n) combined with the lower surface albedo leads to a strong cloud-induced cooling at the
828 surface by up to ~-100 Wm^{-2} (Figure 6d), again in agreement with Ebell et al. (2020). During
829 spring, the polar clouds have almost a neutral effect over the sea-ice and a slight cooling effect
830 over the open ocean in the lower latitudes (Figure 6c).

831 The anomalies in longwave and shortwave radiation are calculated by the mean
832 differences in the corresponding predictions between RaFSIP and ALLSIP, the combination of
833 which produced the final surface anomalies, ΔCRF_{surf} (Young et al., 2019). Note that the mean
834 ΔCRF_{surf}, is projected onto a 49 × 49 mesh by averaging over 3 × 3 sub-grids, similar to the
835 averaged maps shown in Figure 3. For the interpretation of ΔCRF_{surf}, the red (blue) colors
836 indicate that more (less) shortwave radiation is reaching the ground in the RaFSIP simulation,
837 which in turn implies the presence of more (less) glaciated clouds than in ALLSIP. Replacing the
838 detailed inline parameterizations of SIP in the M05 scheme with the new RaFSIP
839 parameterization can lead to CRF_{surf} biases between -2.5 and 2.5 Wm^{-2}, with a non-uniform
840 pattern across the model domain (Figures 6e-6h). Compared to the CRF_{surf} magnitudes illustrated
841 in Figure 6, such radiative biases can be considered negligible.

842

844 **Figure 6.** Latitude-longitude maps of (top panel): seasonally-averaged cloud radiative forcing at
845 the surface (CRF_{surf}) simulated by the ALLSIP simulation, and (bottom panel): anomalies with
846 respect to the ALLSIP simulation (ΔCRE_{surf}) derived from the WRF simulation coupled with the
847 RaFSIPv2 parameterization, extracted respectively for (a, e) fall, (b, f) winter, (c, g) spring and
848 (d, h) summer.

849

850   During summer, when ice enhancement from SIP is the strongest (Table 3), the largest
851 ΔCRF_{surf} values are largely observed over the sea-ice and ocean grid cells at latitudes higher than
852 70°N (Figure 6h). At this time, the RaFSIPv2 predictions of the ice (Figure 4p) and liquid
853 (Figure 5p) cloud phase partitioning can be biased by up to a factor of 3, leading to an
854 underestimation of the liquid-dominating clouds compared to ALLSIP, and consequently, an
855 excess of up to ~2.5 Wm^{-2} of shortwave radiation at the surface. However, in the continental and
856 ocean regions of lower latitudes, mostly negative CRF_{surf} biases are observed, indicating that
857 RaFSIPv2 is lacking some ICNCs compared to ALLSIP there. A similar ΔCRF_{surf} pattern
858 characterizes spring (Figure 6g), with the colors shifted towards lighter tones, indicating
859 relatively smaller radiative errors (between -1.5 and 1.5 Wm^{-2}). Fall exhibits a cooling effect
860 (down to -1 Wm^{-2}), with some localized areas of warming (~1 Wm^{-2}) spread around the WRF
861 domain (Figure 6e), while winter is the season with the minimum SIP contribution and the
862 smallest cloud radiative biases, confined mostly to the bottom part of the model domain (Figure
863 6f).

864   Figure S15 displays the outcome of the WRF simulations using RaFSIPv1 as a substitute
865 for the RaFSIPv2 parameterization. The obtained ΔCRF_{surf} ranges from -3 to 3 Wm^{-2}, indicating
866 slightly higher radiative biases in all seasons compared to the results shown in Figure 6. The
867 differences between the two SIP parameterizations are most significant in the warm season
868 (Figure S15g and h), where all the positive biases resulting from RaFSIPv2 are replaced by
869 negative ones. The most considerable negative bias appears in the sea area to the east of
870 Greenland (latitudes between 70-80°N), where ~3 Wm^{-2} less shortwave radiation reaches the
871 surface during summer (Figure S15h) compared to the ALLSIP simulation, indicating the
872 tendency of RaFSIPv1 to overestimate the amount of liquid hydrometeors in the summer MPCs.
873 Its reduced predictive ability to capture all the enhanced SIP events present in the ALLSIP
874 simulation stems mainly from the fact that it is limited by the presence of PIP, and hence it
875 cannot be activated for the whole range of conditions that would favor ice multiplication.
876

5 Summary and outlook

878   This study introduces a new ML-based framework aimed at representing the impact of
879 ice multiplication in stratiform MPCs within large-scale models. The new RF parameterization,
880 referred to as RaFSIP, is developed using two different approaches to describe the effect of SIP
881 at temperatures as low as -25°C. The first approach indirectly describes SIP through the use of an
882 ice multiplication factor applied to the primary ice production rates, while the second approach
883 directly predicts the SIP tendencies, providing a more explicit representation of the underlying
884 physical processes. RaFSIP is trained on two years of 10-km horizontal resolution WRF
885 simulations over the pan-Arctic region. We evaluate the parameterization both offline and online,
886 and demonstrate that RaFSIP can accurately predict tendencies of unresolved physics in the 50-
887 km horizontal resolution domain, comparable to the conventional SIP schemes. RaFSIP skillfully
888 captures how SIP affects the glaciation state and evolution of polar stratiform MPCs, predicting
889 their ice- and liquid-phase partitioning with an uncertainty of less than a factor of 3. Importantly,
890 RaFSIP exhibits only minor radiative biases, not exceeding ±3 Wm^{-2} at the climatologically-
891 sensitive Arctic surface. This implies that biases in the predicted SIP_{rate} or IEF (depending on the
892 version of RaFSIP used) do not translate into significant errors in simulated cloud microphysical
893 properties and cloud radiative forcing.

894 The intrinsic property of RF algorithms to make conservative predictions by averaging
895 over the predictions of the individual decision trees allowed the coupled WRF-RaFSIP scheme to
896 run efficiently and without instabilities for a year. The key advantage of our approach is that SIP
897 can be represented using inputs, such as temperature, ice- and liquid water content, riming
898 tendencies, and relative humidity with respect to ice, which are commonly predicted by most
899 models. This facilitates its integration in host models with horizontal grid spacings comparable to
900 or larger than the 10-km resolution grid used for training RaFSIP. This is crucial, as SIP can
901 significantly impact cloud evolution, rapidly glaciating them, altering precipitation and
902 eventually climate.

903 The incorporation of the RaFSIP framework in the microphysics scheme of 3 GCMs,
904 namely ECHAM-HAM, NorESM2, and EC-Earth, participating in the CMIP assessments is one
905 of the undergoing studies we are currently addressing (Ickes et al., 2023; Costa-Surós et al.,
906 2023). The modular nature of the new SIP parameterization allows for seamless integration with
907 the dynamical core of each GCM model, provided that the input features are well located inside
908 the stratiform cloud microphysics routine. Preliminary results indicate that utilizing grid-box
909 averaged atmospheric variables predicted by GCMs as inputs to the RaFSIP scheme, leads to
910 computationally efficient simulations without numerical instabilities or explosive SIP (not
911 shown). This model intercomparison project will evaluate the robustness of our approach as well
912 as any potential limitations.

913 As the RaFSIP scheme is trained on a wide range of stratiform conditions where SIP is
914 likely to occur, it can effectively capture the underlying mechanisms behind ice multiplication in
915 any type of single or multi-layered clouds in the polar regions. The limitations for our work stem
916 mostly from the fact that RaFSIP is trained based on regional simulations, and it therefore may
917 not be applicable for the entire globe (e.g., tropical marine or deep convective clouds). To
918 address this, the training dataset can be expanded by incorporating simulation results from
919 various locations worldwide where SIP is recognized (Hoose, 2022). Additionally, the dataset
920 can be augmented to include the description of other SIP processes, such as fragmentation during
921 ice particle sublimation under ice subsaturated cloudy conditions (e.g., Deshmukh et al., 2022).
922 Our study demonstrates that by leveraging a relatively small number of grid points from the
923 regional climate modeling framework, the training dataset can effectively encompass a broader
924 range of cases not covered in our initial analysis.

925 Finally, this study highlights the significant potential of ML techniques and high-
926 resolution data for the development of computationally efficient and accurate subgrid-scale
927 parameterizations of cloud microphysical processes, addressing the current gaps and limitations
928 in large-scale models. By integrating physics-guided ML algorithms and utilizing feature
929 importance metrics, we increase the transparency of the inner workings of these algorithms, even
930 if they are initially considered uninterpretable (Beucler et al., 2021; McGovern et al., 2019). This
931 is a promising pathway towards model simplification and improved process representation
932 within GCMs. Moving forward, further exploration and implementation of such techniques can
933 contribute to advancements in GCMs, ultimately leading to more robust and comprehensive
934 climate simulations.
935

Open Research

943   This manuscript uses the Weather Research and Forecasting model version 4.0.1, which can be

944   accessed at (https://github.com/wrf-model/WRF). The raw WRF outputs reach several terabytes

945   in size, and can be obtained upon request from the corresponding authors. The codes and training

946   dataset for the development of RaFSIP, along with the updated WRF microphysics routines and

947   result analysis, will be made publicly available at https://github.com/pgeorgakaki/RaFSIP upon

948   publication.
