#### 13 Abstract

Some space weather models, such as the Space Weather Modeling Framework (SWMF) 14 used in this study, use solar wind propagated from the first Lagrange point (L1) to the 15 bow shock nose (BSN) to forecast geomagnetic storms. The SWMF is a highly coupled 16 framework of space weather models that include multiple facets of the Geospace envi-17 ronment, such as the magnetosphere and ionosphere. The propagated solar wind mea-18 surements are used as a boundary condition for SWMF. The solar wind propagation method 19 is a timeshift based on the calculated phase front normal (PFN) which leads to some un-20 21 certainties. For example, the propagated solar wind could have evolved during this timeshift. We use a dataset of 123 geomagnetic storms between 2010-2019 run by the SWMF Geospace 22 configuration to analyze the impact solar wind propagation and solar wind driving has 23 on the geomagnetic indices. We look at the probability distributions of errors in SYM-24 H, cross polar cap potential (CPCP), and auroral electrojet indices AL and AU. Through 25 studying the median errors (MdE), standard deviations and standardized regression co-26 efficients, we find that the errors depend on the propagation parameters. Among the re-27 sults, we show that the accuracy of the simulated SYM-H depends on the spacecraft dis-28 tance from the Sun-Earth line. We also quantify the dependence of the standard devi-29 ation in SYM-H errors on the PFN and solar wind pressure. These statistics provide an 30 insight into how the propagation method affects the final product of the simulation, which 31 are the geomagnetic indices. 32

<sup>33</sup> Plain Language Summary

Space weather models use measurements from spacecraft that measure the space 34 plasma heading towards Earth. The plasma can cause storms to occur in space. In an-35 ticipation of the plasma arriving at Earth, predictions are made using physics principles 36 about when the plasma will arrive at Earth. The assumption that the plasma has not 37 changed over time may cause inaccuracies in the model's final product, which is the pre-38 diction of the space storm's strength. We investigate the errors that may arise due to 39 these assumptions. We show the dependency on the errors to the methods used to pre-40 dict arrival times and strength of the space plasma. 41

#### 42 **1** Introduction

The modern society relies on space-based and ground-based technologies that are 43 susceptible to space weather hazards (National Research Council, 2008). Accurate and 44 timely space weather forecasts can mitigate risks associated with, for example, increased 45 errors in positioning and navigation applications, malfunctioning satellites and their sub-46 systems, or large-scale power failures caused by geomagnetically induced currents (GIC) 47 (Maynard, 1995). Such models that forecast these kinds of events, be they global mag-48 netospheric simulations or empirical models derived from observations, rely on observa-49 tions in the solar wind and/or in the magnetosphere–ionosphere system. While the re-50 quirements for model accuracy increase, it is important to review all potential error sources 51 in the input-output analyses. 52

A geomagnetic index is typically a summary of ground magnetometer observations 53 that can be used as a proxy of the global level of geomagnetic activity. The hourly Dis-54 turbance Storm-Time index Dst and its one-minute-cadence variant SYM-H are computed 55 as a weighted average of magnetic perturbations of mid-latitude magnetic stations (Sugiura, 56 1964; Iyemori, 1990), and give a proxy of the ring current intensity. On the other hand, 57 the polar cap index (PCI) is based on observations of a single ground magnetometer at 58 the Thule station, and is used as a proxy for the electric potential across the polar cap 59 (O. A. Troshichev et al., 1988). The Auroral Electrojet indices are aggregates of the min-60 imum (AL) or maximum (AU) observations made by a set of northern hemisphere high-61

<sup>62</sup> latitude ground magnetometer stations (Davis & Sugiura, 1966), and provide an estimate

of the westward and eastward electrojet current intensity, respectively. The interpretabil-

<sup>64</sup> ity of these indices and the wide availability of the data make them useful for model val-

idation, especially when the models can easily output corresponding time series.

Operationally, the National Oceanic and Atmospheric Administration (NOAA) Space 66 Weather Prediction Center (SWPC) predicts geomagnetic indices such as the Auroral 67 Electrojet (AE, AU and AL) and the Disturbance Storm-Time (Dst) by running global 68 magnetohydrodynamic (MHD) simulations, whose results can be used to compute cor-69 70 responding model indices (A. Pulkkinen et al., 2013). Generally, these models use ideal MHD coupled with modules representing processes in the ionosphere (Janhunen et al., 71 2012) and the inner magnetosphere (Toffoletto et al., 2003; Lyon et al., 2004; Gombosi 72 et al., 2021). The Space Weather Modeling Framework (SWMF) Geospace configuration 73 is a combination of models that represent the magnetosphere, inner magnetosphere and 74 ionosphere, and uses solar wind input and the solar radio flux  $(F_{10,7})$  to forecast geomag-75 netic geomagnetic activity (Tóth et al., 2012). 76

The solar wind input for the global MHD simulations is prepared from solar wind 77 observations that are typically obtained from spacecraft such as the Advanced Compo-78 sition Explorer (ACE) (Stone et al., 1998) and Wind (Wilson III et al., 2021) that or-79 bit close to the first Lagrangian point (L1). The solar wind observations are then prop-80 agated to the magnetospheric bow shock nose (BSN) to serve as inputs into the mod-81 els (A. Pulkkinen & Rastätter, 2009). This propagation is done to avoid running an MHD 82 simulation from L1 to the BSN, over a distance that is similar to the length of the en-83 tire magnetotail. Here we focus on one particular aspect of the propagation problem, the 84 accuracy of the empirically estimated time shift from the observing solar wind spacecraft 85 to the magnetopause. 86

87

#### 1.1 Model Validation through Geomagnetic Indices

M. W. Liemohn et al. (2018) discuss guidelines for model validation using geomag-88 netic indices SYM-H, AL, and AU. For prediction of geomagnetic indices, the study eval-89 uated the model accuracy using multiple criteria, which can be divided into fit metrics 90 or event detection performance metrics. The fit metrics include statistical evaluation of 91 the error defined as the difference between the model and the observed values. These met-92 rics include the root mean squared error (RMSE), the mean error (ME), and the mean 93 absolute error (MAE). Event detection performance metrics are binary evaluations of 94 the model ability to correctly assess whether an event would exceed a chosen index thresh-95 old. These metrics include skill scores such as the Heidke Skill Score (HSS), probabil-96 ity of detection (POD), and probability of false detection (POFD). 97

Many efforts have been undertaken to validate SWMF's ability to predict geomag-98 netic indices (Rastaetter et al., 2013; Haiducek et al., 2017; Welling et al., 2017; M. Liemohn 99 et al., 2018). SWMF has been shown to predict SYM-H well with an RMSE of 17–18 100 nT, when the ring current effects simulated by the Rice Convection Model (RCM) are 101 included. In the case of a pure MHD magnetosphere, the RMSE is almost double,  $\sim 29$ 102 nT (Haiducek et al., 2017). Rastaetter et al. (2013) studied the performance of 30 model 103 configurations regarding their ability to predict SYM-H, and showed that physics-based 104 models that include a ring current model are comparable to empirical or statistical mod-105 els, indicating that models such as the SWMF can predict magnetic disturbances at the 106 mid-latitudes associated with the ring current processes. 107

Several studies have also addressed the auroral latitude index predictions. The SWMF
has been shown to underpredict the magnitude of AL with RMSE of 230-270 nT (Haiducek
et al., 2017; Al Shidi et al., 2022; T. I. Pulkkinen et al., 2022). However, the skill scores
of SWMF are relatively good (HSS of 0.4-0.6) if a threshold value of 200 nT is used (Al Shidi

et al., 2022). This means although the model underpredicts the actual currents, it can still detect the times of auroral electrojet intensification during geomagnetic storms.

Finally, Morley, Brito, and Welling (2018) present robust accuracy metrics for the radiation belt electron flux predictions. An interesting outcome of that study is that they found the median absolute error (MdAE) to be a robust metric, while the MAE/RMSE in their data set was not. The signed median is of interest to this study, as it indicates whether a model is over/under-predicting, and is easy to interpret. These results led us to use the median error (MdE) for this study.

120

# 1.2 Solar Wind Propagation

Generally, the solar wind input for any input-output analyses relies on solar wind 121 observations propagated from L1 to close to the BSN. L1 monitors such as Wind or ACE 122 have orbits that can be as far as  $\sim 236$  Earth radii  $(R_E)$  from the Earth, and  $>100 R_E$ 123 away from the Sun-Earth line. There are multiple ways to propagate the solar wind the 124 200  $R_E$  to reach the vicinity of the Earth's magnetosphere – one way would be to run 125 an MHD simulation from L1 to the Earth and use that as input. However, in practice, 126 most applications use a time-delay technique based on 1-D propagation and the method 127 of characteristics (Weimer et al., 2003; Cash et al., 2016). 128

The propagation time is determined using the solar wind speed, distance to the ob-129 serving spacecraft, and by finding a phase front normal (PFN) that describes the orien-130 tation of the solar wind front that is approaching the Earth (see Figure 1). The PFN 131 can be found using several methods, such as the minimum variance analysis (MVA) tech-132 nique (Sonnerup & Scheible, 1998; Weimer et al., 2002) or the cross-product technique 133 (Horbury et al., 2001). Typically, a combination of these techniques are used, and this 134 is also what is used for the widely available propagated solar wind dataset in the OMNI 135 database (King & Papitashvili, 2023). 136

In Figure 1, we show a schematic drawing that shows the principle behind solar wind 137 propagation from L1 to the BSN. The axes are in the Geocentric Solar Ecliptic (GSE) 138 coordinate system with the Earth marked by a blue circle at the origin. The bow shock 139 enveloping the Earth is shown in brown. The black cross represents the location of the 140 L1 spacecraft observing the solar wind. The phase front normal ( $\hat{n}$  see calculation be-141 low) is shown by the the red arrow and the phase front is illustrated by the red dashed 142 line. The instantaneous solar wind measurement is propagated along the phase front line 143 to the location marked by a red cross. The velocity of the solar wind is shown as a blue 144 arrow at the propagated location. The position of the spacecraft relative to the BSN, r, 145 is represented as well as its components,  $\Delta x$  and  $\Delta y$ . In this 2-dimensional case  $\Delta y$  would 146 represent the perpendicular distance of the spacecraft to the Sun-Earth line. The uncer-147 tainty arises when from the assumption that the solar wind quantities at the measure-148 ment point can be propagated unchanged to the Earth and/or the satellite is in similar 149 conditions to the location being propagated. 150

While the solar wind and IMF parameters have their intrinsic uncertainties related to the measurement techniques, the uncertainties related to the time shifting to the bow shock create an additional source of (timing) errors. The time shift of the solar wind is calculated by considering a solar wind front detected at time t at an upstream spacecraft (at location  $r_{spacecraft}$ ), and assuming that it reaches the bow shock nose at time  $t + \Delta t$ . The transit time or timeshift  $\Delta t$  can be calculated by advecting the phase front normal plane using the equation

$$\Delta t_{arrival} = \frac{(\boldsymbol{r}_{BSN} - \boldsymbol{r}_{spacecraft}) \cdot \hat{\boldsymbol{n}}}{\boldsymbol{V} \cdot \hat{\boldsymbol{n}}},\tag{1}$$

where  $r_{BSN}$  is the location of bow shock nose, V is the solar wind velocity observed at L1, and  $\hat{n}$  is the shock phase front normal derived from the solar wind observations at the spacecraft location (see Figure 1 demonstrating the principle of the PFN advection).
 Errors of this propagation method will arise from errors in the solar wind speed, positioning accuracy of the spacecraft, as well as the evaluation of the PFN orientation.

Cameron and Jackel (2019) have shown that using a numerical simulation to propagate the solar wind can capture some features that the time shifting method cannot. Weimer et al. (2003) suggests that using the MVA technique to determine PFN is prone to some uncertainty based on the number of data points used. Several studies conclude that the errors in timing the arrival of the phase fronts can be of the order of several minutes (A. Ridley, 2000; Weimer et al., 2002, 2003; Mailyan et al., 2008; A. Pulkkinen & Rastätter, 2009; Milan et al., 2022).

Figure 1. A diagram (not to scale) showing a simplified version of how solar wind parameters are propagated from L1. The Earth is shown in blue at the origin of the GSE coordinate system, with the bow shock engulfing the magnetosphere oriented by the direction of the solar wind flow velocity V (blue arrow). The spacecraft situated upstream (black cross) observes a phase front plane (dashed red line; phase front normal  $\hat{n}$  is shown with the red arrow) The position rfrom the bow shock to the spacecraft has GSE components ( $\Delta x$ ) and ( $\Delta y$ ). The distance of the front plane from the bow shock along the solar wind flow direction is marked with a red x. The propagation time from the front plane to the bow shock is then determined by the distance of xto the bow shock and the solar wind speed.

This study focuses on the uncertainty and errors that are related with the solar wind 163 propagation. Specifically, we analyze the relationship between solar wind propagation 164 parameters (i.e PFN, time shift, spacecraft displacement from Sun-Earth line) to the fi-165 nal product of the simulation (geomagnetic indices). The aim is to statistically quantify 166 the errors and conditional distributions of the errors in order to have a better understand-167 ing of how SWMF performs based on the preparation of the measurements in the input. 168 We find the median errors, which show the tendency of the simulation to over/underestimate 169 geomagnetic indices, and the standard deviation of errors, which shows the spread of the 170 distribution of the errors. The following sections will focus on how we achieve this anal-171 ysis. 172

# 173 2 Methodology

#### 174

## 2.1 The SWMF Geospace Model

The SWMF Geospace configuration (Tóth et al., 2012) consists of three coupled models describing the different regimes in the global magnetosphere-ionosophere system (Gombosi et al., 2021). The Block-Adaptive-Tree-Solarwind-Roe-Upwind-Scheme (BATSRUS) code (Powell et al., 1993) solves the ideal magnetohydrodynamic equations in the solar wind

and magnetosphere regions. The model uses Adaptive Mesh Refinement (AMR) to re-179 fine the grid size in regions of large gradients or of special interest. The highest resolu-180 tion used for the simulations analyzed in this study was set to 1/8 Earth radii  $(R_E)$ , which 181 is mostly used in the inner magnetosphere and close to the magnetospheric boundaries. 182 The simulation box covers the region around the Earth with the x-axis spanning from 183  $-224 R_E$  in the magnetotail to  $32 R_E$  in the sunward direction, and the y and z-axes span 184 from  $-128R_E$  to  $128R_E$  in Geocentric Solar Magnetospheric coordinates. The Rice Con-185 vection Model (RCM) is an inner-magnetosphere model primarily used to account for 186 the effects of the ring current (Wolf, 1983). RCM solves bounce-averaged drift kinetic 187 equations for the particle populations on a polar grid (Toffoletto et al., 2003). RCM is 188 two-way coupled between BATSRUS and the the Ridley Ionosphere Model (RIM) iono-189 sphere. The coupling takes place every 10 seconds. BATSRUS supplies the electromag-190 netic fields to the RCM, and RCM nudges the plasma pressure to account for the ener-191 getic particle impacts for the BATSRUS inner magnetosphere region. RIM is a poten-192 tial solver for the ionosphere that solves the Poisson equation on a spherical grid (A. J. Ri-193 dley et al., 2004). It is coupled with RCM and the BATSRUS, and uses an empirical con-194 ductance model to find the electric field in the ionosphere. The coupling between BAT-195 SRUS with RIM happens every 5 seconds. BATSRUS supplies RIM with field-aligned 196 currents (FAC), which enables RIM to solve the electric potential using the conductance 197 model. 198

2.2 Simulation Runs

199

206

We ran 123 storms using SWMF in the Geospace configuration for a previous study of ground magnetometer observations (Al Shidi et al., 2022; Al Shidi & Pulkkinen, 2022). In this study, we use that dataset and its output of geomagnetic indices. The storms were selected based on having a minimum Dst stronger than -50 nT. Each storm was run for 54 hours in total, including 6 hours before the storm onset time and 48 hours thereafter. Thus, the dataset comprises a mix of quiet time, storm main and recovery phases.

2.3 Simulation Inputs

The storms were simulated with the SWMF Geospace model using the OMNI so-207 lar wind and interplanetary magnetic field (IMF) observations (N. Papitashvili et al., 2014) 208 as input for the simulation Sunward (upstream) boundary. The observations come from a collection of spacecraft, most of them located at or near the first Lagrangian point L1. 210 The solar wind observations are then propagated to the BSN to represent the solar wind 211 and IMF parameters encountered by the Earth's magnetosphere. We use the multi-spacecraft 212 solar wind parameter data as input into the model. Also, from OMNI, we use the hourly 213 average 10.7 cm solar radio flux  $(F_{10,7})$  as an input to RIM which uses it for its conduc-214 tance model (A. J. Ridley et al., 2004). 215

In this study, we use the IMF components in GSM coordinates  $(B_x, B_y, B_z)$ , the solar wind speed (V) and density (n) to get the solar wind dynamic pressure (p), solar wind electric field  $(E_y = -VB_z)$  and an empirical solar wind–magnetosphere coupling function (Newell et al., 2007)

$$\frac{d\Phi}{dt} = \alpha \left[ v^2 B_T \sin^4 \left(\frac{\theta}{2}\right) \right]^{2/3} \tag{2}$$

where  $\theta = \tan^{-1}(B_y/B_z)$  is the IMF clock angle and  $B_T = (B_y^2 + B_z^2)^{1/2}$  is the transverse component of the magnetic field perpendicular to the Sun-Earth line. The normalizing factor  $\alpha \sim 10^3$  provides conversion to units of Wb/s, which allows interpretation of the parameter as the rate of magnetic flux conversion at the dayside magnetopause (Newell et al., 2007). The dynamic pressure was chosen as a solar wind driving parameter because of its ability to affect SYM-H and AL (Zhao et al., 2021; O. Troshichev et al., 2022). The Newell coupling function is a good analogue that combines the IMF and
 flow pressure effects of the solar wind.

We use the 1-min cadence OMNI dataset which combines spacecraft solar wind observations propagated to the BSN as input to BATSRUS. When there are data gaps in the input, BATSRUS uses the previously given solar wind measurement. OMNI includes ACE and WIND measurements but does not include certain solar wind propagation parameters such as the PFN. Therefore, we use the separate propagated WIND measurements provided by NASA Space Physics Data Facility (SPDF) to collate missing parameters such as the phase front normal with the outputs.

#### 231 2.4 Simulation Outputs

Each storm simulation was configured to output geomagnetic indices including SYM-H, AL, AU, and the northern hemisphere polar cap index PCI, which can be used to derive an estimate for the Cross-Polar Cap Potential (CPCP) (A. J. Ridley & Kihn, 2004) in the form

$$CPCP = 29.28 - 3.31\sin(T + 1.49) + 17.81PCI,$$
(3)

where the time of year is specified as  $T = 2\pi (N_{MONTH}/12)$  with numbering of months starting from zero (Jan = 0).

To examine the errors in the local geomagnetic field prediction, the simulation out-234 put includes magnetic field perturbations  $\Delta \boldsymbol{B}$  at over a hundred ground magnetometer 235 station locations perturbations (the amount of stations depend on data availability at 236 the time) at 1-minute cadence (Al Shidi & Pulkkinen, 2022). The simulation output also 237 includes geomagnetic indices at 1-minute cadence derived from virtual ground magne-238 tometer perturbations in their respective latitude bands. The ground magnetic field is 239 calculated through a Biot-Savart integral from the inner boundary of the simulation through-240 out the simulation box (Gombosi et al., 2021). 241

#### 2.5 Error Analysis

242

The observations and simulation outputs are compiled to time series vectors  $y_{j,observed}$ and  $y_{j,model}$ , where  $y_j$  is the value of the geomagnetic index j (j = SYM-H, AU, AL, CPCP). The simulation prediction error at time  $t_i$  is then defined as

$$\epsilon_j(t_i) = y_{j,\text{model}}(t_i) - y_{j,\text{observed}}(t_i).$$
(4)

Using the time series of errors for each index, we then bin conditional probability distributions under different solar wind driving and propagation parameters,  $k = (E_y, d\Phi/dt,$ PFN, the perpendicular distance from the Sun-Earth line  $|\hat{x} \times r|, \Delta t\rangle$ , where  $r = r_{spacecraft} - r_{BSN}$ . Statistical analyses are then performed on these errors, such as calculating the median error and standard deviation. For both median and standard deviation, when a 95% confidence interval is presented, a bootstrapping method was used. The number of resamples chosen was 100 due to the large sample sizes, n, in the data.

#### <sup>250</sup> 3 Results and Analysis

This study focuses on the magnitude of the errors in the simulation output as com-251 pared to the observations for given solar wind input. We note that the solar wind driver 252 parameters used here are not independent, but reflect different characteristics of the in-253 coming solar wind. Specifically, we examine the intensity of the driving using the solar 254 wind electric field and the Newell et al. (2007) coupling function  $(E_y, d\Phi/dt)$ , which both 255 depend on solar wind velocity and magnetic field. Likewise, parameters associated with 256 solar wind front orientation and its propagation to the bow shock nose (see Figure 1, PFN) 257  $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{x}}, |\hat{\boldsymbol{x}} \times \boldsymbol{r}|, \text{ and timeshift } \Delta t)$  are functions of magnetic field orientation and solar 258 wind velocity. 259

Table 1 gives a quantitative summary of the median errors (MdE) and their 95%260 confidence intervals between the simulated and observed magnetospheric response pa-261 rameters CPCP, SYM-H, AL, and AU. The distributions of the errors are approximately 262 Gaussian with skewness  $(g_1)$  being  $-0.5 < g_1 < 0.5$  for all but the AL index. The 263 distributions of errors in AL is right-skewed ( $g_1 = 1.66$ ), which is consistent with pre-264 vious studies showing that the simulation has a tendency to underpredict the observa-265 tions (model value less negative than observed) (Haiducek et al., 2017; T. I. Pulkkinen 266 et al., 2022). A skewness test for each distribution results in a p-value of zero ( $p_{skew} =$ 267 0), which confirms they are skewed from the normal distribution. 268

Table 1. A quantitative summary of the overall error distributions for the geomagnetic indices. From left to right the columns give the geomagnetic parameter, the median error (MdE), the 95% confidence interval of the MdE, and the skewness respectively.

Parameter	MdE	$95\%~{\rm CI}$		Skewness
CPCP [kV]	3.27	3.15	3.41	-0.25
SYM-H [nT]	3.61	3.52	3.67	-0.22
AL [nT]	38.49	37.59	39.15	1.66
AU [nT]	6.53	6.20	6.86	0.30

#### 3.1 Univariate Analysis

In this section, we examine the probability distributions of the errors for each of 270 the driver parameters. Figures 2, 5, and 6 show the error probability distributions as a 271 functions of the driver parameters for each of the activity measures  $y_i$ . The error dis-272 tributions are computed for 10 ranges of the driver parameter values, and the figures show 273 the errors normalized for each driver value (vertical bin). The error distributions were 274 discretized into 50 bins. Normalization of each driver parameter bin means that the fig-275 ures do not give the absolute value of the error, but rather a distribution of the error mag-276 nitudes within that particular range of the driver parameter. 277

For more quantitative assessment of the SYM-H and AL indices, which are routinely 278 used for evaluation of model performance (M. W. Liemohn et al., 2018), we tabulate the 279 MdE and standard deviation of errors ( $\sigma_E$ ). The conditional bounds and limits to cal-280 culate the errors were chosen to encompass 95% of all the samples in the data set. Sec-281 tion 3.1.1 discusses the errors related to the global geomagnetic indices, while section 3.1.2 282 assesses the capability of the model to predict localized errors by examining magnetic 283 perturbations at two individual ground magnetometer stations, one at auroral and an-284 other at sub-auroral latitude. We focus mainly on the global geomagnetic indices errors. 285

286

#### 3.1.1 Global Geomagnetic Indices

The four panels in Figure 2 show the errors in the activity indices (from left to right) 287 SYM-H, CPCP, AL, and AU as a function of the intensity of the solar wind electric field 288  $E_{y}$  (top row) and the Newell et al. (2007) coupling parameter (bottom row). The errors 289 are mostly centered around zero. The error distributions widen in the polar cap poten-290 tial slightly both for strong driving (strongly positive  $E_y$ ) and for strong electric field 291 in a closed magnetosphere configuration (strongly negative  $E_y$ ). The SYM-H, AL, and 292 AU index errors have widest distributions for strong driving, with SYM-H and AU cen-293 tered around zero, but the AL errors strongly biased toward positive error (model un-294 derestimating the observed AL) typical of the Geospace simulation results (Haiducek et 295 al., 2017; Al Shidi et al., 2022; T. I. Pulkkinen et al., 2022). These trends are similar for 296

both solar wind driving functions (compare positive  $E_y$  on the top row and and the al-

ways positive coupling function in the bottom row for each of the indices).

**Figure 2.** From left to right: Binned probability distribution of errors in SYM-H, CPCP, AL and AU as a function of the (top) solar wind electric field and (bottom) the Newell coupling function at the bow shock nose. The driver parameters were binned into 10 bins, and the errors into 50 bins. Each driver bin is normalized to highlight the distribution of the errors rather than their magnitude.

Taking a closer look at the numbers, Table A1 shows the MdE and  $\sigma_E$  with their 299 95% CI. Figure 3 and Figure 4 provide a visual representation of the aforementioned Ta-300 ble. The number of samples in each bin of  $E_y$  values, n, is also included (note that the 301 bin ranges are asymmetric due to the choice of including 95% of all data in the analy-302 sis). For the SYM-H index, the median error is closest to zero for high solar wind driv-303 ing, while the error increases toward lower driving and has a strongly negative bias for 304 the strongly negative electric field (strongly positive IMF  $B_z$  and/or high solar wind speed). 305 This means that under those conditions, the model overpredicts SYM-H, which may be 306 an indication of the model's ability to reproduce the magnetospheric configuration un-307 der a closed magnetosphere conditions. On the other hand, the SYM-H error standard 308 deviation increases with larger solar wind driving. 309

The median error MdE of the AL index increases with increasing  $E_y$ , as does its 310 standard deviation  $\sigma_E$ : During the strongest solar wind driving  $(E_y > 6 \text{ mV/m})$ , the 311 MdE is 351.91 nT with the standard deviation  $\sigma_E$  being to 359.34 nT. This is a signif-312 icant difference from the overall AL error distribution where the MdE = 38.49 nT (see 313 Table 1). A 2-sample Kolmogorov-Smirnov test (KS test) (Hodges, 1958), which will test 314 how likely the overall distribution of errors  $(-\infty < E_y < \infty)$  and the error distribu-315 tion with the strongest solar wind driving  $(E_y > 6 \text{ mV/m})$  confirms these two distributions are from different distributions  $(p_{ks} = 1.1 \times 10^{-319})$ . The sample sizes are 316 317 173269 and 5592, respectively, and the KS statistic is 0.44. The small p-value is a reflec-318 tion on how the subsampling  $(E_y > 6 \text{ mV/m})$  of the parent distribution generates a 319 distinct distribution. 320

Figure 5, similarly to Figure 2, shows probability distributions of errors in (left to right) SYM-H, CPCP, AL, and AU in relation to (top to bottom) phase front normal (PFN,  $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{x}}$ ), spacecraft perpendicular distance ( $|\hat{\boldsymbol{x}} \times \boldsymbol{r}|$ ), and timeshift ( $\Delta t$ ). Examina-

Figure 3. From top to bottom, left to right, the blue line shows median errors calculated in bins for SYM-H and AL, with respect to  $E_y$ , PFN  $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{x}}$ , and spacecraft perpendicular distance. The orange bars show the 95% CI of the calculated medians for each bin.

tion of the error distributions of the global indices as a function of PFN shows that there is less dependence of the error distributions on the phase front orientation than on the solar wind driver function magnitude: The standard deviations and the medians are relatively similar for angles perpendicular and oblique to the sun-earth line (smaller and larger  $\hat{n} \cdot \hat{x}$ , respectively).

The error distributions in the geomagnetic indices as function of the perpendicu-329 lar distance of the spacecraft to the Sun-earth line  $(|\hat{x} \times r|)$  show mostly consistent 330 standard deviation throughout. However, there is a noticeable change in the medians (not 331 shown) for each given distance whose origin remains unclear. For example, calculating 332 Cohen's D for a SYM-H errors between the two ranges of (0, 20) Re and (80, 100) Re 333 gives a value of -0.48 which shows a medium-sized effect of half a standard deviation be-334 tween the two. Lastly, we examine the effect of the time shift  $\Delta t$  from the spacecraft lo-335 cation to the bow shock nose. Noting that most of the OMNI observations come from 336 spacecraft at or near L1, higher values of  $\Delta t$  imply slower solar wind and the lower val-337 ues imply high solar wind speed. Alternatively (referring to Figure 1), higher values of 338  $\Delta t$  imply close to perpendicular PFN angles and smaller propagation times imply more 339 oblique PFN orientation. The error distributions for all parameters are slightly larger 340 for low time shifts (high solar wind speed, oblique fronts). The polar cap potential and 341 the AU index show very little variation across the range of values in  $\Delta t$ . 342

Table A2, Figure 3, and Figure 4 show a summary of the corresponding numerical values. The bounds were chosen to correspond to Figure 5, but including fewer bins to maintain readability. Table A2 shows the number of samples and the bin sizes, the

Figure 4. From top to bottom, left to right, the blue line shows standard deviation of errors calculated in bins for SYM-H and AL, with respect to  $E_y$ , PFN  $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{x}}$ , and spacecraft perpendicular distance. The orange bars show the 95% CI of the calculated standard deviation for each bin.

median error MdE and standard deviation  $\sigma_E$  with their 95% CI conditional to phase front normal (PFN  $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{x}}$ ) and the perpendicular distance from the spacecraft location to the Sun-Earth line ( $|\hat{\boldsymbol{x}} \times \boldsymbol{r}|$ ).

The SYM-H MdE and its 95% CI decreases when the PFN is closer to the Sun-Earth 349 line, from 9.52 nT in its most oblique orientation to 1.05 nT in cases where the front is 350 close to perpendicular to the Sun-Earth line. The uncertainty in the median at the most 351 oblique angles could be caused by lack of samples (n = 192) (see Table A2), but the 352 trend can still be seen with smaller CI widths of around  $\sim 0.4$  nT in the next bin 0.2 <353  $|\hat{\boldsymbol{n}}\cdot\hat{\boldsymbol{x}}| < 0.4$ , which has a much larger sample size (n = 17664). However, the standard 354 deviation  $\sigma_E$  increases when the PFN projects closer to the Sun-Earth line from 13.78 355 nT to 18.19 nT. Thus, both the errors and standard deviation show a conditional depen-356 dence on the PFN, which may be related to the fact that the oblique fronts are almost 357 in the direction of the solar wind velocity. 358

The next section of Table A2 shows the errors in AL conditional to the PFN  $|\hat{n} \cdot \hat{x}|$ . The dependence of the errors seems relatively weak. The overall distribution MdE and its 95% CI from Table 1 is 38.49 [37.59, 39.15] nT. The MdE conditional to PFN are relatively close to that with the closest distribution being 37.86 [36.16, 38.81] nT, which has some overlap in their CI. Again, the uncertainty in the median (the MdE CI width) is larger than the rest when  $\hat{n} \cdot \hat{x} < 0.2$  (55.18 nT to  $\sim 3$  nT). This is likely due to the

Figure 5. From left to right: Binned conditional probability distribution of errors in SYM-H, CPCP, AL and AU as a function of the (top) the PFN projection to the x axis  $(\hat{x} \cdot \hat{n})$ , (middle) the perpendicular distance from the Sun-Earth line  $(|\hat{x} \times r|)$ , and (bottom) time shift to the bow shock nose  $\Delta t$ . The driver parameters were binned into 10 bins, and the errors into 50 bins. Each driver bin is normalized to highlight the distribution of the errors rather than their magnitude.

smaller sample size, the large uncertainty when the PFN angle is so oblique to the Sun Earth line, or a combination of both.

We then discuss the effects of the perpendicular distance of the spacecraft to the BSN. The third section of Table A2 shows the SYM-H errors conditional to the perpendicular distance. A conditional dependence is especially noticeable when the distance is  $< 20R_E$ . The MdE in the  $< 20R_E$  case suggests that SWMF is in these cases overpredicting SYM-H, as opposed to the more typical underprediction (MdE = -4.16 [-4.77, -3.61] nT). The  $\sigma_E$  stays relatively constant ( $\sim 17$  nT) and becomes larger in the case of the closer distance ( $< 20R_E$ ), to 20.52 [20.27, 20.82] nT.

The MdE of the AL index shows a similar trend to that of SYM-H, as shown in the right most sub-figures of Figure 3 and bottom section of Table A2. In the  $< 20R_E$ case, the MdE becomes smaller (from ~ 40 nT to 14.86 [12.14, 16.59] nT). However, unlike the SYM-H, the standard deviation also becomes smaller, reducing from ~ 210 nT to 187.76 [182.43, 198.50] nT. In both SYM-H and AL cases, however, we note that the smallest distance bin has a factor of 3-5 smaller sample size.

The table and figure summaries confirm a conditional dependence between propagation parameters (PFN and perpendicular distance) and MdE and/or  $\sigma_E$ . We note here that the errors analyzed are errors in magnitude between the observed and simulated values, not errors related to timing. Perhaps the most noteworthy result is for the <sup>384</sup> smallest spacecraft perpendicular distance from the Sun-Earth line ( $< 20R_E$ ). In that <sup>385</sup> case, both SYM-H and AL errors show a marked change in behavior. The conclusion from <sup>386</sup> Figure 5 suggesting that stronger solar wind driving leads to a larger spread in errors <sup>387</sup> (larger  $\sigma_E$ ) is quantitatively confirmed by the standard deviations and their confidence <sup>388</sup> intervals given in Table A2.

#### 3.1.2 Local Magnetometer Recordings

The analysis in the previous section focused on global geomagnetic activity as de-390 scribed by the geomagnetic indices. In order to study the localized effects, in this sub-391 section, we examine the role of each of the driver parameters in generating errors at in-392 dividual magnetometer stations. We select two representative stations, Yellowknife, Canada 393 (YKC) in the auroral latitudes recording both eastward and westward ionospheric elec-394 trojets (Lyatsky et al., 2006), and Boulder, CO, USA (BOU), at the mid-latitude range 395 that mostly reacts to the ring current and field-aligned currents coupling the magneto-396 sphere and ionosphere (Dubyagin et al., 2014). The errors computed use the observed 397 and simulated ground magnetic perturbations horizontal (magnitude of northward and 398 eastward components) to the Earth's surface. 399

The four panels in each row of Figure 6 shows the error probability distributions 400 for each of the driver parameters  $(E_y, d\Phi/dt, \hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{x}}, \text{ and } |\hat{\boldsymbol{x}} \times \boldsymbol{r}|)$  for YKC at the top 401 and BOU at the bottom panel. Note that due to the very different scales of the signals 402 (the auroral zone magnetometers record variations in the 100s of nT, whereas the mid-403 latitude stations typically record variations of the order of 10s of nT), the horizontal scales 404 are different for the two stations. The local individual recordings show similar dependence 405 on the driver parameters to the aggregated global indices, although the error distribu-406 tions in the perpendicular component are narrower than those of the global indices (see 407 also Table A3). Note, however, that for the solar wind driver functions the horizontal 408 components are centered around zero error. This result is consistent with the detailed 409 analysis of individual stations by Al Shidi et al. (2022), who concluded that the errors 410 for the north and east components are typically larger than the total horizontal compo-411 nent. As the geomagnetic indices are based on the north component records, any errors 412 in that will translate to errors in the indices. Furthermore, the stations show an increase 413 in standard deviation for strong driving in the closed magnetosphere configuration (strongly 414 positive  $E_y$ ). Neither station show a dependence of the standard deviations on either the 415 phase front normal or the perpendicular distance to the Sun-Earth line. 416

The results of this section were meant to illustrate the more localized effects of solar wind propagation and driving. The primary motivation of this study is the geomagnetic indices errors that are a summary of individual stations like these. The YKC station is a station that can be used to find AL or AU. The BOU station is a station that can be used to find Dst or SYM-H. We show that solar wind driving has a dependence on the standard deviations of the  $B_H$  errors.

#### 3.2

423

389

#### 3.2 Regression Analysis

In order to study the relationship between the solar wind parameters and the simulation errors, we perform a linear regression analysis to examine how the errors change with the varying inputs. We determine the regression coefficients,  $b_k$ , where k is the offaxis distance of the spacecraft to the BSN ( $|\hat{x} \times r|$ ), the PFN projection on the Sun-Earth line ( $|\hat{n} \cdot \hat{x}|$ ), solar wind driving electric field analogues  $VB_y$ , and  $VB_z$  and lastly the solar wind dynamic pressure (p). We then compute the Standardized Regression Coefficients ( $SRC_{jk}$ ) to determine the magnitude of the effect of a solar wind quantity k on the errors for each geomagnetic index j. The SRC is given by the equation

$$\mathrm{SRC}_{jk} = \frac{\sigma_k}{\sigma_j} b_k,\tag{5}$$

Figure 6. From left to right: Binned probability distribution of errors the horizontal magnetic field at (top) YKC and (bottom) BOU as a function of the solar wind  $E_y$ , the Newell coupling function  $d\Phi/dt$ , the PFN projection to the x axis  $(|\hat{x} \cdot \hat{n}|)$ , and the perpendicular distance from the Sun-Earth line  $(|\hat{x} \times r|)$ . The driver parameters were binned into 10 bins, and the errors into 50 bins. Each driver bin is normalized to highlight the distribution of the errors rather than their magnitude.

where  $\sigma$  is the standard deviation of the solar wind parameter k or activity index error 424 j. The SRC is a measure of how much of the standard deviation in the errors can be at-425 tributed to the standard deviation in the inputs. This allows us to make a relational in-426 ference between the solar wind inputs and activity index errors, and to directly compare 427 across the parameters as the SRCs are unitless. Table 2 shows the SRCs found for each 428 solar wind input and geomagnetic index error and the SRC confidence intervals. 429

Table 2. Table of the SRC and their 95% confidence intervals in brackets. From top to bottom the rows are the geomagnetic index errors of SYM-H, CPCP, AL and AU, respectively. The columns from left to right are the off-axis distance of the spacecraft  $(|\hat{x} \times r|)$ , the PFN projected on the Sun-Earth line  $(\hat{n} \cdot \hat{x})$ , solar wind drivers  $VB_y$ ,  $VB_z$ , and flow pressure p, respectively.

Driver	SYM-H	CPCP	AL	AU
$ \hat{m{x}}  imes m{r} $	$0.077 \ [0.074, \ 0.082]$	$0.018 \ [0.013, \ 0.022]$	$0.005 \ [0.001, \ 0.010]$	$0.021 \ [0.017, \ 0.025]$
PFN $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{x}}$	$0.123 \ [0.117, \ 0.128]$	$0.105 \ [0.100, \ 0.109]$	$0.018 \ [0.014, \ 0.022]$	$0.013 \ [0.008, \ 0.017]$
$VB_y$	$0.017 \ [0.012, \ 0.022]$	$0.095 \ [0.088, \ 0.102]$	$0.312 \ [0.307, \ 0.316]$	$0.480 \ [0.475, \ 0.486]$
$VB_{z}$	$0.153 \ [0.148, \ 0.160]$	$0.109\ [0.101,\ 0.117]$	$0.294 \ [0.289, \ 0.299]$	$0.066 \ [0.060, \ 0.074]$
Pressure $\boldsymbol{p}$	$0.293 \ [0.288, \ 0.299]$	$0.071 \ [0.058, \ 0.083]$	$0.098 \ [0.090, \ 0.104]$	$0.008 \ [0.001, \ 0.016]$

430 431

The SRCs show that the standard deviation in the errors of SYM-H relates strongest to the standard deviation in pressure with an SRC of 0.293. It also suggests relationships with the PFN and  $VB_z$  with SRC's between ~0.1–0.2. Interestingly, the SRC of the space-432 craft off-axis distance,  $|\hat{\boldsymbol{x}} \times \boldsymbol{r}|$ , is strongest with SYM-H when compared with the other 433 indices. The standard deviation of errors in AL have strongest dependence on the stan-434 dard deviations in solar wind driving  $VB_y$  and  $VB_z$  with SRC ~0.3. We note that the 435

relation of AL and AU to the propagation parameters  $|\hat{x} \times r|$  and  $\hat{n} \cdot \hat{x}$  are relatively weak (SRC~0.01–0.02).

Through the SRC analysis, we can conclude that the standard deviations in solar wind propagation parameter  $|\hat{x} \times r|$  and  $\hat{n} \cdot \hat{x}$  does have a connection to the SYM-H, and  $\hat{n} \cdot \hat{x}$  to the CPCP as they both have an SRC of around 0.1. This is in contrast to other indices such as AL and AU, whose SRCs are an order of magnitude smaller (~0.01). We can also conclude that the electric field components  $VB_y$  and  $VB_z$  shows a strong relationship with AL (SRC 0.3). This is to be expected, as it is widely accepted that there is a correlation between solar wind electric field and AL (e.g., O. Troshichev et al., 2022).

#### 445 4 Discussion

This study focuses on the analysis of the magnitude and probability distribution 446 of errors between observations of geomagnetic indices and their predictions using the Space 447 Weather Modeling Framework Geospace simulation. The errors can arise either from in-448 accuracies in the measurement (measurement errors), errors in the predicted magnitude 449 with the correct driver profile (model error), or errors in timing of the arrival of the so-450 lar wind and IMF at the bow shock nose. The dataset is over-represented by storm-time 451 data, however, this is a conscious choice to evaluate the performance of SWMF during 452 storm time specifically and not dominate the analysis with quiet time conditions. For 453 a dataset that includes a month long of data which includes quiet time intervals, please 454 see M. Liemohn et al. (2018). 455

Our results indicate that the median errors show a dependence on the geometric 456 parameters such as the phase front normal angle or the perpendicular distance from the 457 Sun-Earth line of the observing spacecraft, while the widest distributions of the errors 458 are obtained for high solar wind driving and high dynamic pressure. An earlier study 459 (A. J. Ridley, 2000) demonstrated that the uncertainty in timing between measurements 460 at L1 with WIND and closer to the BSN with the spacecraft IMP 8 can be on average 461 7.5–8.5 minutes. However, their study was limited to the solar wind, and did not assess 462 the impact of these timing errors on the errors in geomagnetic indices, which have their 463 own intrinsic time scales as they respond to the variable solar wind driving. More recently, Milan et al. (2022) found that the correlation of peaks in the cusp field-aligned currents 465 observed by the AMPERE satellites with IMF  $B_y$  deteriorates with larger perpendicu-466 lar distance of the solar wind monitor from the Sun-Earth line. Furthermore, they find 467 an average time lag of about 17 minutes between the solar wind front arrival at the bow 468 shock nose and the response caused by the front in the ionosphere. The simulation is ex-469 pected to also respond with the same time lag and follow the same processes which makes 470 calculating errors on the same minute fair. BATS-R-US has been shown in the past its 471 ability to recreate the global circulation pattern (Gordeev et al., 2011). 472

The nonlinear relationship between the solar wind inputs and the geomagnetic in-473 dex errors poses limitations to the regression analysis performed in Section 3.2. The value 474 of the regression analysis is in its ability to address the relationship between the stan-475 dard deviations of both input and output simultaneously, characterized by the standard-476 ized regression coefficients. The fact that the SRC of the spacecraft perpendicular dis-477 tance in relation to the errors is relatively small could be due to the lack of standard de-478 viation in the spacecraft orbit. The spacecraft flies a steady path and that path's stan-479 dard deviation is truly independent to the standard deviation in the errors. 480

We note that this study does not address errors in propagation time. We believe it is important for solar wind monitor measurements to publish error bars as that could strengthen studies like this and provide better insight as to the origins of certain errors, specifically measurement uncertainty. Inputs such as  $F_{10.7}$  would provide better detail if we are provided error bars. Further investigations into the cause of the errors would <sup>486</sup> require better metadata for the observational inputs and outputs: Neither the geomag-

<sup>487</sup> netic indices nor the space-borne solar wind measurements and propagation times come

with uncertainty estimates or error bars. Such parameters would be necessary to under-

stand how the uncertainties propagate from the input to the output measurements, and

would be valuable for uncertainty quantification and validation of space weather forecasts.
 Lacking these, Morley, Welling, and Woodroffe (2018) attempted to quantify the uncer-

tainty of measurement errors in the solar wind input by ensemble modeling with SWMF,

and showed that using ensemble modeling can improve the mean error of SYM-H by a

494 few nT.

521

#### 495 5 Conclusion

We present the conditional dependence of the SWMF Geospace simulation errors in geomagnetic indices (as compared to observed ones) of the solar wind driver and propagation (from L1 to bow shock nose) parameters. Based on a large simulation dataset, we draw the following conclusions of SWMF behavior during geomagnetic storm times:

- 1. The standard deviation of the errors is generally dependent on the intensity of the driving, such that stronger driving (larger  $E_y$ ) produces larger standard deviations in SYM-H and AL errors. This implies that the errors are known to lesser accuracy during strong geomagnetic activity.
- 2. We show that there is a dependence of the median error (MdE) on the phase front normal angle and spacecraft perpendicular distance from the Sun-Earth line. The MdE for both SYM-H and AL decreases when the perpendicular distance is  $< 20R_E$ . An interesting detail is that the SYM-H that typically is underpredicted by the model (observed values show higher activity than the simulation), shows the opposite behavior when the perpendicular distance is  $< 20R_E$ .
- 3. The standard deviations of the errors are more dependent on the intensity of the solar wind driving,  $E_y$ , than on the solar wind propagation parameters, such as PFN and spacecraft perpendicular distance to the Sun-Earth line.
- 4. Using standardized regression coefficients, we show the dependence of the error standard deviations on the inputs. We confirm that there is a relationship between the standard deviations in the phase front normal (PFN) with the standard deviations in SYM-H, and an even stronger relationship between the flow pressure and SYM-H standard deviations.
  - 5. Perhaps not surprisingly, the standard deviations in the electric field components  $VB_y$  and  $VB_z$  show the strongest relationship with standard deviations in AL. The standardized regression coefficients provide a (unitless) measure of the degree to which the solar wind parameters impact the errors.

For future studies, we propose a multivariate approach: The phase front normal 522 (PFN) and solar wind monitor locations are not direct inputs into the simulation, and 523 are not necessarily orthogonal to the real inputs. It would be interesting to see the de-524 pendence of the errors with PFN during stronger solar wind driving. Furthermore, a more 525 3-dimensional approach instead of only investigating projections to the Sun-Earth line 526 might provide valuable insights of the spatial structuring of the solar wind and its im-527 pacts on solar wind – magnetosphere coupling. We believe the different components, el-528 liptical and zenithal, of the distances can contribute to errors in the geomagnetic indices. 529

Table A1. Statistics of the (top) SYM-H and (bottom) AL errors [nT] conditional to  $E_y$  [mV/m]. From left to right the columns give the number of samples in driver  $(E_y)$  bin of the geomagnetic parameter (SYM-H or AL), the bounds of the driver bin, the median error (MdE), the 95% confidence interval of the MdE, the standard deviation and its 95% confidence interval, respectively.
