Abstract

Carbon capture and storage (CCS) is forecast to play a significant role towards CO2 emissions reduction. Cost-effective and simplified monitoring will be essential for rapid adoption and growth of CCS. Seismic imaging methods are regularly utilized to monitor low-velocity anomalies generated by injection of CO2 in the subsurface. In this study we generate active and passive synthetic seismic datasets at different stages of CO2 injection in the subsurface based on geologically constrained subsurface models of the Pelican storage site in the Gippsland Basin, Australia. We apply full waveform inversion (FWI) and waveequation dispersion (WD) inversion to seafloor deployed distributed acoustic sensing (DAS) data to reconstruct the low-velocity anomalies. We model both strain (DAS) and displacement datasets for the active data component of the study and show that they

result in similar reconstruction of the CO2 anomaly. FWI based time-lapse imaging of active data yields the most accurate results. However, this approach is expensive and also suffers from complex issues because of the near-onshore location of the storage site. Alternatively inverting passive data results in only minor differences, but can still effectively monitor changes in the subsurface, and assist in monitoring the CO2 plume at the reservoir depth. Furthermore, we demonstrate the capability of WD for inverting Scholte-waves derived from ambient noise for shallow detection of CO2 in the unlikely event of a leakage. Therefore, we propose a mixed mode monitoring strategy where passive data is utilised for routine monitoring while active surveys are deployed only when further investigation is required.

13 Abstract

Carbon capture and storage (CCS) is forecast to play a significant role towards CO_2 emis-14 sions reduction. Cost-effective and simplified monitoring will be essential for rapid adop-15 tion and growth of CCS. Seismic imaging methods are regularly utilized to monitor low-16 velocity anomalies generated by injection of CO_2 in the subsurface. In this study we gen-17 erate active and passive synthetic seismic datasets at different stages of CO_2 injection 18 in the subsurface based on geologically constrained subsurface models of the Pelican stor-19 age site in the Gippsland Basin, Australia. We apply full waveform inversion (FWI) and 20 wave-equation dispersion (WD) inversion to seafloor deployed distributed acoustic sens-21 ing (DAS) data to reconstruct the low-velocity anomalies. We model both strain (DAS) 22 and displacement datasets for the active data component of the study and show that they 23 result in similar reconstruction of the CO_2 anomaly. FWI based time-lapse imaging of 24 active data yields the most accurate results. However, this approach is expensive and 25 also suffers from complex issues because of the near-onshore location of the storage site. 26 Alternatively inverting passive data results in only minor differences, but can still effec-27 tively monitor changes in the subsurface, and assist in monitoring the CO_2 plume at the 28 reservoir depth. Furthermore, we demonstrate the capability of WD for inverting Scholte-29 waves derived from ambient noise for shallow detection of CO_2 in the unlikely event of 30 a leakage. Therefore, we propose a mixed mode monitoring strategy where passive data 31 is utilised for routine monitoring while active surveys are deployed only when further in-32 vestigation is required. 33

³⁴ Plain Language Summary

Carbon capture and storage has been identified as a key technology to combat cli-35 mate change. The Pelican field in the Gippsland Basin, Australia has been identified as 36 a potential storage site for CCS. Cost-effcient, high fidelity, low impact monitoring of 37 the CO_2 plume would be essential for satisfying the regulations relating to measuring, 38 monitoring and verification of CO_2 storage. In this desktop study we use subsurface mod-39 els representative of the Pelican field to synthesize active and passive datasets. To make 40 the seismic monitoring more cost-effcient, high fidelity and low impact we explore the 41 use of distributed acoustic sensing (DAS) over conventional seismic sensors in this off-42 shore setting. We then use seismic imaging techniques to study the limits of these meth-43 ods to monitor the evolution of CO_2 plume stored underground as subsequent injections 44 take place. Our findings show that application of state of the art seismic imaging tech-45 niques to passive and active datasets, in a multifaceted fashion can optimize the costs 46 and environmental footprint associated with monitoring of CO_2 storage. 47

48 1 Introduction

Carbon capture and storage (CCS) has been identified as a key contributor towards
mitigation of climate change and the achievement of the net zero goal by 2050 (IEA, 2021).
CCS refer to the technologies that involve the capture of CO₂ from the environment or
industrial emissions, followed by the storage of the captured CO₂ at a secure and longlasting storage site. Under the CarbonNet project, the Pelican site in the Gippsland Basin
has been identified as a potential storage site (Hoffman, 2018) in Australia.

Long-term monitoring of CO_2 storage is crucial for safety and regulatory purposes 55 and therefore is essential for a functional CCS project (Glubokovskikh et al., 2016; Uro-56 sevic et al., 2011; Jenkins et al., 2015). A successful monitoring program is needed to 57 ensure conformance and containment of the injected CO_2 in the reservoir (Harvey et al., 58 2022). For subsurface CO_2 geological storage in offshore settings 4D timelapse seismic 59 survey have been used for CO_2 plume imaging and monitoring (Furre et al., 2017). Con-60 ventional 4D Marine control source seismic surveys with towed systems or ocean bot-61 tom nodes combined with full-waveform inversion (FWI) technology provide highly-resolved 62

images of the Earth's subsurface. This technology's efficacy has been successfully demonstrated on various CCS projects like Sleipner (Chadwick & Noy, 2015). Although conventional 4D seismic is capable of producing very accurate results it can be expensive,
environmentally intrusive and poses a logistically complex challenge as the Pelican site
lies in an off-shore/onshore transition zone.

More recently there have been rapid advancements in seismic acquisition using fibre-68 optic based sensors, also known as distributed acoustic sensing (DAS). DAS systems are 69 a cost-efficient way of deploying a permanent reservoir monitoring (PRM) system for long 70 71 term monitoring. DAS measures the strain/strain-rate measurement along the length of the fibre averaged over a gauge length (Ajo-Franklin et al., 2019). It is capable of pro-72 ducing broadband measurements that are densely sampled data in space and time, thereby 73 creating large volumes of data (Lindsey et al., 2017). Active surveys only make measure-74 ments during a limited period of time but progress has been made towards continuously 75 exciting sources combined with DAS as a recording system, which results in a truly per-76 manent reservoir monitoring system (Tsuji et al., 2021). DAS can also be utilized to record 77 passive seismic data which consists primarily of oceanic waves, anthropogenic sources 78 (traffic noise, etc.) and microseismic events. Virtual active data can be generated by ap-79 plying ambient noise processing workflows (Bensen et al., 2007) to the passive data. These 80 virtual data are usually rich in surface waves, which can be inverted to obtain a shal-81 low shear-wave velocity model. 82

In this work, we use wave-equation based inversion methods for imaging the sim-83 ulated CO_2 plume. These methods perform well when the data is rich in low-frequency 84 content and has dense raypath coverage. Availability of low-frequencies in broadband 85 DAS data can mitigate cycle-skipping and the requirement of an accurate starting model 86 can be relaxed. Additionally, densely spaced DAS sensors provide increased raypath cov-87 erage which can improve the image-resolution and makes the inversion well-conditioned. 88 Therefore, wave-equation inversion methods in theory should combine very well with off-89 shore DAS to produce high-quality subsurface images. 90

91 2 Methodology

92

96

105

2.1 Full Waveform Inversion for Time-Lapse Imaging

FWI has been used extensively to invert highly-resolved earth models from seismic data. In its naive implementation, it seeks out the subsurface model \mathbf{m} which minimizes the L_2 norm misfit between the observed d^{obs} and the predicted data $d(\mathbf{m})^{pred}$

$$J(\mathbf{m}) = \frac{1}{2} \sum \left(d(\mathbf{m})^{pred} - d^{obs} \right)^2.$$
(1)

FWI implementation and gradient derivation for conventional data recordings such as
displacement data are well known (Tarantola, 1986; Mora, 1987). When it comes to DAS
data which is a strain based measurement the formulation of FWI needs to be adapted
to account for strain which is essentially the gradient of the displacement field.

We simplify the DAS data to strain measuring point sensors and ignore the averaging effect over gauge length. A spectral-element based modelling engine Salvus was used for forward and inverse simulations. Isotropic wave equation shown below was used for forward modelling (Afanasiev et al., 2018)

$$\rho(\mathbf{x})\frac{\delta^2 \mathbf{u}(x,t)}{\delta t^2} - \nabla (2\mu(\mathbf{x})\epsilon(\mathbf{u}(\mathbf{x},t)) + \lambda(\mathbf{x})(\nabla \mathbf{u}(\mathbf{x},t))I) = f(\mathbf{x},t), \tag{2}$$

where u and $\epsilon(\mathbf{u})$ are the displacement vector and strain tensor fields, respectively and λ and μ are the Lamé parameters. DAS cables acquires the projected component of the strain sensor along the tangent-direction of the optical fiber given by ϵ_{tt} . Eaid et al. (2020) ¹⁰⁹ expressed the mathematical relationship as shown here:

121

135

139

 ϵ_{tt}

$$(s) = (\hat{\mathbf{e}} \cdot \hat{\mathbf{x}})^2 \epsilon_{xx} + (\hat{\mathbf{e}} \cdot \hat{\mathbf{y}})^2 \epsilon_{yy} + (\hat{\mathbf{e}} \cdot \hat{\mathbf{z}})^2 \epsilon_{zz} + 2(\hat{\mathbf{e}} \cdot \hat{\mathbf{x}})(\hat{\mathbf{e}} \cdot \hat{\mathbf{y}}) \epsilon_{xy} + 2(\hat{\mathbf{e}} \cdot \hat{\mathbf{x}})(\hat{\mathbf{e}} \cdot \hat{\mathbf{z}}) \epsilon_{xz} + 2(\hat{\mathbf{e}} \cdot \hat{\mathbf{y}})(\hat{\mathbf{e}} \cdot \hat{\mathbf{z}}) \epsilon_{yz}$$
(3)

In this equation $\hat{\mathbf{e}}(s)$ is the unit vector tangent to the fibre at s and \hat{x} , \hat{y} , \hat{z} are unit vectors along the orthogonal axes of a Cartesian coordinate system. For a horizontal fibre oriented along the $\hat{\mathbf{x}}$ direction would result in a tangent vector $\hat{\mathbf{e}} = \hat{\mathbf{x}}$ for all s along the fibre, which implies that ϵ_{xx} is effectively recorded at the DAS cables.

The optimization problem in equation 1 is solved using gradient-based methods (Nocedal & Wright, 2006). This is done by estimating the Frechét derivatives for different model parameters using the adjoint state method (Plessix, 2006). As the predicted and observed data in the DAS case is the tangential component (ϵ_{tt}) of the strain tensor, the backpropagated adjoint source needs modification. This adjoint source is a moment tensor source given by Yust et al. (2023) as

$$(\epsilon_{tt}{}^{pred} - \epsilon_{tt}{}^{obs})\hat{e}\hat{e}^T.$$
(4)

For a DAS cable lying on a flat seabed oriented along the \hat{x} direction the adjoint source from equation 4 simplifies to a moment tensor source with M_{xx} being the only non-zero component, with $M_{xx} = \epsilon_{xx}^{pred} - \epsilon_{xx}^{obs}$.

Time-lapse imaging relies on imaging of datasets (two-sets) acquired at different 125 stages of monitoring. Conventional time-lapse change can be evaluated by differencing 126 the inverted models from the baseline and monitor datasets. Gradient based methods 127 provide local minima as solutions, this can introduce uncertainties in time-lapse estima-128 tion due to the sensitivity of FWI convergence to starting models. This may lead to spu-129 rious time-lapse changes arising from convergence of the two inversions to unsuitable lo-130 cal minimas. A joint inversion alternative to conventional time-lapse inversion is the double-131 difference waveform inversion strategy proposed by Yang et al. (2016) to mitigate this 132 issue. This is a two-stage strategy which begins by inverting 133

• the baseline dataset to invert baseline subsurface model $\mathbf{m}_{\mathbf{base}}$

$$J(\mathbf{m}_{\mathbf{base}}) = \frac{1}{2} \sum \left(d_{base}^{pred}(\mathbf{m}_{\mathbf{base}}) - d_{base}^{obs} \right)^2, \tag{5}$$

where d_{base}^{obs} and d_{base}^{pred} are observed and predicted baseline datasets, respectively. The inverted baseline model \mathbf{m}_{base} is chosen as the initial model for minimizing a double-difference misfit to invert for baseline model \mathbf{m}_{mon} given as

$$J(\mathbf{m_{mon}}) = \frac{1}{2} \sum \left(\left(d_{mon}^{pred}(\mathbf{m_{mon}}) - d_{mon}^{obs} \right) - \left(d_{base}^{pred}(\mathbf{m_{base}}) - d_{base}^{obs} \right) \right)^2, \quad (6)$$

the two newly introduced data variables are observed (d_{mon}^{obs}) and predicted (d_{mon}^{pred}) monitor datasets. Alternatively, this misfit can be interpreted as a difference between the observed and predicted time-lapse data difference.

This approach is limited by the need for good repeatability between the two datasets. The method requires that the illumination from the raypaths remain the same, which is possible for active seismic surveys with carefully chosen source and receiver locations. However, this condition is rarely satisfied for natural events like microseismic events and earthquakes.

148 149

2.2 Wave-Equation Inversion of Passive Seismic Waves for Near Surface Imaging

In an offshore setting Scholte waves are generated at the water-sediment interface (seafloor) and these are dispersive in nature. This characteristic of Scholte-waves can be exploited to reveal the shallow S-wave velocity model of the shallow subsurface underneath the seafloor. Williams et al. (2021) utilize the dispersion curves obtained from ambient noise crosscorrelations to invert a 1D S-wave velocity structure using phase velocity inversion at different locations. Alternatively, Chen and Saygin (2022) used the waveequation based WD method described below to generate 2D shear-wave velocity images
and interpolated them to construct a 3D velocity model.

In the absence of low-frequencies and sufficiently accurate starting models the inversion can easily converge to a cycle-skipped local minima. A skeletonized attribute of seismic data is the dispersion curve extracted from the shot-gathers containing dispersive interface waves (surface and guided waves). Li et al. (2016) devised an optimization problem which searches for the best shear-wave velocity model by matching the observed and predicted dispersion curves, depicted as κ in the equation below

$$J(\mathbf{m}) = \frac{1}{2} \sum \left(\kappa_{\omega}^{obs} - \kappa_{\omega}(\mathbf{m})^{pred} \right)^2, \tag{7}$$

where κ_{ω}^{obs} and κ_{ω}^{pred} are the dispersion curves extracted form the observed and predicted data, respectively through a τ -p transform.

Using a simplified version of the data, dispersion curves, results in a smoother misfit surface, which makes the inversion process more robust, and it also avoids the simplified layered media assumptions of convention dispersion-curve inversion methods. We use WD method for inverting ambient noise crosscorrelations derived for simulated passive data recorded by DAS fibres. The underlying equations for the calculating the gradients using a connective function approach are given in Liu et al. (2022).

¹⁷³ **3** Numerical Examples

180

181

All numerical examples are based on velocity models derived from 3D seismic survey in the Pelican field. The Vp velocity model was derived from the active seismic survey Pelican 3D MSS (CarbonNet) 2018, the shear-wave velocity model was established using the $\frac{V_p}{V_s}$ ratio from well-logs in the area. The density values in non-water part of the model kg/m^3 were derived from the P-wave velocity model in m/s using the Gardner's relationship

$$\rho = 1000 \times (0.31 \times V_p^{0.25}). \tag{8}$$

3.1 Simulated 2D Active Reservoir Monitoring

The observed datasets were simulated for 21 shots placed evenly every 500 m be-182 tween 5 km and 15 km. These were recorded by 20 km long DAS cable lying on the seafloor 183 corresponds to 4001 sensors spaced at an interval of 5 m. DAS cable is oriented along 184 x-direction, so it records the ϵ_{xx} component of the strain tensor. We also record the sim-185 ulated data on conventional sensors recording u_x component of the displacement vec-186 tor field for comparison. All models are 20.8 km long in x-direction with a maximum depth 187 of 5.5 km. 2D isotropic elastic wave equation was modelled using spectral element method 188 for mesh sizes supporting a maximum frequency of 9 Hz. Figure 1 shows the acquisition 189 setup superimposed on the baseline and monitor velocity models. Initial injection of CO_2 190 leads to a 10% drop in V_p for the baseline survey, followed by further injection causes 191 increased saturation of CO_2 in existing areas results in further decrease in acoustic impedance, 192 but also leads to migration of the CO₂ plume to newer areas of the reservoir as depicted 193 by the difference of the monitor and baseline velocity models depicted in Figures 2 (a-194 b). 195

Initial model used for baseline FWI is the same as pre-injection FWI model shown in Figure 2a. As the baseline and monitor survey acquisition parameters remaining unchanged implies excellent repeatability, so we use the double-difference approach for estimating the time-lapse change through FWI. The inverted baseline anomaly and the

Figure 2. Anomalies introduced by addition of CO₂: true (a) baseline anomaly(difference between the baseline and pre-injection velocities) (b) true time-lapse change (difference between monitor and baseline velocities). Inverted baseline and time-lapse results for u_x data (c-d) and DAS data (e-f).

Figure 3. Double-difference displacement misfit at the (a) initial and (b) final iterations of the time-lapse inversion for u_x data. Double-difference DAS misfit at the (c) initial and (d) final iterations of the time-lapse inversion.

time-lapse change derived from u_x and DAS data are shown in Figures 2 (c-d) and Figures 2 (e-f), respectively. The results are in good agreement with each other, and therefore establishes the suitability of surface DAS cables as an alternative to conventional OBN sensors as a monitoring tool.

Figures 3 (a-b) and 3 (c-d) show the evolution of double-difference misfits (shot in 204 the center of the domain) for u_x and the DAS data, respectively. Final iteration misfits 205 for both datasets are much reduced from the initial point and majority of the model up-206 dates are driven by the intermediate and wide-angled reflections in the data. The DAS 207 data for the recorded P-waves, suffer from an obliquity factor of $\cos^2\theta$ which is stronger 208 than that of the horizontal component u_x by a factor of $\cos \theta$ (Lindsey & Martin, 2021), 209 therefore minimum angle threshold for a meaningful update is slightly greater for DAS 210 data. 211

212

3.2 Wave Equation Inversion of Simulated Passive DAS Data

The synthetic passive dataset consists of 50 ambient-noise recordings, each being 30 seconds long. The ambient noise records were synthesized using 3D isotropic elastic modelling with 10,000 randomly located sources which are excited with random timedelays for a maximum frequency of 3 Hz. These ambient noise records are recorded by a single 15 km long DAS cable lying on the flat sea-floor. The map view of the acquisition setup is depicted in Figure 4a. Even though a leakage is unlikely, to test the mon-

Figure 4. (a) Plan view of the ambient noise source and DAS cable. The orange line is the seafloor DAS cable and the blue dots represent the source locations.(b) The true V_s velocity model with the CO₂ leakage anomaly and (c) pre-leakage V_s velocity model (also the initial model for inversion).

itoring systems ability to detect CO₂ in shallow subsurface intervals we simulate a lowvelocity leakage anomaly of 5% as shown in Figure 4b. The model size is 15.2 km long and 1 km deep in x and z directions, respectively with a grid spacing of 20 m.

DAS records were crosscorrelated and then followed by normalization and stacking, with a 50% overlap between the ambient noise records. 350 virtual shot gathers (VSGs) are synthesized using the aforementioned workflow for WD inversion spaced at an interval of 40 m with a modified receiver spacing of 20 m. An example ambient noise record and a VSG are shown in Figures 5a and 5b, respectively. The VSG is able to reconstruct the Scholte waves fairly well, and the dispersive nature of these surface waves can be exploited by WD method.

The dispersion curves extracted from these VSGs serve as the observed dispersion 229 curve in equation 7. The pre-leakage model without the low-velocity anomaly shown in 230 Figure 4b is used as the initial model for WD inversion. After 25 iterations of WD we 231 arrive at a model which best matches the observed dispersion curve obtained from the 232 VSGs. The true CO_2 anomaly and the recovered CO_2 perturbation by WD method are 233 shown in Figure 6. The CO_2 anomaly is roughly reconstructed in the correct location 234 but it fades with depth due to the limited depth sensitivity of Scholte waves at this fre-235 quency band. 236

For quality control purposes, we examine the convergence in the dispersion curve domain. The dispersion curves were obtained by applying Radon transform to the Fourier transformed VSG. We only show frequency greater than 0.9 Hz portion of the dispersion curve for inversion, as the observed dispersion curve below this threshold was noisy

Figure 5. (a) Ambient noise record and the synthesized (b) virtual shot gather (VSG).

Figure 6. (a) True CO_2 leakage anomaly and (b) the recovered anomaly after 25 iterations of WD method.

Figure 7. (a) Observed dispersion curve and picks (red) from the VSG shown in Figure 5. Dispersion curves and picks (red) from modelled elastic shots using the (b)initial and (c) final models, respectively. (d) Dispersion curve comparison of the picked dispersion curves shows the convergence of the model.

leading to spurious picks. The observed dispersion curve picks derived from the VSG and
the initial model-based dispersion curve picks in Figures 7a and Figures 7b are shown
in green and red colours in the Figure 7d. Figure 7d illustrates that the effect of injecting CO₂ has been captured in the dispersion curve domain effectively. The final dispersion curve estimated from the WD inversion result (shown in blue) matches the observed
dispersion curve fairly well. This establishes that WD has converged to a suitable local
minima in the dispersion curve domain.

More importantly, this implies that the dispersion curve comparisons extracted from ambient noise cross-correlations derived from pre-leakage and post-leakage scenarios can aid in early detection of shallow leakages. A drop in shear wave velocity caused by leakage of shallow CO_2 could be substantial enough to cause a shift in the dispersion curve domain. On establishing this translation of dispersion curve towards lower velocities from the baseline curve, a more thorough inversion based investigation can be launched for imaging the simulated subsurface leakage spatially.

255

3.3 Time-Lapse FWI with Simulated Microseismic and Earthquake Events

In this section we demonstrate the usage of earthquake and microseismic events for monitoring the CO₂ plume within the reservoir in the subsurface. The model domain is 20.8 km and 8 km long in x and y directions, respectively with a maximum depth of

Figure 8. Focal mechanisms for (a) earthquake and (b) microseismic sources. Baseline (blue) and monitor (orange) source locations for (c) earthquake and (d) microseismic events. DAS cables on the seabed are shown in green.

5.5 km. 10 earthquake and 20 microseismic events were simulated for the synthetic ex-259 periment. Figures 8c and 8d show the baseline (in blue) and monitor (in orange) events 260 for earthquakes and microseismics, respectively. Earthquake and microseismic event source 261 location are chosen randomly with different random locations for the baseline and mon-262 itor inversions, implying that the time-lapse setup suffers from poor repeatability un-263 like the case of active experiment discussed previously. The earthquake and microseis-264 mic datasets were simulated for record lengths of 6 s and 10 s, respectively. The max-265 imum frequency for these elastic simulations was limited to 4 Hz. The source mechanism 266 for the microseismic events are a combination of a dominant double-couple (DC) with 267 a compensated linear vector dipole (CLVD) and an isotropic component (Kamei et al., 268 2015). For the earthquake events we use the focal mechanism of the Mw 5.9 Woods Point 269 Earthquake, the strongest earthquake recorded in the state of Victoria since the avail-270 ability of modern seismic instrumentation (Hoult et al., 2021). The base focal mecha-271 nism for the modelled earthquakes and microseismic sources are shown in Figures 8a and 272 8b, respectively. 273

The monitoring setup consists of 5 horizontal DAS cables (Figure 8(c-d) in green) oriented along the x-axis spaced at an interval of 200 m in y-direction, where each DAS cable consists of 800 channels spread at an interval of 20 m recording the ϵ_{xx} component of the strain field. This has been done to capture the 3D nature of the seismic wavefield and thus aid in more accurate monitoring of the plume as opposed to a single cable utilized in previous experiments.

280 2D slices of the 3D velocity models are shown in Figure 9, where the leftmost col-281 umn shows the pre-injection model (initial model for FWI), followed by the velocity mod-

Figure 9. 2D slices of the (a-c) pre-injection velocity model and (d-f) baseline and (g-i) monitor P-wave velocity models.

els used for generating the baseline and monitor datasets in the center and the rightmost columns, respectively. As shown previously, introduction of CO_2 leads to a drop in V_p values for both the baseline and monitor injections.

The perturbation caused by CO_2 baseline injection is emphasized in Figure 10 (ac), which is the difference between baseline (Figure 9 (d-f)) and pre-injection (Figure 9 (a-c)) velocity models. The ground-truth for the time-lapse change is shown in Figures 11 (a-c), and it is equivalent to the difference between the monitor (Figure 9 (g-i)) and baseline velocity models (Figure 9 (d-f)).

The earthquake locations are clustered at the edge of the model, we have chosen 290 the deepest allowable depths for the model ranging from 5 to 5.5 km. The magnitudes 291 of the simulated earthquakes vary between 2 to 4. In practice, natural earthquakes oc-292 curring in a chosen time-interval after the baseline and monitor injections take place. Con-293 ventional L2-norm FWI was used for inverting both baseline anomaly and time-lapse changes. 294 As the repeatability suffers from varying source locations in this case we use a sequen-295 tial approach as opposed to the double difference misfit used for the active case. In this 296 approach the final inverted baseline model is used as the initial guess for carrying out 297 FWI of the monitor dataset. The resulting baseline anomaly and time-lapse change cal-298 culated from earthquake data are depicted in Figures 10 (d-f) and 11 (d-f), respectively. 299 We are able to decipher the drop in P-wave velocity caused by the injection of CO_2 . Now 300 we try to evaluate the performance of FWI in presence of noise, where we add random 301 Gaussian noise to result in a datasets with a signal to noise ratio (SNR) of 5 dB. The 302 FWI results obtained from inversion of noisy earthquake datasets for the basline and time-303 lapse inversions are shown in Figures 10 (g-i) and 11 (g-i), respectively. Our results show 304 that despite the adverse effects of the random noise at the current noise level we can still 305 decipher the low-velocity anomaly induced by CO_2 injection. For increased noise levels 306 more robust FWI implementations can be used to overcome the challenge. 307

The magnitudes of the microseismic events range between 0.3 to 1, and are randomly distributed in all directions at the reservoir depth-level ranging from 1.5 to 2 km as opposed to a directional bias associated with earthquake locations. This leads to a more diverse raypath coverage in comparison to the earthquake scenario. Baseline and monitor events in this case refer to microseismic events that occur when CO₂ is introduced into the subsurface. Similar to the earthquake-scenario we employ a sequential baseline-monitor FWI strategy for inverting the monitor dataset. Inverted baseline anomaly

Figure 10. Ground truth for the true (a-c) baseline anomaly. Inverted 2D slices of baseline anomaly inverted from FWI of earthquake (d-f) and microseismic data (j-l). Baseline inversion results obtained from noisy earthquake (g-i) and microseismic datasets (m-o).

Figure 11. Ground truth for the true (a-c) time-lapse changes. Inverted 2D slices of the time-lapse change estimated from FWI of earthquake (d-f) and microseismic data (j-l). Time-lapse inversion results calculated from noisy earthquake (g-i) and microseismic datasets (m-o).

and time-lapse change models in Figures 10 (j-l) and 11 (j-l) highlight the low-velocity drop created during the two stages of the injection.

Analogous to the earthquake case we also ran a noise-sensitivity test for microseismic inversion with the a SNR of 5 dB. The inverted baseline and time-lapse results derived from noisy microseismic data shown in Figures 10 (m-o) and Figures 11 (m-o) are affected by the added noise, but we can still manage to locate the subsurface changes fairly accurately.

On observing the results derived from the earthquake and microseismic events, we can see that the inverted anomalies from microseismic events are better resolved in comparison to the inverted perturbations from the earthquakes. This is even more evident when we compare the noisy counterparts of the earthquake and microseismic inversion results. The aforementioned diversity of raypaths available for microseismic events leads to a better delineation of the baseline anomaly and the time-lapse changes relative to the subsurface images obtained from the earthquake dataset.

We also examine the data residuals for the four sets of time-lapse inversions corresponding to noisy and noise-free earthquake and microseismic datasets. We select two events each for microseismic and the earthquake scenarios and analyze the data residuals for the central DAS cables. The selected events and the recording DAS cable are highlighted for the earthquake and microseismic events in Figures 12a and 13a, respectively.

Figure 12 show the data residuals for noisy and noise-free earthquake datasets. FWI is fairly robust to the current noise level as seen by the model domain reconstructions and the data residual, coherent arrivals are well explained despite the addition of noise. Similar observations can be made from the data-domain residuals for the microseismic datasets shown in Figure 13.

340 4 Discussion

We show that time-lapse imaging using active seismic in an offshore setting is ca-341 pable of producing highly detailed images of the CO_2 plume in the subsurface as shown 342 by the example. Our results show that offshore DAS is a reliable alternative to conven-343 tional OBC/OBN sensors. A DAS based acquisition setup can be low-cost, environmen-344 tally adaptable and provides enhanced spatial coverage in comparison to conventional 345 seismic sensors (Gorshkov et al., 2022). Active seismic surveys can be repeated more re-346 liably than passive datasets, but they are expensive, difficult to carry out, and can be 347 environmentally invasive. 348

To overcome the challenges of active seismic surveys, we can use passive data recorded 349 by DAS sensors to image the subsurface. Our results show that it is possible to extract 350 useful information about the CO_2 plume using natural events such as earthquakes and 351 microseismic activity caused by the injection of the greenhouse gas. However, because 352 the occurrence of these events is random in nature, the time-lapse dataset we assemble 353 has poor repeatability. Another thing to keep in mind is that earthquakes are usually 354 spaced sparsely in time so the inversion result is representative of average subsurface CO_2 355 distribution during this time interval. Despite these shortcomings FWI inverted time-356 lapse estimates from microseismic and earthquake events provides useful information re-357 garding the subsurface changes with time. 358

By design, CCS sites are selected in areas of low seismicity, the Pelican site is no exception. Earthquakes are less likely to occur in the area as seismicity of the region was studied before selection of Pelican field as a storage site. A baseline passive seismic monitoring study (Attanayake et al., 2023) of the area revealed that no seismic activity was recorded within a 10 km radius of the site. Microseismic events are more likely to be recorded

Figure 12. Baseline initial and final data residuals for clean (a-b) and noisy earthquake data(c-d), followed by selected initial and final monitor data residuals (e-h).

Figure 13. Baseline initial and final data residuals for clean (a-b) and noisy microseismic data(c-d), followed by selected initial and final monitor data residuals (e-h).

when a fluid is injected into an underground reservoir. Around 1500 microseismic events 364 were detected in a space of three years at the In Salah storage site in Algeria, and these 365 occurrences coincided with increased injection rates (Oye et al., 2013). Glubokovskikh 366 et al. (2022) reported that low-pressure injection of CO_2 managed to induce detectable microseismic events of M_w 0.5 in the Otway project, Australia. A small fault was reac-368 tivated as the CO_2 plume passed through it, causing these events. Inaccuracies in locat-369 ing the microseismic hypocentres and earthquake epicentres in relation to depth uncer-370 tainties will effect the FWI imaging negatively. One can overcome that by incorporat-371 ing the source location into the FWI framework. Also, especially for microseismic events 372 additional information in the form of borehole DAS would aid in narrowing down on the 373 depth uncertainty of the microseismic hypocentre (Jones et al., 2014). 374

Virtual shot data derived from ambient noise cross-correlations of passive data can 375 be beneficial for monitoring the shallow subsurface for any potential leakages. Ambient 376 noise based shot gathers are rich in surface waves and these events are mostly sensitive 377 to shallow S-wave velocity structure. We exploit this feature to detect any shallow leak-378 ages in the example. Figure 7 shows an observable shift of the observed dispersion curve 379 (green) towards lower velocities in comparison to the dispersion curve corresponding to 380 the pre-injection shallow subsurface (red). This serves as a clear indicator of low-velocity 381 anomaly, which could be potentially be turned into a early-warning system for detection 382 of potential leakages. 383

All numerical examples in the study assume perfect coupling between the sea-floor 384 and the optical fibre. But in practice uneven coupling can persist across the DAS cable 385 arising from the undulating bathymetry leading to suspended cables in certain portions 386 of the optical fibre cable (Celli et al., 2023). These variations can cause distortions which 387 lead to recorded data with poor SNR. These discrepancies can be mitigated by burying 388 the cable a few meters below the sea-floor as done by Shinohara et al. (2022). Another 389 way to handle these distortions is by applying robust imaging methods which focus on 390 the kinematic or phase information stored in the waveforms, such as the traveltimes and 391 phase dispersion phenomena. WD method is used here is to overcome the reliance on 392 absolute amplitudes in the observed data and mitigating the effect of distortions on the 393 inverted results. The acquisition geometry setup of the DAS cables is pivotal in mon-394 itoring of the plume. Due to the broadside limitation of conventional DAS the measure-395 ments are sensitive to waves propagating along the cable, so for a horizontal cable ly-396 ing on the sea-floor most of the information of the CO_2 plume comes from diving or re-397 fracted events and wide-angle reflections. This may lead to poor detection of smaller CO_2 398 anomalies. There have been recent advances to overcome this limitation by utilising he-399 lical fibres which are able to sense a diverse range of arrivals (Kuvshinov, 2016). 400

401 5 Conclusions

We have developed a multifaceted monitoring workflow for CCS by combining pas-402 sive and active DAS data with wave equation imaging methods. We first validated that 403 the simulated DAS measurements can provide equivalent results to conventional geophones 404 by means of synthetic comparison. Then, we established that even with poor repeata-405 bility we can salvage sensible time-lapse estimates from passive data. By circumventing 406 the need for an active survey, we can reduce the monitoring costs and the associated en-407 vironmental footprint. Additionally, we have shown that the WD method can be used 408 to identify potential leaks in the shallow subsurface. Based on our results we recommend 409 a hierarchical approach to provide the most cost-efficient and lowest environmental foot-410 print solution for monitoring CO_2 in the subsurface. The passive datasets recorded us-411 ing DAS can serve as an early warning trigger should an unexpected change be detected. 412 This will then inform a more detailed monitoring response using targeted active seismic 413 surveys to further refine the timelapse estimate. 414

415 Open Research Section

The velocity models and well data used for this study can be downloaded from National Offshore Petroleum Titled Administrator website (https://nopims.dmp.wa.gov .au/nopims) under the survey named Pelican 3D MSS (CarbonNet) 2018. All time-lapse imaging synthetics were run on Salvus (Afanasiev et al., 2018). The notebooks used for generating the synthetic datasets and their corresponding inversions are provided here https://doi.org/10.5281/zenodo.10584281. The velocity model used for generating the synthetics is also shared on the aforementioned link.

423 Acknowledgments

This research was fully funded by the Deep Earth Imaging Future Science Platform, CSIRO. We are grateful to CSIRO HPC for providing us with access to their HPC resources for this project. This work was also supported by resources provided by the Pawsey Supercomputing Research Centre with funding from the Australian Government and the Government of Western Australia. The Carbonnet project team are thanked for the provision of 3D velocity models. We also acknowledge their thoughtful comments on the results of the study.

(a) Ambient noise record and the synthesized (b) virtual shot gather (VSG).

(a) True CO leakage anomaly and (b) the recovered anomaly after 25 iterations of WD method.

Figure 7. (a) Observed dispersion curve and picks (red) from the VSG shown in Figure 5. Dispersion curves and picks (red) from modelled elastic shots using the (b)initial and (c) nal models, respectively. (d) Dispersion curve comparison of the picked dispersion curves shows the convergence of the model.

leading to spurious picks. The observed dispersion curve picks derived from the VSG and
the initial model-based dispersion curve picks in Figures 7a and Figures 7b are shown
in green and red colours in the Figure 7d. Figure 7d illustrates that the e ect of injecting CO₂ has been captured in the dispersion curve domain e ectively. The nal dispersion curve estimated from the WD inversion result (shown in blue) matches the observed
dispersion curve fairly well. This establishes that WD has converged to a suitable local
minima in the dispersion curve domain.

More importantly, this implies that the dispersion curve comparisons extracted from ambient noise cross-correlations derived from pre-leakage and post-leakage scenarios can aid in early detection of shallow leakages. A drop in shear wave velocity caused by leakage of shallow CQ could be substantial enough to cause a shift in the dispersion curve domain. On establishing this translation of dispersion curve towards lower velocities from the baseline curve, a more thorough inversion based investigation can be launched for imaging the simulated subsurface leakage spatially.

- 255
- 3.3 Time-Lapse FWI with Simulated Microseismic and Earthquake Events

In this section we demonstrate the usage of earthquake and microseismic events for monitoring the CO₂ plume within the reservoir in the subsurface. The model domain is 20.8 km and 8 km long in x and y directions, respectively with a maximum depth of
