Abstract

Wave ripples can provide valuable information on their formative hydrodynamic conditions in past subaqueous environments by inverting dimension predictors. However, these inversions do not usually take the mixed non-cohesive and cohesive nature of sediment beds into account. Recent experiments involving sand–kaolinite mixtures have demonstrated that wave-ripple dimensions and the threshold of motion are affected by bed clay content. Here, a clean-sand method to determine wave climate based on orbital ripple wavelength has been adapted to include the effect of clay and a consistent shear-stress threshold parameterisation. Based on present-day examples with known wave conditions, the results show that the largest clay effect occurs for coarse sand with median grain diameters over 0.45 mm. For a 7.4% volumetric clay concentration, the range of possible water-surface wavelengths and water depths can be reduced significantly, by a factor of three and four, respectively, compared to clean sand.

12 **Key Points:**

13 - Wave-ripple dimensions provide important information on past subaqueous environments

14 - Here, a clean-sand method is adapted for clay-sand mixtures by incorporating the effect
15 of changes in the threshold of motion and dimensions

16 - Clay can result in a reduction in the range of past water-surface wavelengths and water
17 depths, which is largest for coarse sand

Abstract

Wave ripples can provide valuable information on their formative hydrodynamic conditions in past subaqueous environments by inverting dimension predictors. However, these inversions do not usually take the mixed non-cohesive and cohesive nature of sediment beds into account. Recent experiments involving sand–kaolinite mixtures have demonstrated that wave-ripple dimensions and the threshold of motion are affected by bed clay content. Here, a clean-sand method to determine wave climate based on orbital ripple wavelength has been adapted to include the effect of clay and a consistent shear-stress threshold parameterisation. Based on present-day examples with known wave conditions, the results show that the largest clay effect occurs for coarse sand with median grain diameters over 0.45 mm. For a 7.4% volumetric clay concentration, the range of possible water-surface wavelengths and water depths can be reduced significantly, by a factor of three and four, respectively, compared to clean sand.

Plain Language Summary

In shallow water, ripples form on the seabed under water-surface waves due to friction. Knowledge of this process allows preserved ripples to be used to infer past environmental conditions. Traditionally, the method of inferring past environments from wave ripples has only involved sand, despite mixtures of sand and sticky mud being more common in nature. Based on the results of recent mixed sand–mud experiments, the effect of including small amounts of mud in the analysis is shown to be an important modifying factor in determining past environments.

1 Introduction

Bed-surface structures in sediments and sedimentary rocks of past subaqueous environments provide important information on flow hydraulics (e.g. Collinson & Mountney, 2019). These structures tend to be classified on the basis of the presence or absence of cohesion in equivalent modern environments: (a) cohesive structures, associated with physical cohesion by clay particles and biological cohesion by extracellular polymeric substances (e.g. biofilms, Vignaga et al., 2013), where the bed is stabilised by cohesion between grains and sudden catastrophic failure may occur under high bed shear stress, e.g. during storms; and (b) non-cohesive bedforms (e.g. wave and current ripples: Wiberg & Harris, 1994; Baas, 1994), where grains can move individually and tend to respond more rapidly and continuously to changes in flow forcing (Perron et al., 2018). Examples of these types of bed-surface structure include roll-ups (Cuadrado, 2020) and non-cohesive wave ripples (e.g. Allen, 1981). Davies (2016) argued that the distinction between cohesive and non-cohesive sedimentary structures is artificial, as they represent end members of a spectrum, and thus predictions based on one classification may result in misinterpretations. This position is re-enforced by recent experiments that have shown how sandy bedforms can be affected by small amounts of biological and physical cohesion (Malarkey et al., 2015; Parsons et al., 2016; Wu et al., 2018; 2022). The consequence for wave ripples of physical cohesion associated with kaolin clay in the bed has been detailed by Wu et al. (2024). Building on the work of Allen (1981), Diem (1985) developed a clean-sand analytical method for the prediction of paleowave climate based on the dimensional measurement of wave ripples in the rock record (Aspler et al., 1994; Wetzel et al., 2003; Allen & Hoffman, 2005; Pochat & Van Den Driessche, 2011, Lamb et al., 2012). Here, Diem's (1985) approach is adapted for sand–clay mixtures, using the synthesis proposed by Wu et al. (2024).

60   Diem's (1985) approach starts by determining the wave orbital diameter from the ripple
61 wavelength, without requiring a specific wavelength predictor. Here, the formulation starts as
62 Diem (1985) did, with linear wave theory and additional constraints based on threshold of
63 motion and wave breaking. It will then return to the effect of clay on ripple-wavelength
64 prediction and the threshold of motion. The importance of clay content is demonstrated with the
65 use of present-day examples from the laboratory and field, where the wave conditions were
66 known.

67 **2 Diem's (1985) method**

68 2.1 Linear wave theory

69 In linear wave theory, the dispersion relation and the wave-velocity amplitude, U_0, are

$$\sigma^2 = gk\tanh kh, \quad U_0 = \pi d_0/T, \tag{1a,b}$$

70 where $\sigma = 2\pi/T$, T is the wave period, g is the acceleration due to gravity (= 9.81 m s^{-2}), $k = 2\pi/L$,
71 L is the water-surface wavelength, h is the water depth, d_0 is the orbital diameter (= $H/\sinh kh$)
72 and H is the wave height. The wave properties, characterised by eqs. (1a,b), are subject to two
73 constraints:

74 2.1.1 Threshold of motion

75 U_t, the critical wave-velocity amplitude associated with the threshold of motion, is a function of
76 d_0 and D_{50}, the median grain diameter. For sediment movement $U_0^2 > U_t^2$, which when combined
77 with eqs. (1a,b) gives

$$x < \tanh kh, \tag{2}$$

78 where $x = L/L_{t\infty}$ and $L_{t\infty} = \frac{1}{2}\pi g(d_0/U_t)^2$ is the deep-water surface wavelength corresponding to the
79 threshold of motion.

80 2.1.2 Wave breaking

81 According to Miche (1944), the wave-breaking criterion defines the maximum possible wave
82 steepness as, $H/L \le 0.142\tanh kh$, which when combined with d_0 and $L_{t\infty}$ gives

$$x \ge A\cosh kh, \tag{3}$$

83 where $A = d_0/0.142L_{t\infty} = U_t^2/(0.071\pi g d_0)$. It will be shown below that $A < \frac{1}{2}$, so if $A =$
84 $\frac{1}{2}(U_t/U_m)^2$, where $U_m = (0.0355\pi g d_0)^{1/2}$ is the maximum wave-velocity amplitude ($U_m > U_t$), then
85 $U_t < U_0 \le U_m$ and from eq. (1b) $\pi d_0/U_m \le T < \pi d_0/U_t$.

86 Eqs. (2) and (3) represent the range of possible conditions between threshold and wave breaking
87 for the wave climate. The limits of these constraints can be found by combining eqs. (2) and (3)
88 using the identity $1-\tanh^2 kh = \operatorname{sech}^2 kh$, such that the maximum and minimum in x satisfy the
89 equation $x^4 - x^2 + A^2 = 0$, so that $x_{\max,\min}$ are

$$x_{\max,\min} = [\tfrac{1}{2} \pm \tfrac{1}{2}(1 - 4A^2)^{1/2}]^{1/2}, \tag{4}$$

90 where $A < \frac{1}{2}$, for there to be two distinct values. Here, x and kh are in the ranges $x_{\min} \le x < x_{\max}$
91 and $\text{arctanh}x < kh \le \text{arccosh}(x/A)$, respectively.

92 Figure 1 shows kh versus x for the limiting single-value case where $U_m^2 = U_t^2$ ($A = \frac{1}{2}$, $x = 2^{-\frac{1}{2}}$
93 and $kh = \text{arctanh}2^{-\frac{1}{2}} \sim 0.88$) from shallow water ($kh \ll 1$) to deep water ($kh \gg 1$). Figure 1 also
94 shows the $A = \frac{1}{4}$ case ($U_m^2 = 2U_t^2$), corresponding to typical above-threshold wave conditions. In
95 the latter case, the shaded region in Figure 1 shows the allowable values of x ($\frac{1}{4}\cosh kh \le x <$
96 $\tanh kh$) and the dots mark $x_{\max,\min} = \frac{1}{2}(2\pm3^{\frac{1}{2}})^{\frac{1}{2}}$ and $kh_{\max,\min} = \text{arctanh}(x_{\max,\min})$. The breaking-
97 wave curves ($x = A\cosh kh$) are concave downward and the threshold curve ($x = \tanh kh$) is
98 concave upward. Notice for the breaking-wave curves, $x \to A$ for $kh \ll 1$ and A also controls the
99 slope for larger kh. In dimensional terms, the water-surface wavelength, L, is therefore limited by
100 the threshold scale ($L_{t\infty}$) and breaking-wave scale ($AL_{t\infty}$) according to $AL_{t\infty} < L \le L_{t\infty}$. Then, from
101 eqs. (2) and (3), the range of h can be expressed as a function of L as

$$(L/2\pi)\text{arctanh}(L/L_{t\infty}) \le h \le (L/2\pi)\text{arccosh}(L/AL_{t\infty}). \tag{5}$$

102 2.2 The ripple predictor

103 Diem's (1985) central assumption is that the orbital diameter can be expressed in terms of an
104 equilibrium ripple wavelength, λ_e, as

$$\lambda_e = \alpha_0 d_0, \tag{6}$$

105 where $\alpha_0 = 0.65$, based on Miller and Komar's (1980) experiments, provided that $\lambda_e < 200$ mm
106 ($d_0 = 308$ mm). Above this limit, Diem (1985) proposed the use of Sleath's (1975) predictor.
107 This arbitrary 200-mm limit represents the lower boundary of the suborbital and anorbital ranges,
108 where the wavelength is dependent on both d_0 and D_{50} for suborbital ripples and only dependent
109 on D_{50} for anorbital ripples. However, while a value of α_0 in the range $0.5 \le \alpha_0 \le 0.75$ in eq. (6) is
110 widely accepted, there is little agreement in the literature on the precise nature of the orbital,
111 suborbital, and anorbital limits. Wiberg and Harris (1994) defined orbital, suborbital and
112 anorbital ripples by $d_0/D_{50} \le 1754$, $1754 < d_0/D_{50} \le 5587$ and $d_0/D_{50} > 5587$, respectively
113 (Malarkey & Davies, 2003), whereas Mogridge et al. (1994) and Pedocchi and García (2009)
114 argued the anorbital limit should have wave-period dependence. Provided that eq. (6) *does* hold,
115 which is what will be assumed here, all quantities involving d_0 can now be expressed in terms of
116 λ_e.

117 **3 Adaptions to Diem's (1985) method**

118 3.1 Threshold of motion parameterisation

119 Based on Soulsby's (1997) critical threshold of motion for clean sand, Appendix A derives an
120 expression for U_t^2, eq. (A2), such that U_t^2, $L_{t\infty}$ and $AL_{t\infty}$ can be written

$$U_t^2 = B(gd_0^{0.52}D_{50}^{0.48}), \quad L_{t\infty} = \frac{\pi}{2B}\left(\frac{d_0^{1.48}}{D_{50}^{0.48}}\right), \quad AL_{t\infty} = \frac{d_0}{0.142}, \tag{7a,b,c}$$

121 where $B = 3.653(s-1)\theta_0$, s is the relative density of sediment in water (eq. A1), θ_0 is the critical
122 skin friction Shields parameter (eq. A1), and $d_0 = \lambda_e/\alpha_0$ from eq. (6). Diem (1985) used Komar
123 and Miller's (1973) mobility threshold prescription. Here, Soulsby's expression has been used,
124 as it allows U_t^2 to be directly related to θ_0 and it avoids the need for two different functional
125 forms, for $D_{50} < 0.5$ mm and $D_{50} \ge 0.5$ mm (eqs. (B1) and (B2)).

3.2 Inclusion of the effect of clay

Wu et al. (2024) showed that the ratio of wavelength to orbital diameter, α, which replaces α_0 in eq. (6), can be expressed as

$$\alpha = \alpha_0 \times \begin{cases} 1, & C_0 \leq C_{0m}, \\ 1 - 5.5(C_0 - C_{0m}), & C_0 > C_{0m}, \end{cases} \tag{8}$$

where α_0 is the clean-sand constant of proportionality (= 0.61), C_0 is the clay content in the bed and $C_{0m} = 7.4\%$ is the minimum value of C_0 where α can change from α_0, and $\alpha = \frac{1}{2}\alpha_0$ for $C_0 = 16.3\%$. Whitehouse et al. (2000) showed that the threshold of motion is enhanced by the clay content according to

$$\theta_{0E} = \theta_0 B_\theta, \tag{9}$$

where θ_0 is the clean-sand threshold, $B_\theta = 1 + P_\theta C_0$ and P_θ is a constant that depends on the sediment properties. Based on their experiments, Wu et al. (2024) determined that $P_\theta = 6.3$ for $D_{50} = 0.143$ mm and $P_\theta = 23$ for $0.45 \leq D_{50} \leq 0.5$ mm (between these two ranges, it will be assumed that P_θ can be linearly interpolated). Notice in eq. (9) that even small amounts of clay produce an enhancement which is strongly dependent on grain size.

Thus, the two main effects of including clay are that α is reduced and θ_{0E} is increased. Substituting eqs. (8) and (9), into eqs. (7a,b,c) gives U_t^2, $L_{t\infty}$ and $AL_{t\infty}$ as

$$U_t^2 = B\left[\frac{B_\theta}{\alpha^{0.52}}\right](g\lambda_e^{0.52}D_{50}^{0.48}), \quad L_{t\infty} = \frac{\pi}{2B[B_\theta\alpha^{1.48}]}\left(\frac{\lambda_e^{1.48}}{D_{50}^{0.48}}\right), \quad AL_{t\infty} = \frac{\lambda_e}{0.142[\alpha]}, \tag{10a,b,c}$$

where λ_e is the mixed clay–sand ripple wavelength and only the square-bracketed quantity in each expression depends on C_0.

3.3 The method

The method begins with the determination of the ripple wavelength, λ_e, and bed-clay content, C_0. Once these have been determined, the following calculations are undertaken:

(i) Use λ_e and C_0 in eqs. (10a,b,c), with α and B_θ given by eqs. (8) and (9), to determine U_t, $L_{t\infty}$ and $AL_{t\infty}$

(ii) Use A in eq. (4) to determine $x_{max,min}$, so that $x_{min} \leq x \leq x_{max}$

(iii) Use $L = L_{t\infty}x$ to determine the range of h based on eq. (5) and U_t and $U_m = (0.0355\pi g\lambda_e/\alpha)^{1/2}$ to determine the ranges of U_0 and T: $U_t < U_0 < U_m$ and $\pi\lambda_e/\alpha U_m < T < \pi\lambda_e/\alpha U_t$

4 Example cases

With specific examples from the rock record, Diem (1985) was able to show how local considerations and context could be used to further limit the theoretical ranges described in the previous section. Here, modern-day examples, where the wave properties are known, are used, so that attention can be focussed on the effect of clay on the theoretical ranges alone. The example cases correspond to clean, coarse-, medium- and fine-grained sand from the laboratory and field, and involve determining how wave conditions based on the measured ripples change if the clay content is varied in the range $0 \leq C_0 \leq 16.3\%$.

4.1 Wu et al. (2018), coarse-sand laboratory data

159   Wu et al. (2018) conducted a series of experiments involving a single-wave condition over a bed
160   composed of well-sorted coarse sand, $D_{50} = 0.496$ mm ($\theta_0 = 0.032$), and varying clay content, $0 \le$
161    $C_0 \le 7.4\%$. For the clean sand experiment ($C_0 = 0\%$), the wave conditions were given by $h = 0.6$
162   m, $H = 0.16$ m and $T = 2.49$ s ($L = 5.62$ m), corresponding to $d_0 = 0.223$ m. This experiment
163   produced ripples with a wavelength $\lambda_e = 278D_{50}$ (Wu et al., 2024). Figure 2a show the threshold
164   and wave-breaking scales, $L_{t\infty}$ and $AL_{t\infty}$, versus C_0. $L_{t\infty}$, which is smallest at $C_0 = 7.4\%$, has a
165   much larger range than $AL_{t\infty}$, which is constant for $C_0 \le 7.4\%$ and then doubles up to $C_0 =$
166   16.3%. Figure 2d shows the corresponding L-h phase space, based on eq. (5), for the clay
167   contents depicted in Figure 2a ($C_0 = 0$, 7.4 and 16.3%). Compared to the dimensionless x–kh plot
168   (Figure 1), the threshold curves are still concave downwards, but more exaggerated, and the
169   breaking-wave curves are close to straight lines. The change in ranges is largely due to changes
170   in $L_{t\infty}$. The reduction in range between the largest and smallest (corresponding to $C_0 = 0\%$ and
171   7.4%) is by a factor of 3 and 4 for the water-surface wavelength and water depth, respectively
172   (Figure 2d). Notice that the actual surface wavelength and water depth ($L = 5.62$ m, $h = 0.6$ m)
173   are within all three ranges. Figures 2a,d can be compared with Figures B1a,b to see the effect of
174   using the Komar and Miller (1973) clean-sand mobility description for the threshold. This shows
175    $L_{t\infty}$ to be about 63% of its value in Figure 2a, because $B = 0.21(s–1) = 0.34$ as opposed to
176    $3.653(s–1)\theta_0 = 0.19$. Thus, using Diem's (1985) clean-sand mobility description underpredicts
177   the range of water-surface wavelengths and heights in an absolute sense. In a relative sense, the
178   change in the ranges of clay content is similar, because the powers of d_0 and D_{50} are similar (eq.
179   (B2), for $D_{50} < 0.5$ mm, and eq. (10a)), but this will not be the case for $D_{50} > 0.5$ mm. Also, the
180   measured L and h are not within the $C_0 = 7.4\%$ range (Figure B1b). As L and h are below the
181   threshold curve, this would imply that ripples of this size are relict for this clay content. This is
182   inconsistent with the experimental results, since Wu et al. (2024) showed no reduction in λ_e for
183    $C_0 \le 7.4\%$.

184   4.2 Doucette (2000), medium-sand field data

185   Doucette's (2000) field measurements were taken on a microtidal beach of Wambro Sound (run
186   1) where $h = 0.47$ m, $H = 0.2$ m and $T = 5.6$ s ($L = 11.9$ m), corresponding to $d_0 = 0.79$ m. The
187   bed was composed of medium sand, with $D_{50} = 0.22$ mm ($\theta_0 = 0.045$), and the measured ripples
188   had a wavelength of $\lambda_e = 250$ mm. Since $d_0/D_{50} = 3591$, the ripples were in the suborbital range
189   (see section 2.2), where the wavelength is dependent on both the orbital and grain diameters.
190   Notice this wavelength is above Diem's (1985) 200-mm limit. The supporting information
191   demonstrates that, whilst using Sleath's (1975) predictor for $C_0 = 0$ produces a difference, it is
192   similar to the other two example cases, which are below Diem's (1985) limit, and so is not
193   considered significant. From interpolation, P_θ in eq. (9) is determined to be 10. Figure 2b shows
194    $L_{t\infty}$ and $AL_{t\infty}$ versus C_0 and Figure 2e shows the L–h phase space, for $C_0 = 0$, 7.4 and 16.3%.
195   These reveal similar behaviour to that of the coarse-grained sand case, but less extreme: in
196   Figure 2b, $L_{t\infty}$ is still at its minimum at $C_0 = 7.4\%$ and $AL_{t\infty}$ shows the same enhancement as in
197   Figure 2a. The reduction in range between the largest and smallest ($C_0 = 0\%$ and 7.4%) is by a
198   factor of 2 for both the water-surface wavelength and water depth (Figure 2e). Again, the actual
199   surface wavelength and water depth ($L = 11.9$ m, $h = 0.47$ m) are within all three ranges.

200   4.3 Boyd et al. (1988), fine-sand field data

201   Boyd et al.'s (1988) field measurements were undertaken about 1 km from Martinique Beach on
202   the Atlantic coast of Nova Scotia during a period of relative calm (day 167, hour 9) where $h = 10$

203 m, $H = 0.5$ m and $T = 6.2$ s ($L = 50.7$ m), corresponding to $d_0 = 0.32$ m. The bed was composed
204 of well-sorted fine sand, with $D_{50} = 0.11$ mm ($\theta_0 = 0.076$), and the measured ripples had a
205 wavelength of $\lambda_e = 180$ mm. $d_0/D_{50} = 2873$ puts the ripples into the suborbital range. Assuming
206 that P_θ in eq. (9) is the same as for 0.143 mm ($P_\theta = 6.3$), Figure 2c shows $L_{t\infty}$ and $AL_{t\infty}$ versus C_0
207 and Figure 2f shows the L–h phase space, for $C_0 = 0$, 7.4 and 16.3%. $L_{t\infty}$ in Figure 2c is still at its
208 minimum at $C_0 = 7.4\%$, but, because of far weaker clay enhancement of the threshold for fine
209 sands in eq. (9), $L_{t\infty}$ is largest for $C_0 = 16.3\%$. In Figure 2f, the measured water-surface
210 wavelength and water depth ($L = 50.7$ m, $h = 10$ m) are below the threshold curve and outside
211 the range for the $C_0 = 0$ and 7.4% clay contents, and just above the threshold curve and within
212 range for $C_0 = 16.3\%$, because, unlike the previous cases, $C_0 = 16.3\%$ produces the largest $L_{t\infty}$.
213 Since there was little clay at the field site, the wave conditions were probably below threshold,
214 implying that the observed ripples were relict. This is supported by the fact that Boyd et al.'s
215 (1988) previous observation at day 167, hour 3, showed the same wavelength and no ripple
216 migration. The reduction in range between the largest and smallest ($C_0 = 16.3\%$ and 7.4%) is
217 again by a factor of 2 for both the water-surface wavelength and water depth (Figure 2f).

218 **5 Discussion**

219 The range of L shown in Figure 2 is largely controlled by $L_{t\infty}$, so it is of interest to determine
220 how the change in clay content affects $L_{t\infty}$, eq. (10b), compared to the original clean-sand Diem
221 method using Komar and Miller (1973), $L_{t\infty KM}$, eq. (B2) with $C_0 = 0\%$. The net effect is shown as
222 a ratio in Figure 3 for $C_0 = 0$, 7.4 and 16.3% and $0.1 \leq D_{50} \leq 0.8$ mm, for the approximate limits
223 in the range of λ_e/D_{50} of 250 and 1,000. There are two competing effects: the reduction because
224 of clay content (Figure 2) and the increase because of using Soulsby's (1997) threshold condition
225 rather than Komar and Miller's (1973). Figure 3 shows a discontinuity for clean sand at $D_{50} = 0.5$
226 mm as a result of eq. (B2), leading to the largest difference ($L_{t\infty}$ is increased by up to 161% for
227 $\lambda_e/D_{50} = 250$), which decreases with increasing λ_e/D_{50} (although Diem's (1985) method has
228 rarely been applied for $D_{50} > 0.5$ mm). Otherwise for $D_{50} \leq 0.19$ mm, $L_{t\infty}$ is reduced by up to
229 36%, and for $0.19 < D_{50} \leq 0.5$ mm, $L_{t\infty}$ is increased by up to 64%. For $C_0 = 7.4\%$, $L_{t\infty}$ is
230 consistently decreased by between 35 and 56%, and for $C_0 = 16.3\%$, $L_{t\infty}$ varies only slightly
231 (increased by up to 14%, for $0.12 \leq D_{50} \leq 0.37$ mm, and otherwise reduced by up to 15%). The
232 absence of a discontinuity in the present formulation, compared to Diem's (1985) original
233 formulation, is clearly preferable. Also, the net effect of the clay on $L_{t\infty}$ will be stronger for
234 smaller than for larger clay contents.

235 It is important to clarify how a representative clay content, C_0, for the ripples should be
236 determined. In the modern environment this usually involves measuring C_0 below the active
237 layer (below trough level), as efficient winnowing often removes clay from the body of the
238 ripples during development (Wu et al., 2022). In the geological record, clay content in deposits
239 should be based on primary clay minerals and diagenetic alterations for which it can be
240 established that the original mineral was part of the primary clay fraction.

241 **6 Conclusions**

242 Preserved sedimentary bedforms provide important information for reconstructing past
243 hydraulics in subaqueous environments by inverting bedform predictors, but this is usually based
244 exclusively on non-cohesive sand. The present work incorporates the effects of sand-clay
245 mixtures on bedforms, using the experimental results of Wu et al. (2024) in the non-cohesive

246 inversion method of Diem (1985). Based on wave breaking and threshold of motion limitations,
247 Diem's (1985) approach results in ranges for wave conditions. Here we have shown that the
248 inclusion of as little as 7.4% clay in the most extreme case of coarse sand, $D_{50} \geq 0.45$ mm,
249 reduces the possible ranges of water-surface wavelengths and water depths by factors of 3 and 4,
250 respectively. For fine sand, the ranges are reduced by a factor of two. In short, not accounting for
251 the modifying effect of clay in ripple growth and equilibrium geometries, may lead to
252 underestimating the prevailing flow conditions if clay is present.

Appendix A: Determination of U_t^2 based on Soulsby (1997)

254 According to Soulsby (1997), the Shields parameter for the critical threshold of motion of clean
255 sand is

$$\theta_0 = \frac{0.3}{1+1.2D_*} + 0.055(1-e^{-0.02D_*}), \tag{A1}$$

256 where $D_* = [(s–1)g/\nu^2]^{1/3}D_{50}$, $s = \rho_s/\rho$, ρ_s and ρ are the water and sediment densities and ν is the
257 kinematic viscosity (~ 1 mm^2 s^{-1}). For waves, $\theta_0 = f_w U_t^2/2(s–1)gD_{50}$, where $f_w = 1.39(6d_0/D_{50})^{-0.52}$
258 is the skin friction factor (Soulsby et al., 1993). Rearranging the θ_0 wave expression gives U_t^2 as

$$U_t^2 = B(gd_0^{0.52}D_{50}^{0.48}), \tag{A2}$$

259 where $B = 6^{0.52}(s–1)\theta_0/0.695 = 3.653(s–1)\theta_0$. Eq. (A2) can be compared with eq. (B1).

Appendix B: Diem's (1985) threshold of motion constraint

261 Diem (1985) used the Komar & Miller (1973) expression for U_t^2, namely

$$U_t^2 = (s-1)g \times \begin{cases} 0.21(d_0^{0.5}D_{50}^{0.5}), & D_{50} < 0.5 \text{ mm}, \\ 0.46\pi(d_0^{0.25}D_{50}^{0.75}), & D_{50} \geq 0.5 \text{ mm}, \end{cases} \tag{B1}$$

262 such that with the inclusion of clay $L_{t\infty} = \pi g d_0^2/2B_\theta U_t^2$, $d_0 = \lambda_e/\alpha$ and B_θ and α are given by eqs.
263 (8) and (9), giving $L_{t\infty}$ as

$$L_{t\infty} = \frac{\pi}{2(s-1)} \times \begin{cases} \dfrac{1}{0.21[B_\theta\alpha^{1.5}]}\left(\dfrac{\lambda_e^{1.5}}{D_{50}^{0.5}}\right), & D_{50} < 0.5 \text{ mm}, \\ \dfrac{1}{0.46\pi[B_\theta\alpha^{1.75}]}\left(\dfrac{\lambda_e^{1.75}}{D_{50}^{0.75}}\right), & D_{50} \geq 0.5 \text{ mm}, \end{cases} \tag{B2}$$

264 and $AL_{t\infty}$ as $\lambda_e/0.142[\alpha]$ remains the same. Figure B1 shows the effect of this parameterisation of
265 the threshold of motion for the first example case of Wu et al. (2018) depicted in Figures 2a,d.
266 Unlike Figure 2d, the measured values of h and L are outside the range predicted for $C_0 = 7.4\%$.

Figure 1 kh versus x ($L/L_{t\infty}$) for the limiting case of $A = \frac{1}{2}$ and also $A = \frac{1}{4}$. Dots correspond to $x = 2^{-\frac{1}{2}}$ and $kh = \mathrm{arctanh}\,2^{-\frac{1}{2}}$, for $A = \frac{1}{2}$; $x_{\max,\min} = \frac{1}{2}(2\pm3^{\frac{1}{2}})^{\frac{1}{2}}$ and $kh_{\max,\min} = \mathrm{arctanh}[x_{\max,\min}]$, for $A = \frac{1}{4}$, and shading represents allowable values of x and kh for $A = \frac{1}{4}$ ($\frac{1}{4}\cosh kh \le x \le \tanh kh$).
Figure 2 (a,b,c) Threshold, $L_{t\infty}$, and wave-breaking, $AL_{t\infty}$, scales, eqs. (10b,c), versus C_0 and (d,e,f) L–h phase space from eq. (5), showing the different ranges for $C_0 = 0$, 7.4 and 16.3% and the measured L and h. For (a,d) Wu et al. (2018), $\lambda_e = 278D_{50}$, $D_{50} = 0.496$ mm, $\theta_0 = 0.032$, $L = 5.62$ m and $h = 0.6$ m; for (b,e) Doucette (2000), $\lambda_e = 250$ mm, $D_{50} = 0.22$ mm, $\theta_0 = 0.045$, $L = 11.9$ m and $h = 0.47$ m, and for (c,f) Boyd et al. (1988), $\lambda_e = 180$ mm, $D_{50} = 0.11$ mm, $\theta_0 = 0.076$, $L = 50.7$ m and $h = 10$ m. Legend applies to d,e,f; colours in a,b,c are consistent with the legend.
Figure 3 Relative size of $L_{t\infty}(C_0)$ from eq. (10b) normalised by the clean-sand $L_{t\infty}$ from eq. (B2), $L_{t\infty KM}$, for $C_0 = 0$, 7.4 and 16.3%. $\lambda_e/D_{50} = 250$ and 1000, and the dots correspond to Wu et al.'s (2018) clean-sand experiment in Figure 2a.
Figure B1 (a) Threshold, $L_{t\infty}$, and wave-breaking scales, $AL_{t\infty}$, eqs. (B2) and (10c), versus C_0 and (b) L–h phase space from eq. (5) showing the different ranges for $C_0 = 0$, 7.4 and 16.3% and the measured h and L for Wu et al. (2018), $\lambda_e = 278D_{50}$, $D_{50} = 0.496$ mm, $h = 0.6$ m and $L = 5.62$ m.
