#### Abstract

Four underwater glider missions were carried out to sample the physical and bio-optical properties inside a Loop Current Eddy (LCE) in the Gulf of Mexico (GoM), to investigate whether the winter deepening of the mixed-layer and erosion of the nitracline stimulates phytoplankton growth. Recent coupled physical-biogeochemical numerical models support this mechanism, but observations using Lagrangian floats suggest that there is no seasonal cycle on integrated phytoplankton biomass. Here, data collected by underwater gliders during a full seasonal cycle and inside the LCE Poseidon support the occurrence of a seasonal cycle, which is consistent with nutrient entrainment into the euphotic zone. The changes in fluorescence emission per chlorophyll-a unit and its implications for interpreting bio-optical variability were also assessed. Linear regressions between in vivo chlorophyll-a fluorescence and satellite chlorophyll-a concentration show the largest (smallest) slopes during winter (summer), suggesting a shift in the phytoplankton community along the year. Although the glider dataset is convolved by temporal and spatial variability, and chlorophyll-a fluorescence is affected by several factors, the concomitant enhancement of particle backscattering coefficient and chlorophyll-a observed during winter supports the occurrence of a seasonal cycle in phytoplankton biomass. Deep winter convection inside the core of the LCE, can promote fertilization through vertical diffusion of nutrients. Poseidon was an extraordinary, large, and strong, LCE that prompted phytoplankton blooms in winter highlighting their relevance for primary production and in general for biogeochemical processes.

#### 14 Abstract

Four underwater glider missions were carried out to sample the physical and bio-optical 15 properties inside a Loop Current Eddy (LCE) in the Gulf of Mexico (GoM), to inves-16 tigate whether the winter deepening of the mixed-layer and erosion of the nitracline stim-17 ulates phytoplankton growth. Recent coupled physical-biogeochemical numerical mod-18 els support this mechanism, but observations using Lagrangian floats suggest that there 19 is no seasonal cycle on integrated phytoplankton biomass. Here, data collected by un-20 derwater gliders during a full seasonal cycle and inside the LCE Poseidon support the 21 occurrence of a seasonal cycle, which is consistent with nutrient entrainment into the eu-22 photic zone. The changes in fluorescence emission per chlorophyll-a unit and its impli-23 cations for interpreting bio-optical variability were also assessed. Linear regressions be-24 tween *in vivo* chlorophyll-a fluorescence and satellite chlorophyll-a concentration show 25 the largest (smallest) slopes during winter (summer), suggesting a shift in the phytoplank-26 ton community along the year. Although the glider dataset is convolved by temporal and 27 spatial variability, and chlorophyll-a fluorescence is affected by several factors, the con-28 comitant enhancement of particle backscattering coefficient and chlorophyll-a observed 29 during winter supports the occurrence of a seasonal cycle in phytoplankton biomass. Deep 30 winter convection inside the core of the LCE, can promote fertilization through verti-31 cal diffusion of nutrients. Poseidon was an extraordinary, large, and strong, LCE that 32 prompted phytoplankton blooms in winter highlighting their relevance for primary pro-33 duction and in general for biogeochemical processes. 34

#### <sup>35</sup> Plain Language Summary

Recent technological advancements have revolutionized our ability to monitor changes 36 in the primary producers of the sea. Specialized robots are nowadays capable of mea-37 suring bio-optical properties, such as chlorophyll-a fluorescence and the particle backscat-38 tering coefficient even during severe climate conditions. However, interpreting chlorophyll-39 a fluorescence measurements can be challenging, as they are influenced by multiple fac-40 tors, including phytoplankton community shifts, and nutritional status. Here, we used 41 data acquired by remotely controlled platforms to track a large coherent rotating oceanic 42 eddy as it propagated westward through the Gulf of Mexico. Near the center of the eddy, 43 the upper 170 meters of the water column were mixed thoroughly by strong winds dur-44 ing winter, redistributing particles from deeper layers towards the upper ones including 45 nutrients required for phytoplankton growth. The dataset revealed a correlation between 46 the strong winter mixing and an increase in both, the chlorophyll-a concentration and 47 particle backscattering. Therefore, nutrient injection stimulated phytoplankton growth 48 during winter. We also found that fluorescence per chlorophyll-a concentration changes 49 dramatically during the year, presumably because the types of phytoplankton shift along 50 the seasons. Observed high-frequency phytoplankton response to winds in this dataset 51 is still to be analyzed and will be the basis for future work. 52

#### 53 1 Introduction

Seasonal variability of wind speed and turbulent heat fluxes at the sea surface mod-54 ulate the Mixed Layer Depth (MLD), which ultimately plays a key role in regulating the 55 light and nutrient availability for the phytoplankton (Mann & Lazier, 2006). According 56 to Sverdrup's hypothesis, the critical depth is a horizon defining the maximum depth that 57 the MLD can reach before causing a light limitation for a net phytoplankton population 58 growth. For example, in the North Atlantic and some regions of the Mediterranean Sea, 59 winter convection deepens the mixed layer down to the depth of the nitracline, promot-60 ing nutrient injection into the euphotic zone. Eventually, the MLD becomes deeper than 61 critical depth, reducing the light availability, and delaying the onset of the phytoplank-62

ton bloom until the spring, when the MLD restratifies (Sverdrup, 1953; Lavigne et al., 2013; Mignot et al., 2018).

The phenology of phytoplankton blooms can differ from the classical North Atlantic 65 bloom. Maximum phytoplankton biomass also occurs in phase with the MLD during win-66 ter, in the so-called entrainment blooms (Cullen et al., 2002). In this scenario, the MLD 67 is shallower than the critical depth, the light does not become a limiting factor, and phy-68 toplankton growth is supported by the injection of new nutrients during the winter deep-69 ening of the mixed layer. Entrainment blooms are thought to explain the seasonal cy-70 71 cle of phytoplankton in the Gulf of Mexico (GoM) based on satellite-derived sea surface chlorophyll-a. Maximum values are observed during winter and minimum values are ob-72 served during summer (Muller-Karger et al., 1991, 2015). 73

In recent years, the annual seasonal cycle of phytoplankton biomass in the GoM 74 has been questioned. Pasqueron et al. (2017), using Lagrangian floats show constant depth-75 averaged chlorophyll-a concentration along the year in the GoM, suggesting that win-76 ter convection only redistributes the phytoplankton cells from the deep chlorophyll-a max-77 imum (DCM) towards the surface. Certainly, this process can increase the pigment con-78 centration at the surface but, in an average sense, the phytoplankton biomass remains 79 constant. Therefore, enhancement of surface chlorophyll-a is not necessarily related to 80 a net phytoplankton growth within the euphotic layer. In this respect, results from cou-81 pled physical and biogeochemical numerical models have shed light reconciling both views 82 (i.e. redistribution versus enhancement of phytoplankton biomass). 83

Damien et al. (2018) suggest that the distance between the MLD and the nitra-84 cline varies regionally in the GoM, and it is a key variable in determining if either a re-85 distribution of chlorophyll-a or an increase on the integrated phytoplankton biomass drives 86 the Gulf's seasonal cycle. The authors found that in regions where the MLD and the ni-87 tracline are close or overlap, nutrients are injected into the euphotic zone, causing an in-88 crease in the phytoplankton biomass. Conversely, when the MLD is shallower than the 89 nitracline, the DCM is redistributed within the mixing layer. Moreover, Damien et al. 90 (2021) shows that the MLD frequently reaches the nitracline inside Loop Current Ed-91 dies (LCEs) because stratification is weaker, producing deeper mixed layers. That is, it 92 is required less momentum input inside the LCE to mix the water column to the depth 93 of the nitracline ( $\sim 180$  m in average inside LCEs; 140m outside; Portela et al. (2018)). 94

LCEs are important because not only drive the GoM's mesoscale circulation but, 95 also shape the distribution of physical, chemical, and biological properties (Meunier, Pallás-96 Sanz, et al., 2018; Portela et al., 2018; Lee-Sánchez et al., 2022; Linacre et al., 2015, 2019; 97 Damien et al., 2021). Inside these mesoscale eddies, vertical pumping of nutrients into 98 the euphotic layer (Falkowski et al., 1991; McGillicuddy & Robinson-F, 1997; McGillicuddy 99 et al., 1998; McGillicuddy, 2016; Siegel et al., 2011) and changes in the Photosynthet-100 ically Active Radiation (Vaillancourt et al., 2003) are important factors controlling the 101 heterogeneity of chlorophyll-a concentration. The nature of oceanic pumping is diverse 102 (Klein & Lapeyre, 2009), including frictional decay (P. J. S. Franks et al., 1986; Flierl 103 & Mied, 1985), linear and non-linear Ekman pumping (Ekman, 1905; Stern, 1965; Wene-104 grat & Thomas, 2017; Chen et al., 2020), eddy-wind interaction (McGillicuddy et al., 105 2007; Gaube et al., 2013; Martin & Richards, 2001), and horizontal strain deformation 106 (Hoskins et al., 1978; Pallàs-Sanz & Álvaro Viúdez, 2005; Barceló-Llull et al., 2017; Estrada-107 Allis et al., 2019). Moreover, different processes can be at work simultaneously. For in-108 stance, He et al. (2017) found that coupled eddy-induced Ekman pumping and winter 109 mixing is a robust physical mechanism to explain phytoplankton blooms inside the mixed 110 layer of anticyclonic eddies. 111

In the GoM, the role of light on the seasonal cycle of the phytoplankton has been formally assessed only in the work of Yang et al. (2022) who implemented a diagnostic model to compute the net primary production based on *in situ* estimations of phytoplank-

**Table 1.** General information of the glider missions designed to sample the Poseidon LCE in the GoM. It includes the mission number, number of dive cycles done during the whole mission, start date and end date of each mission, the Eco WETlabs triplet (BBFL2IRB) serial numbers, and their corresponding scale factor (SF) reported by the manufacturer in the calibration sheet.

Mission	Dive cycles	Start date	End date	BBFL2 SN	SF $[mg \operatorname{count}^{-1}]$

0004	639	07-12-2016	29-03-2017	1374	0.0121
0005	711	10-02-2017	25-05-2017	1375	0.0121
0006	507	25-05-2017	22-08-2017	1376	0.0121

ton carbon. They found that the net primary production integrated in the upper 100 115 m is higher during the summer and lower during winter, because of the seasonal cycle 116 of irradiance in the GoM. This highlights the lack of consensus on the factors control-117 ling phytoplankton growth and primary productivity in the GoM. Especially inside deep 118 water LCEs (> 1000 m depth), where different mechanisms can affect the phytoplank-119 ton communities dominated by *Prochlorococcus* cells (Linacre et al., 2015, 2019), adapted 120 to proliferate in oligotrophic regions (Partensky et al., 1999; Partensky & Garczarek, 2010; 121 Biller et al., 2014). 122

Although previous studies have contributed to the understanding of the seasonal 123 cycle of phytoplankton in the GoM, including LCEs dynamics, they are also limited in 124 several aspects. Satellite data are constrained to surface waters, while data collected by 125 Lagrangian floats profiling the water column every 14 days can filter out high-frequency 126 processes important for phytoplankton dynamics (Platt et al., 1989; Lewis et al., 1984; 127 P. J. Franks, 2015; Taylor & Ferrari, 2011). On the other hand, the results of numer-128 ical modeling require validation with in situ measurements, especially during winter and 129 inside the eddy core, where the lack of observations reduces the skill of the model in sim-130 ulating realistic vertical profiles of chlorophyll-a (Damien et al., 2018, 2021). Here a full 131 seasonal cycle of bio-optical properties inside a westward propagating LCE is investigated, 132 by using a combination of high-resolution and quality-controlled, measurements of hy-133 drography, in vivo chlorophyll-a fluorescence, and particle backscattering. 134

#### <sup>135</sup> 2 Data and Methods

Four underwater glider missions (Table 1) were designed to sample a LCE called 136 Poseidon, that propagated through the GoM between 2016 and 2017 (Figure 1). Glid-137 ers sampled the water column from the surface up to 1000 m depth in a saw-tooth pat-138 tern, with a suite of sensors to simultaneously measure physical and biogeochemical prop-139 erties. The sensors used were: unpumped CT-Sail (temperature and conductivity), an 140 optode Aanderaa 4831 (dissolved oxygen), and the ECO-Wetlabs triplet (BBFL2IRB; 141 Table 1) which measures light backscattering (at 700 nm and with a centroid angle of 142 124°), in vivo fluorescence of chlorophyll-a (ex: 470 nm, em: 695 nm), and fluorescence 143 emitted from colored dissolved organic matter (ex: 370 nm, em: 460 nm). During mis-144 sion 3, the ECO-Wetlabs triplet was turned off below 200 m to reduce the glider's bat-145 tery consumption. For calibration purposes, two dive cycles were performed down to dark 146 and deep waters of 1000 m depth. 147

A glider dive cycle includes measurements collected during the downcast and upcast, with horizontal and time resolution at the surface of 4 km and 6 hours, respectively. The averaged vertical resolution was 0.6 m for the physical variables and 1 m for the biogeochemical sensors. TEOS-10 equation of seawater was used to compute density anomaly

**Figure 1.** The trajectory of the LCE Poseidon and the paths followed by underwater gliders during the four missions. Glider's trajectories for each mission (see Table 1) are represented by the blue line, while the Poseidon track is color-coded based on the days since its detachment from the Loop Current (April 15, 2016; Meunier, Pallás-Sanz, et al. (2018)). Background colors (blue to white) represent the bathymetry of the GoM, and the contours of the 200, 500, 1000, 2000, and 3000 m are shown. Note the sampling pattern of the glider during mission 4, which was produced by the glider drifting with the Poseidon depth-averaged currents.

referred to the surface. Squared Brunt-Väisälä frequency and the MLD were derived from potential density anomaly. The MLD was determined as the depth at which density exceeds a threshold of  $0.125 \text{ kg m}^{-3}$  relative to the value recorded near the surface (i.e. 10 m depth).

The particle backscattering coefficient at 700 nm  $(b_{bp}700)$  was obtained following 156 Schmechtig, Poteau, et al. (2018), after removing the contribution of seawater. It was 157 quality controlled following Argo data processing (Schmechtig et al., 2019). The chlorophyll-158 a concentration from fluorescence was obtained by subtracting the dark counts (i.e., the 159 blank or the signal of the fluorometer in the absence of chlorophyll-a) and by using a scale 160 factor (SF), that is,  $([Chl_a] = (Fl_{raw} - \text{dark counts}) \cdot SF)$ . Even though the manufac-161 turer provides the calibration coefficients, it is important to note that they might exhibit 162 deviations from one sensor to another, and during the field mission. Here, the *in situ* dark 163 count coefficient was obtained by averaging the deepest observations of fluorescence (be-164 low the euphotic layer), a procedure used by the Argo-BGC program (Schmechtig, Claus-165 tre, et al., 2018). 166

In this study, two scale factors were used to convert fluorescence into chlorophylla concentration: (i) from the calibration sheet provided by the manufacturer (Table 1), and (ii) an adjusted scale factor inferred from the linear fit between the satellite-derived chlorophyll-a concentration and the glider's fluorescence. On one hand, the adjusted scale factor is used to assess the relation between fluorescence and chlorophyll-a concentration, and on the other hand, it attempts to reduce bias in the chlorophyll-a estimation along the seasonal cycle.

The non-photochemical quenching correction on chlorophyll-a fluorescence was done 174 according to the methodology described in Thomalla et al. (2018), which takes advan-175 tage of the high spatio-temporal resolution of gliders, and the relation between chlorophyll-176 a and  $b_{hp}700$ . This procedure interpolates vertically and removes anomalous spikes from 177 chlorophyll-a and  $b_{bp}700$  data. High-frequency variability in chlorophyll-a was removed 178 by applying a 7-point running mean with a Hann window. All points exceeding three 179 times the standard deviation were considered spikes. The  $b_{bp}700$  de-spiked signal is in 180 agreement with the baseline described in Briggs et al. (2011). 181

182 183

#### 2.1 Relation between glider *in situ* fluorescence and satellite chlorophylla concentration

Changes in the relation between fluorescence and extracted chlorophyll-a are a func-184 tion of phytoplankton taxonomic composition, nutritional status, and growth phase (Proctor 185 & Roesler, 2010; C. Roesler et al., 2017). Since water samples were not available dur-186 ing the four glider missions, satellite data was used to obtain adjusted scale factors for 187 the region (C. Roesler et al., 2017). The method of Boss et al. (2008), which compares 188 the chlorophyll-a fluorescence with a satellite data product, assumed to be the ground 189 truth, was followed. Night-time fluorescence measurements were only considered to avoid 190 introducing variability related to the correction of non-photochemical quenching. 191

Here it was used the daily ESA OC-CCI v5 dataset (ESAOC-CCI;https://climate 192 .esa.int/en/projects/ocean-colour/data/), with a spatial resolution of  $4 \text{ km} \times 4 \text{ km}$ . 193 In this product, ocean color measurements are obtained from multiple satellite radiomet-194 ric sensors and merged, reducing artifacts introduced by differences in sensor design (i.e., 195 differences in sampled wavelengths). Also, the algorithm used to retrieve chlorophyll-a 196 concentration from remote sensing reflectance is selected by taking into consideration 197 the optical classification of a water body (Sathyendranath et al., 2019). Moreover, by 198 merging data from multiple sensors, the ESA OC-CCI improves spatial coverage, which 199 is an important advantage in regions frequently covered by clouds like the GoM. 200

A critical step to establish and interpret relationships between satellite data and 201 in situ measurements, is to identify observations that can be properly compared, given 202 the differences in the spatial and temporal resolutions captured by both platforms (Gordon 203 et al., 1983; Bailey & Werdell, 2006; Concha et al., 2021). The procedure to find such 204 observations is called match-up analysis, and there are different approaches. They are 205 not interpolations of the satellite data into the position of field measurements, which can 206 fail due to the presence of clouds, and do not take into account differences in the reso-207 lution of different platforms. More details about the match-up analysis can be found else-208 where in the literature (Gordon et al. (1983); Bailey and Werdell (2006); Concha et al. 209 (2021)).210

The match-up analysis used here was consistent with the protocols to validate the 211 ESA-OC-CCI product (Sathyendranath et al., 2019; Valente et al., 2019). Briefly, the 212 glider observations of chlorophyll-a fluorescence (in digital counts) within the upper 10 213 m depth were averaged. The 10 m depth criterion was selected because it is the max-214 imum valid depth to relate *in situ* and satellite data in the ESA OC-CCI products, and 215 it is a compromise between the optical depth in oligotrophic and eutrophic waters (Sathyendranath 216 et al., 2019; Valente et al., 2019). Matched-up satellite observations are obtained as the 217 median of a 3x3 pixel window centered at each glider position. The median value was 218 considered valid only if the central pixel was not affected by clouds. If several glider ob-219 servations fall inside the 3x3 box, only the nearest to the center was used. 220

The relationship between the matched pairs was analyzed using a type I linear regression. To account for the auto-correlation of the glider's measurements and the heteroskedasticity, the confidence intervals of the coefficients and best-fit line were adjusted, as recommended by Fox (2016). The slope of this regression was used to estimate the adjusted scale factor for estimating the chlorophyll-a concentration. Outliers were detected by visual inspection of scatter plots and removed accordingly.

2.2 Eddy detection

227

The center and periphery of the LCE Poseidon were identified by using an algo-228 rithm applied over Sea Level Anomalies (SLAs). In this work, the daily SLAs were ob-229 tained from the Delayed-Time merged all satellites Global Ocean Gridded SSALTO/DUACS 230 Sea Surface Height, an L4 product available in the Copernicus Marine Service (https:// 231 marine.copernicus.eu/access-data). Before the use of the eddy detection algorithm, 232  $0.25^{\circ} \times 0.25^{\circ}$  gridded data were filtered with a two-dimensional LOESS smoother to at-233 tenuate processes with wavelengths greater than 20° in longitude and 10° in latitude (Chelton, 234 Schlax, & Samelson, 2011), that can remove the large scale effects on the sea level like 235 steric effect. 236

The LCE Poseidon was identified as a closed contour of SLA that meets the fol-237 lowing criteria: (i) the SLA closed contour should contain a minimum of 8 pixels, but 238 not more than 1000, (ii) there is at least one local maximum of SLA, (iii) the amplitude 239 of the eddy is greater than 1 cm, and (iv) all pairs of pixels within the contour have dis-240 tances smaller than a threshold that depends on latitude (for details see Appendix B in 241 Chelton, Schlax, and Samelson (2011)). The outermost closed contour of SLA full-filling 242 243 the four criteria defines the so-called effective contour of the eddy. A successive search within the effective contour is conducted to find the closed SLA contour with the largest 244 swirl geostrophic speed. 245

The contour inside the eddy is called the maximum speed contour, and it is a natural border separating the interior of the eddy dominated by vorticity, from external regions dominated by straining. Tracers cannot escape from within the vortical region when diffusion is neglected (Chelton, Schlax, & Samelson, 2011; Meunier, Pallás-Sanz, et al., 2018). This is an important characteristic of nonlinear eddies (Flierl, 1981), that can trap fluid in their interior for long distances without exchanging fluid with the surrounding waters.

The trajectory of Poseidon was computed by searching for the nearest eddy center (i.e. the centroid of the effective contour) between consecutive days according to Chelton, Schlax, and Samelson (2011). On the other hand, the distance between the glider and the eddy centroid (d) was computed and normalized by the eddy length scale (L). This normalized distance (R = d/L) was used to select the vertical profiles inside the core of the eddy (R < 0.55), which allows constraining the variability to vertical (1D) processes by neglecting horizontal advection.

The trajectory of the eddy was smoothed using a 1-D LOESS with a half-span of 42 days (Chelton, Schlax, & Samelson, 2011). The time derivative of the smoothed trajectory provides the eddy's translation speed, and the rotational speed of the eddy was computed as the averaged swirl speed along the maximum speed contour. The degree of nonlinearity of the eddy is given by the ratio between rotational and translation speed (Flierl, 1981; Chelton, Schlax, & Samelson, 2011). Rotational and translation speed and the nonlinearity parameter were averaged in 0.5° bins, and were used to describe the kinematical properties of LCE Poseidon along its westward propagation across the GoM.

268

#### 2.3 Ancillary variables

Two main factors stimulating phytoplankton growth are the nutrient concentra-269 tion and the amount of Photosynthetically Active Radiation (PAR). Since the gliders 270 do not measure these variables, estimating them from proxies is required. Changes in 271 nutrient availability can be assessed from the distance between the MLD and the nitr-272 acline depth (Damien et al., 2018) because entrainment of nutrients can occur when they 273 are close or overlap. Following Pasqueron et al. (2017), the top of the nitracline is equal 274 to the depth of the  $25.5 \text{ kg m}^{-3}$  isopycnal, which was determined to be the nitrate de-275 pletion density (Omand & Mahadevan, 2015). 276

The 25.5 kg m<sup>-3</sup> isopycnal can overestimate the depth of the nitracline (see table 4 in Lee-Sánchez et al. (2022)), and other methods can be used as an alternative. For example, it is possible to obtain the depth of the nitracline from reconstructed nitrates plus nitrites ([N+N]) profiles based on hydrographic variables Velásquez-Aristizábal et al. (2022). From these profiles, the nitracline (nitracline-VA22 hereinafter) can be considered the depth where the [N+N] exceed  $0.5 \,\mu$ mol kg<sup>-1</sup>.

A combination of satellite data products is used to estimate the underwater dis-283 tribution of PAR (400-700 nm). The datasets used for this purpose were: (i) the previ-284 ously described ESA OC-CCI to compute the diffuse attenuation coefficient for the PAR 285 (Kd(PAR)), and (ii) the EPICS/DISCOVR dataset with a satellite measurement of the 286 daily averaged PAR just above the sea surface  $(Ed(0^+, PAR), R. J.$  Frouin et al. (2018); 287 R. Frouin et al. (2022)). Both products are daily available but differ in their spatial res-288 olution. ESA-OC-CCI is a 4 km product, while EPICS/DISCOVR is in a regular grid 289 of  $18 \,\mathrm{km} \times 18 \,\mathrm{km}$  (https://asdc.larc.nasa.gov/). 290

The procedure is based on the Lambert-Beer law, which describes the exponential 291 decay of irradiance with depth, given the irradiance reaching the sea surface and the dif-292 fuse attenuation coefficient  $(K_d)$ . Both quantities depend on the wavelength. The inter-293 est was to find the depth of an isolume with physiological significance (for a discussion about the depth of the euphotic zone see Letelier et al. (2004) and Banse (2004)), defin-295 ing the base of the euphotic zone. The attenuation coefficient of the PAR (Kd(PAR))296 was estimated from the value obtained at the single wavelength of 490 nm (Kd(490)), 297 which is only available in the ESA-OC-CCI product. At each pixel the Kd(PAR) was 298 obtained following the relation provided by Morel et al. (2007): 299

$$Kd(PAR) = 0.0665 + 0.874 \cdot Kd(490) - 0.00121 \cdot Kd(490)^{-1}.$$
 (1)

Given the presence of clouds in the ESA-OC-CCI dataset, a representative value 300 of Kd(PAR) was used. Similar to the match-up analysis, this value was the median of 301 a 3x3 pixel box centered at each glider position. PAR from the EPICS/DISCVR dataset 302 was interpolated at each glider surface position, taking advantage that does not present 303 data gaps by clouds and because it was not used for comparisons with *in situ* data. The depth of the  $0.08 \text{ molQ m}^{-2} \text{ day}^{-1}$  isolume was computed by solving the Lambert-Beer 305 law, following to Mignot et al. (2018). This isolume value was selected because is the com-306 pensation irradiance for low-light adapted ecotypes of *Prochlorococcus* (Moore et al., 1995). 307 which have been found at the base of the euphotic zone in the GoM (Linacre et al., 2015, 2019). Daily averaged isolume depth was used to study the vertical displacements of the 309 DCM in relation to the seasonal changes in underwater light, similarly as in other stud-310 ies (Letelier et al., 2004; Mignot et al., 2014). 311

<sup>312</sup> Phytoplankton light limitation inside LCE Poseidon was assessed through a com-<sup>313</sup> parison of the MLD and the Sverdrup's critical depth ( $Z_{cr}$ ) (Sverdrup, 1953; Siegel et <sup>314</sup> al., 2002; Lavigne et al., 2013), which can be obtained from the relationship given by:

$$\frac{1}{Kd(PAR) \cdot Z_{cr}} \left( 1 - e^{-Kd(PAR) \cdot Z_{cr}} \right) = \frac{Ed_c}{Ed(0^+, PAR)}$$
(2)

where  $Kd(PAR) = 0.075 \text{ m}^{-1}$  is the attenuation coefficient of PAR averaged along the winter mission 0004.  $Ed(0^+, PAR)$  is the PAR just above the sea surface, and  $Ed_c$ is the community compensation irradiance.  $Ed(0^+, PAR)$  was obtained from the EPICS/DISCOVR dataset, and  $Ed_c$  was set to  $1.1 \text{ molQ m}^{-2} \text{ day}^{-1}$  (Regaudie-De-Gioux & Duarte, 2010; Siegel et al., 2002).  $Z_{cr}$  was averaged daily.

#### 3.1 Relation between fluorescence and satellite chlorophyll-a concentration

In the four missions, there were linear associations between fluorescence and chlorophyll-324 a (Table 2) as shown in Figure 2. However, the coefficients of the linear model were dif-325 ferent from one mission to another (Table 2), as well as their uncertainties, and the amount 326 of explained variance by the linear model (i.e., squared Pearson correlation coefficient, 327  $r^{2}$ ). Winter missions show the highest slopes, but also the highest uncertainties in the 328 model coefficients (Table 2). Mission 0004 shows the largest scattering of values around 329 the predicted line, and consequently, the linear model explains less of the total variance 330  $(r^2=0.46; \text{ Table 2}).$ 331

A more complex relation was observed during winter missions (0004 and 0005), which showed the highest uncertainties in the model coefficients and the largest scattering around the best-fit line. This can be associated with the variability of the fluorescence yield, driven by the multiple factors that can affect it such as nutritional status, phytoplankton community composition, and growth phase. All these factors can have a higher spatiotemporal variability during winter, contributing to the total variance and leading to a more scattered distribution of observations (C. S. Roesler & Barnard, 2013).

The relation between chlorophyll-a and fluorescence is thus more convoluted during mission 0004 because the glider sampled the LCE alongstream following a circular pattern, sometimes getting close to the contour of maximum speed (Figure 1b). This suggests that eddy spatial structure may have a role in modulating phytoplankton populations, at least in terms of their fluorescence emission. Some aspects of the spatial dis-

**Figure 2.** Linear regressions between fluorescence and satellite-derived chlorophyll-a concentration for each glider mission: 0003 (a), 0004 (b), 0005 (c), and 0006 (d). In each panel, the least-squares fitted line and the 95% confidence intervals are shown.

**Table 2.** Statistics of the linear regressions between glider fluorescence and satellite chlorophyll-a concentration in each mission. N is the number of observations (valid matchups) for the least squares fitting. The slope and intercept of the linear regression are indicated together with coefficient uncertainties.  $r^2$  is the squared Pearson's correlation coefficient.

Mission	Ν	Slope	Intercept	Pearson's r	$r^2$
0003	62	$41.48 \pm 2.57$	$48.91 \pm 0.21$	0.88	0.77
0004	50	$179.19 \pm 30.49$	$36.38 \pm 6.45$	0.68	0.46
0005	49	$144.51\pm16.87$	$39.17 \pm 1.71$	0.87	0.76
0006	57	$24.88\pm3.66$	$50.82\pm0.37$	0.80	0.64

tribution and transformation of physical and biological properties across mesoscale eddies have been studied in previous works in the GoM and other locations (Sosa-Gutiérrez
et al., 2020; Lee-Sánchez et al., 2022; Damien et al., 2021; Liu et al., 2020; Chelton, Gaube,
et al., 2011; Sánchez-Velasco et al., 2013; Peterson et al., 2011; Velásquez-Aristizábal et
al., 2022).

Linear regressions indicate changes in the adjusted scale factor (the inverse of the slope reported in Table 2), which varied between  $0.006 \text{ mg m}^{-3} \text{ counts}^{-1}$  (mission 0004) to  $0.040 \text{ mg m}^{-3} \text{ counts}^{-1}$  (mission 0006). The variation in the scale factor contrasted with the constant value provided by the manufacturer for all missions ( $0.0121 \text{ mg m}^{-3} \text{ counts}^{-1}$ ; Table 1), which can lead to changes in the estimated chlorophyll-a.

Hence, the estimated chlorophyll-a concentration obtained with the manufacturer and adjusted scale factors were compared with satellite chlorophyll-a concentration (Figure 3). Typically, regardless of the scale factor used, the chlorophyll-a concentration at the surface is large (small) during winter (summer) (Figure 3). However, there are discrepancies relative to the satellite data depending on the scale factor used to obtain the chlorophyll-a from fluorescence.

**Figure 3.** Comparisons of chlorophyll-a concentration estimated from satellite sensors and from glider's fluorescence calibrated using manufacturer's scale factor (a) and adjusted scale factors (b).

Satellite chlorophyll-a concentration is underestimated most of the year and overestimated in early winter from December 2016 to January 2017 with the manufacturer scale factor. By contrast, adjusted scale factors reduce the underestimation of chlorophylla concentration. It means that during some periods, the adjusted scale factor can improve the estimation of chlorophyll-a relative to the values obtained with the manufacturer's scale factor (Figure 3a). The bias can be computed (in the logarithm scale) following Seegers et al. (2018):

$$bias = 10^{\sum log(CHL_{gld} - CHL_{sat})},$$
(3)

where  $CHL_{qld}$  is the chlorophyll-a estimated from glider fluorescence by using ei-368 ther the manufacturer or adjusted scale factors, and  $CHL_{sat}$  is the satellite chlorophyll-369 a concentration. Table 3 shows a large bias using both, the manufacturer's and adjusted 370 scale factor. The manufacturer scale factor provides less biased chlorophyll-a concentra-371 tion related to the adjusted scale factor in missions 0004 and 0005, whereas the adjusted 372 scale factor reduces the bias during missions 0003 and 0006 (Table 3). However, none 373 of the scale factors is consistently less biased than the other in all situations. In this work, 374 the manufacturer scale factor is used to compute chlorophyll-a concentration from glider 375 observations. 376

#### 3.2 Physical and bio-optical variability inside the LCE Poseidon

Young Poseidon swirl speed was about  $U = 70 \,\mathrm{cm \, s^{-1}}$  in average, but then it decayed rapidly west of  $-92 \,\mathrm{W}$  to  $30 \,\mathrm{cm \, s^{-1}}$  (Figure 4a). LCE Poseidon moved hundreds of kilometers westwards at an averaged translation speed of c  $\sim 4 \,\mathrm{cm \, s^{-1}}$  (Figure 4b),

Mission	Bias (Manufacturer's SF)	Bias (Adjusted SF)
0003	0.35~(65~%)	0.70 (30 %)
0004	0.92~(8~%)	0.43~(57~%)
0005	0.52~(48~%)	0.30~(70~%)
0006	0.42~(58~%)	1.41 (41 %)

**Table 3.** The bias (see equation 3.1) of the chlorophyll-a concentration obtained with the manufacturer's and adjusted scale factors relative to the satellite-derived chlorophyll-a. Underestimation (overestimation) occurs for biases smaller (larger) than unity.

leading to a non-linearity parameter U/c always larger than unity (Figure 4c), suggesting that fluid is trapped during Poseidon's entire life (Flierl, 1981).

The potential density anomaly  $(\sigma_{\theta})$  and squared Brunt–Väisälä frequency  $(N^2 =$ 383  $(-g/\sigma_0) \cdot \partial \sigma_{\theta}/\partial z$  are used to describe the seasonal cycle of the thermohaline vertical 384 structure of LCE Poseidon (Figure 5a-b). The  $\sigma_{\theta}$  and MLD have marked seasonal cy-385 cles with lighter upper waters and a shallower mixed layer in the summer, and heavier 386 waters and deeper mixed layers during winter. In addition, summer seasonal pycnocline 387  $(at \sim 30-50 \text{ m})$  separates the mixed-layer from the pycnostad of the eddy located between 50 and 200 m depth (Figure 5b; mission 0003). The MLD increases during Octo-389 ber 2016 (end of mission 0003) and by December reaches up to 150 m depth in agree-390 ment with the MLD climatology of Portela et al. (2018). The upper layer re-stratifies 391 again in June 2017, forming a shallow 30 m mixed layer, and completing a full seasonal 392 cvcle. 393

The  $N^2$  is large at the seasonal and main pycnocline (> 1×10<sup>-2</sup> s<sup>-2</sup>; Figure 5b). 394 The main pychocline of Poseidon holds the entire year at approximately 200 m depth, 305 progressively weakening during eddy's translation westwards (Figure 5b). Contrary, win-396 ter convection due to the passage of cold fronts (Pérez et al., 2022; Zavala-Hidalgo et al., 397 2014) erodes completely the seasonal pycnocline, by mixing pycnostad and upper wa-398 ters. Note that MLD and the depth of the  $25.5 \,\mathrm{kg}\,\mathrm{m}^{-3}$  isopycnal (a proxy of the top of 399 the nitracline) are only a few tens of meters apart during winter, and the alternative proxy 400 of the nitracline (nitracline-VA22) overlap (Figure 5b), indicating that entrainment of 401 nutrients could be possible. 402

The depth of the isopycnal of  $25.5 \text{ kg m}^{-3}$  is related to the spatial structure and dynamical stage of the eddy. In mission 0003, the glider sampled a young Poseidon located east -92 W (Figure 1a) with the isopycnal of  $25.5 \text{ kg m}^{-3}$  reaching up to 250 m depth in the center and ranging between 150-160 m depth at the eddy edge (Figure 5c). Since December 2016 (beginning of mission 0004), the depth of the isopycnal of  $25.5 \text{ kg m}^{-3}$ continuously decreases (Figure 5c) due to Poseidon's lost of heat and salt (Meunier et al., 2020).

Poseidon's decay, west of -92 W (Figure 4a) leads to upwelling of isopycnals. This 410 process is through the eddy pumping, that is,  $\partial \sigma_{\theta} / \partial t > 0$  (Klein & Lapeyre, 2009). Dur-411 ing December 2016 and January 2017 (mission 0004), the  $25.5 \text{ kg m}^{-3}$  isopycnal was at 412 ~ 170 m depth and the normalized radius ranged between  $R \in [0.25 - 0.75]$  (Figure 5c) 413 suggesting that the glider drifted anticyclonically with the depth-averaged currents around 414 the central region of Poseidon. Notice that near the peripheries of the eddy (R > 1), 415 horizontal advection and sub-mesoscale ageostrophic processes dominate the variabil-416 ity of biogeochemical variables (Mahadevan et al., 2008; Chelton, Gaube, et al., 2011). 417 However, these processes are out of the scope of this work because the analyses focused 418 on the bio-optical properties near the eddy core (R < 0.55). 419

**Figure 4.** LCE Poseidon dynamical properties along its trajectory across the GoM: (a) swirl speed (U), (b) translation speed (c), and (c) non-linearity parameter (Flierl (1981); U/c).

Figure 5. Distribution of (a) potential density anomaly referred at the surface ( $\sigma_0$ ) and (b) squared Brunt–Väisälä frequency ( $N^2$ ) as a function of depth. In (a-b), the magenta and white lines represent the MLD and the 25.5 kg m<sup>-3</sup> isopycnal depth respectively. The black line is the alternative proxy of the top of the nitracline ( $[N + N] > 0.5 \,\mu$ mol kg<sup>-1</sup>) based on empirical relations of hydrographic variables and nutrients (Velásquez-Aristizábal et al. (2022); nitracline-VA22). Panel (c) shows the depth of the 25.5 kg m<sup>-3</sup> isopycnal (black line) and normalized glider location (R; blue line).

Figure 6. Vertical distribution of bio-optical properties collected inside the LCE Poseidon along a seasonal cycle as a function of depth. (a) Chlorophyll-a concentration by using the manufacturer scale factor and (b) the particle backscattering coefficient at 700 nm ( $b_{bp}$ 700). The lines in b and c are the smoothed time series of the MLD (black), and the 0.08 isolume (orange). The red line corresponds to the top of the nutricline based on the Velásquez-Aristizábal et al. (2022) method (nitracline-VA22). The smoothed time series were obtained after using a 1D-LOESS to attenuate variability with periods below 3 days.

427

428

429

Contrasting conditions between summer and winter in terms of stratification affected the bio-optical variability across LCE Poseidon (Figure 6). During summer and early fall, the chlorophyll-a was extremely low within the MLD, with a DCM located at 130 m depth; 100 m shallower than the nitracline (Figure 6a). Between December 2016 and March 2017, the chlorophyll-a was mostly distributed through the whole mixed layer, with episodic sub-surface enhancements (Figure 6a). Since April 2017, the DCM becomes a stable structure when the upper ocean stratifies and the MLD shoals. The location of the DCM during the whole period approximately follows the  $\sim 0.08$  isolume (Figure 6a), indicating that photoacclimation is an important process in regulating the vertical distribution of chlorophyll-a (Letelier et al., 2004; Mignot et al., 2014).

The  $b_{bp}$ 700 vertical distribution (Figure 6b) is similar to chlorophyll-a concentra-430 tion except during summer and spring. In summer of 2016, maximum values of  $b_{bp}700$ 431 were found in the mixed-layer  $(< 50 \,\mathrm{m})$  while the maximum chlorophyll-a was located 432 in the DCM (Figure 6a and b). On December 25, 2016,  $b_{bp}$ 700 intensified abruptly in-433 side the core of Poseidon (Figure 6b) and remained elevated until January 17, 2017, with 434 similar subsurface enhancements than chlorophyll-a concentration (Figure 6a and b).  $b_{bp}700$ 435 progressively decreases inside Poseidon towards summer of 2017. The enhancement of 436  $b_{bp}$ 700 observed during winter is unlikely to be driven by horizontal or vertical advec-437 tion, because the  $b_{bp}$  700 signal below the MLD was low, and the glider was near the cen-438

ter between December and January. Thus, data suggest that appropriate environmen tal conditions stimulated phytoplankton production within the winter MLD of the LCE
 Poseidon.

442 443

# 3.3 Seasonal cycle of integrated chlorophyll-a and $b_{bp}700$ in the upper 200 m

Figure 7 shows the time evolution of chlorophyll-a concentration and  $b_{bp}$  700 inte-444 grated from surface to 200 m depth. The vertical integration of bio-optical properties has 445 a double purpose: (i) removing the vertical variability and (ii) assessing the occurrence 446 and reliability of a seasonal cycle of phytoplankton biomass not only at the sea surface 447 but also within the euphotic layer. To analyze the seasonal cycle, the trend in bio-optical 448 signals was removed first. Then, ordinary least-squares were used to fit the seasonal cy-449 cle, defined by the contribution of the mean and the annual and semi-annual harmon-450 ics: 451

$$F_{seas}(t) = F_0 + A_a \cdot \cos(\omega t - \phi_a) + A_s \cdot \cos(2\omega t - \phi_s) \tag{4}$$

where  $F_0$  represents the mean.  $A_a$  and  $A_s$  are the amplitude of the annual and semiannual harmonics.  $\phi_a$  and  $\phi_s$  are the phase of the annual and semi-annual harmonics, and  $\omega$  is Earth's angular frequency  $(2\pi f; f = 1/365.25 \text{ days}^{-1})$ .

The analysis of the integrated variables showed that the seasonal cycle of chlorophylla observed at the surface (Figure 3) even holds when *in situ* chlorophyll-a concentration is vertically integrated (see for instance Pasqueron et al. (2017)). In addition, the seasonal cycles of both integrated chlorophyll-a concentration and  $b_{bp}$ 700 (thick blue lines in Figure 7) were in phase, with maxima values (minima) in winter (summer). The seasonal cycle accounts for a significant fraction of the total variance in both bio-optical variables (Figure 7a and b).

The remaining fraction of the variance seems to be associated with high-frequency processes mostly noticed on the chlorophyll-a during winter, from December 2016 to January 2017 (Figure 6a and 7a). They are noticeable in the integrated variables as considerable departures from the seasonal cycle (see grey dots in Figure 7a). Thus, processes at short temporal scales could be important for modulating the distribution of bio-optical properties inside the eddy. By contrast, during spring and summer, the variability of chlorophylla is notably reduced in agreement with quiescent environmental conditions.

#### 469 4 Discussion

The dataset used here has already contributed to improving understanding of the vertical distribution of physical properties (Meunier, Pallás-Sanz, et al., 2018; Portela et al., 2018), water mass transformation (Sosa-Gutiérrez et al., 2020), and physical submesoscale processes inside the LCE Poseidon (Meunier, Tenreiro, et al., 2018; Meunier et al., 2019). This is possible because underwater gliders can measure the properties of slow-moving mesoscale structures with high temporal and spatial resolution. Here, four glider missions were used to shed some light on the dynamics of phytoplankton in large LCEs.

During autumn and winter, the passage of several cold fronts increased the turbulent heat fluxes (latent and sensible) in the upper MLD of Poseidon, promoting gravitational instabilities inside the eddy core (Pérez et al., 2022). Thermal convection associated with (cold) northerly winds rapidly deepens the MLD (Pérez et al., 2022; Zavala-Hidalgo et al., 2014), which in the LCE Poseidon reaches up to 170 m depth, very close to the nitracline (Figure 5). A deeper MLD, closer to the nitracline, can increase the injection of nutrients into the euphotic zone through vertical diffusion, as it occurs with

Figure 7. Seasonal variability of vertically integrated (0 - 200 m) chlorophyll-a (Chl-a) concentration and particle backscattering coefficient at 700 nm ( $b_{bp}$ 700) inside the core of Poseidon: only are plotted measurements with R < 0.55. The blue line represents the fitted seasonal cycle, and the amount of explained variance (Exp.Var.) by the seasonal cycle is shown. The chlorophyll-a concentration from *in vivo* fluorescence was obtained with the manufacturer's scale factor.

salt (Sosa-Gutiérrez et al., 2020). The strong mixing during the passage of cold fronts
 separates the physical response of the GoM between stratified and mixed conditions with
 consequences for the local phytoplankton populations.

A stratified water column led to the development of a well-defined DCM, which is maintained until winter mixing tends to homogenize the bio-optical properties in the upper 200 m (Figure 6). The presence of DCM and the lack of sub-surface maximum in the  $b_{bp}700$  signal during summer and spring (Figure 6a and b), suggests that the DCM arises from photoacclimation in response to the low-light levels at the bottom of the productive layer. A result that agrees with Linacre et al. (2019), which found a higher biomass of autotrophic organisms at the surface during summer.

A photoaclimation-driven DCM in the GoM has been reported since the work of Steele (1964). Steele's ideas were indeed included in the framework developed by Cullen (2015) to explain the mechanisms generating DCMs under different trophic regimes, pointing out that DCMs produced by photoacclimation are characteristic of oligotrophic environments, as has already been observed in several studies (Letelier et al., 2004; Barbieux et al., 2018; Mignot et al., 2014) and more recently supported in the case of the GoM deep waters (Linacre et al., 2019).

Changes observed in the relation between chlorophyll-a concentration and fluorescence are remarkable (Figure 2 and Table 2). The highest uncertainties in the model coefficients occur during winter (Table 2). Also, during the winter mission 0004, the highest dispersion from the fitted line was possibly associated with the sampling pattern. After reaching the eddy center, the compass failed. Then, the glider started to drift with the depth-averaged velocity, eventually close to the contour of maximum velocity. The sampling pattern of the glider during mission 0004 convolves the spatial and temporal variability as the glider moves anticyclonically within the LCE.

Variations in the physical and chemical conditions across the eddy can impact the 510 taxonomic composition or nutritional status of phytoplankton cells. As a consequence, 511 fluorescence emission can vary spatially inside the LCE. Hence, when analyzed together 512 the measurements near the center and towards the peripheries, the combination of fac-513 tors increase the bio-optical variability, complicating the use of a single linear relation 514 to derive the adjusted scale factor. In other words, the different factors affecting fluo-515 rescence emission act as confounding factors in the regression analysis, reducing the ex-516 plained variance by the linear model  $(r^2 = 0.46 \text{ in Table } 2)$ . 517

On the other hand, the highest slopes were obtained during missions 0004 and 0005 518 (winter), whereas missions 0003 and 0006 (summer) showed the lowest slopes(Table 1). 519 The variability in the magnitude of the slopes was not related to specific sensors. Glid-520 ers in missions 0004 and 0005 used different fluorometers (SNs: 1374 and 1375), yet the 521 slopes were comparable (Table 1). Moreover, the same sensor (SN: 1374) was used dur-522 ing missions 0003 and 0006, but slopes differed by one order of magnitude between them 523 (Table 1). Thus, the observed changes might be associated with seasonally dependent 524 biogeochemical processes. 525

A shift in the taxonomic composition of the phytoplankton populations can cause 526 527 changes in the slopes of the linear regressions because it is a factor of primary importance in the relationship between fluorescence and chlorophyll-a (Proctor & Roesler, 2010; 528 C. S. Roesler & Barnard, 2013; C. Roesler et al., 2017). The seasonal succession of phy-529 toplankton groups between summer and winter can occur inside the LCEs and likely through 530 the GoM, and it will depend on at least two factors: (i) the winter mixing that redis-531 tributes phytoplankton populations and (ii) the seasonal changes of the environmental 532 conditions (i.e. temperature, salinity, nutrient concentration, and irradiance). The re-533 distribution of phytoplankton populations during winter was already considered in pre-534 vious studies (Pasqueron et al., 2017; Linacre et al., 2015), while numerical models sug-535

gest changes in phytoplankton community composition (Damien et al., 2021; Gomez et al., 2018). However, to our knowledge, it is the first time that observations support a shift in the taxonomic composition of phytoplankton in the GoM based on *in situ* optical data.

<sup>539</sup> During summer, bio-optical data indicate the presence of two types of populations: <sup>540</sup> (i) phytoplankton associated with the DCM with high chlorophyll-a and low  $b_{bp}$ 700, adapted <sup>541</sup> to environments with low light availability and temperature at the base of the produc-<sup>542</sup> tive layer; and (ii) phytoplankton living near the surface under higher irradiance and tem-<sup>543</sup> perature, characterized by low chlorophyll-a and high  $b_{bp}$ 700 (Figure 6a and b).

The occurrence of different groups along a stratified water column agrees with the 544 results of the cytometric and genetic analysis presented by Linacre et al. (2019). They 545 found high-light adapted ecotypes of *Prochlorococcus* at the surface and low-light adapted 546 cells at the base of the euphotic layer. During winter, these populations are mixed, but 547 lower irradiance and lower temperatures, driven by the upper ocean seasonal cycle can 548 favor the phytoplankton of the lower euphotic zone already adapted to low light and lower 549 temperatures. Here, it is important to note that fluorescence emission per unit of chlorophyll-550 a increases as irradiance decreases in *Prochlorococcus*, and both chlorophyll-a concen-551 tration and fluorescence emission, tend to be higher in low-light adapted ecotypes (Moore 552 et al., 1995). A succession of phytoplankton populations is thus possible at the ecotype 553 level of differentiation of the picoplanktonic *Prochlorococcus*. 554

Succession between different size groups (pico to nanophytoplankton) is also possible, and actually, it is a result of numerical simulations of the GoM's ecosystem (Damien et al., 2018; Gomez et al., 2018; Damien et al., 2021). It is an accepted paradigm in phytoplankton ecology, associated with changes in turbulence and nutrient availability (Cullen et al., 2002; Margalef, 1978). Some opportunistic species of nanoplankton like *Emiliania huxleyi*, could be favored during the winter conditions if the amounts of new nutrients entrained in the euphotic layer are significant.

A winter increase of the nutrient concentration inside LCEs can be driven primar-562 ily by vertical diffusion when the MLD reaches or extends below the nitracline (Damien 563 et al., 2021). Although the MLD does not reach the  $25.5 \,\mathrm{kg}\,\mathrm{m}^{-3}$  isopyncal (proxy of the 564 top of the nitracline; Figure 6), the entrainment of nutrients cannot be ruled out. Di-565 rect observations of [N+N] profiles, including stations inside Poseidon during its early 566 stages, show that nitracline is shallower than the  $25.5 \text{ kg m}^{-3}$  isopyncal (Lee-Sánchez et 567 al., 2022). Thus, it is concluded that the [N+N] depletion depth was shallower than the 568 MLD during winter inside the LCE Poseidon as indicated by the alternative proxy of the 569 nitracline (Figure 5a and b). 570

Hence, Pasqueron's criteria, used here to define the [N+N] depletion depth, flaws inside the large LCE Poseidon. However, alternative methods are also error-prone when large LCEs are analyzed. Indeed, (Velásquez-Aristizábal et al., 2022) showed that was difficult to predict the vertical distribution of nutrients within the LCE Poseidon based on hydrographic proxies, given its anomalously low concentration of nutrients in upper layers. It means that nitracline-VA22 used here can be an underestimation.

Another result that supports the increase in nutrient concentration in the euphotic 577 zone, is indeed based on the seasonal cycle of the chlorophyll-a and  $b_{bp}700$  integrated in 578 the upper 200 m. Whereas the chlorophyll-a seasonal cycle can be questioned due to the 579 changes in the relation between chlorophyll-a and fluorescence (Figure 2), the  $b_{bp}700$  is 580 a proxy of phytoplankton carbon (Graff et al., 2015) that increases during winter, in phase 581 with the chlorophyll-a concentration (Figure 7). This concomitant change of bio-optical 582 variables supports the idea of a winter enhancement of the phytoplankton biomass, which 583 is difficult to explain without invoking nutrient injection. Especially inside the core of 584 LCEs which remained isolated from surrounding waters. 585

Figure 8. Winter bio-optical variability and its relation to the changes of the MLD and Sverdrup's critical depth. Only winter data was used because is the season when MLD reaches its maximum depth, whereas irradiance decreases by the solar cycle and the shorter day length. In the upper panel, green bars represent the integrated chlorophyll-a in the upper 200 m, while the integrated  $b_{bp}$ 700 (proxy of phytoplankton carbon) are to the brown bars. Data were daily averaged, and the the MLD (gray bars) and Sverdrup's critical depth (black-dotted line) are depicted. According to Sverdrup (1953), low irradiance can inhibit a net phytoplankton growth when MLD exceeds the critical depth.

Alternative explanations for the increase in the  $b_{bp}$ 700 during winter can be related 586 to changes in phytoplankton composition, as in the case of the chlorophyll-a fluorescence. 587 However, what process could promote changes in phytoplankton composition? Again, 588 the answer can be associated with the increase in the nutrient concentration by verti-589 cal diffusion, which arises as a plausible and parsimonious process to explain the observed 590 patterns in the bio-optical variables. Nonetheless, the increase in phytoplankton biomass 591 during winter can be modified by changes in the loss-term (i.e. grazing, viral infection, 592 sinking) of phytoplankton cells, as suggested in other studies (Behrenfeld, 2010; Behren-593 feld & Boss, 2014). 594

A comparison between the MLD and Sverdrup's critical depth is used to assess the 595 light effects on phytoplankton growth. The analyses showed that inhibition due to low-596 light conditions during winter does not occur for extended periods. MLD only exceeds 597 the critical depth for short time lapses of 1-3 days (Figure 8). As the computation of the critical depth relied on constant Kd(PAR) and  $Ed_c$ , the variability is produced by changes 599 in the irradiance at the sea surface, probably by the cloud coverage associated with the 600 passage of cold atmospheric fronts. In addition, the DCM followed approximately the 601 depth of the 0.08 isolume, indicating that phytoplankton is photoacclimated, and pre-602 sumably cannot fix carbon through photosynthesis below this threshold on irradiance, 603 in agreement with experimental works (Moore et al., 1995). 604

Finally, high-frequency variability in the bio-optical properties is noticeable, especially on chlorophyll-a estimated from *in vivo* fluorescence, which is a variable that responds rapidly to the changes in irradiance (Lewis et al., 1984). Patches of enhanced subsurface chlorophyll-a concentration occur inside the mixed layer at 5-day periods (Figure 6b). This variability is related to the passage of cold fronts, characterized by bursts of high speed lasting a few days and influencing the upper layer in the GoM, by turbulent heat exchange and mechanical input of energy during autumn and winter seasons
(Pérez et al., 2022; Zavala-Hidalgo et al., 2014). These processes occurring at 5-day periods can not be resolved by profiling the water column every 10-14 days with Argo floats,
highlighting the capabilities of gliders to capture the ocean's short-term variability, which
can impact phytoplankton dynamics (Platt et al., 1989). Thus, glider data can complement observations made with other valuable platforms monitoring the ocean at other scales
such as the Argo floats and research vessels.

High-frequency variability of bio-optical properties is out of the scope of this paper. Future work will focus on assessing the effect of atmospheric forcing (wind and air temperature) on the occurrence and shutdown of strong convective turbulence, which can modulate phytoplankton dynamics (Lewis et al., 1984; Taylor & Ferrari, 2011). In addition, the role of Ekman pumping could be important especially when the MLD remains close to the top of the nitracline as occurred in the LCE Poseidon.

#### 5 Conclusions

Analyses of physical and bio-optical measurements collected by underwater glid-625 ers showed concomitant seasonal variability between vertically integrated chlorophyll-626 a, and particle backscattering coefficient with maxima during winter. The relation be-627 tween chlorophyll-a concentration and fluorescence was complex during winter, and es-628 pecially during mission 0004. Seasonal varying slopes obtained from the linear regres-629 sions between chlorophyll-a and fluorescence could be related to changes in phytoplank-630 ton composition, as a response to the changes in temperature, nutrient concentration, 631 and irradiance. Indeed, an enhancement in the nutrient concentration in the euphotic 632 zone by vertical diffusion increased the phytoplankton biomass inside Poseidon LCE, which 633 is supported by the increase in  $b_{bp}$  700. Comparison between the MLD and the Svedrup's 634 critical depth suggests that low light during winter conditions is not a limiting factor for 635 most of the year but, it can occur during short lapses of time of 1-3 days given the cloudy 636 atmospheric surges. The present work is in good agreement with previous findings based 637 on numerical simulations, but new questions arise. The importance of top-down processes 638 in the regulation of phytoplankton standing stocks was not solved, and its assessment 639 continues to be a question mark in the ecosystem dynamics of the GoM during winter. 640

#### 6 Open Research

The data used in this work can be downloaded on the group website (https://gliders .cicese.mx/), for the review process, and access can be granted by request to the corresponding author and lead of the project EPS.

#### 645 Acknowledgments

This work was supported by the project "Florecimientos Algales en un Remolino de la 646 Corriente de Lazo" from Consejo Nacional de Humanidades, Ciencias y Tecnologías de 647 México (CONAHCyT), and from the program Hidrocarburos-SENER-CONACyT Con-648 sorcio de Investigaciones el Golfo de México under the project Implementación de re-649 des de observaciones oceanográficas (físicas, geoquímicas, ecológicas) para la generación 650 de escenarios ante posibles contingencias relacionadas a la exploración y producción de 651 hidrocarburos en aquas profundas del Golfo de México (CIGoM). Both projects are lead 652 by EPS and MT. AM was supported by CONAHCyT with a postdoctoral fellowship as-653 sociated to the CVU:516117. We acknowledged the contribution of all the staff of Grupo 654 de Monitoreo Oceanográfico con Gliders at CICESE, specially to Simo Cusí and Adrián 655 Villicaña for piloting underwater gliders, and to Johanna Saavedra for data management 656 of the glider's data. We acknowledge the effort of international agencies which give pub-657 lic access to satellite data used in this study. We are grateful to the European Space Agency 658

for allowing access to the version 5 of the ESA-CCI OC product. We are also grateful

to the National Aeronautics and Space Administration that give public access to the EPICS/DISCOVR

<sup>661</sup> irradiance data. During early versions comments made by Dr. Xiomara Márquez-Artavia

from Universidad Nacional de Costa Rica, helped to improve the work.
