#### Abstract

This study presents a reliable methodology for monitoring streamflow in a dynamic river of the Alps prone to bathymetric changes using non-contact instruments. The method relies on water level and surface velocity radar monitoring, discharge measurements by Large-Scale Particle Image Velocimetry (LSPIV), and topographic surveys. A single proportional relation, resistant to bathymetric changes, is established between maximum surface velocity (Vs,max) and bulk velocity (Umean). Different methods are used to build this relation: (i) an empirical approach calibrated with the LSPIV measurements; (ii) the Isovel model; (iii) the Q-Commander software developed by the Sommer company. The applicability of the method is tested over a 2.5-year dataset. Compared to the empirical approach, both models, which require minimal input data, predict well the Vs,max-Umean relation. The location of the maximum surface velocity, which reveals to be resistant to bathymetric changes, is also well predicted by these models. Discharge is calculated at a time step of 10 min by multiplying the bulk velocity and the wetted area. The results are compared to the discharge series at the historical station located 2.5 km further upstream, which has a stage-discharge rating curve. Good agreement is observed when surface velocity is above 0.7 m/s, but accuracy decreases for lower velocities. A simplified uncertainty analysis estimates a 20% relative error on discharge calculated with the presented method.

12	Key Points:
13 14	• A streamflow monitoring method combining water level radar, surface velocity radar, imagery and topographic surveys is presented
15 16	• A single proportional relation, resistant to bathymetric changes, is established between maximum surface velocity and bulk velocity
17 18	• Theoretical models predict the relation between maximum surface velocity and bulk velocity and the position of the maximum surface velocity

## 19 Abstract

20 This study presents a reliable methodology for monitoring streamflow in a dynamic river of the

21 Alps prone to bathymetric changes using non-contact instruments. The method relies on water

- 22 level and surface velocity radar monitoring, discharge measurements by Large-Scale Particle
- 23 Image Velocimetry (LSPIV), and topographic surveys. A single proportional relation, resistant to
- bathymetric changes, is established between maximum surface velocity  $(V_{s,max})$  and bulk
- velocity ( $U_{mean}$ ). Different methods are used to build this relation: (i) an empirical approach
- calibrated with the LSPIV measurements; (ii) the Isovel model; (iii) the Q-Commander software
   developed by the Sommer company. The applicability of the method is tested over a 2.5-year
- dataset. Compared to the empirical approach, both models, which require minimal input data,
- predict well the  $V_{s,max}$ - $U_{mean}$  relation. The location of the maximum surface velocity, which
- 30 reveals to be resistant to bathymetric changes, is also well predicted by these models. Discharge
- 31 is calculated at a time step of 10 min by multiplying the bulk velocity and the wetted area. The
- results are compared to the discharge series at the historical station located 2.5 km further
- upstream, which has a stage-discharge rating curve. Good agreement is observed when surface
- 34 velocity is above 0.7 m/s, but accuracy decreases for lower velocities. A simplified uncertainty
- analysis estimates a 20% relative error on discharge calculated with the presented method.
- 36

## 37 Plain Language Summary

38 Small rivers are very densely distributed over the world, yet only a few are monitored. Many

- 39 small rivers are located in mountainous areas and are potentially subject to flash floods and
- 40 geomorphological processes. The aim of this study is to propose a monitoring method adapted to
- 41 these environments, with high temporal resolution (~ 10 min) and non-contact instruments
- 42 (water level and surface velocity radars, video camera), able to give a simple and direct access to
- the discharge in order to reduce operating costs and make possible to equip many more small
- 44 rivers in the future. This approach is tested in a river of the Southern Pre-Alps in France. A linear
- 45 relation is determined empirically between the maximum surface velocity (Vs,max) and the
- 46 average velocity of the cross-section (Umean) using image analysis of videos recorded during
- 47 floods. This relation is resistant to morphological changes and the position of the maximum
- 48 surface velocity remains stable over time. The discharge time series is calculated by multiplying
- 49 Umean, derived from the Vs,max-Umean relation (with the radar velocity assimilated to
- 50 Vs,max), and the wetted cross-section, derived from the water level radar. The results are
- 51 validated through comparison with a reference station on the same river.

## 52 **1 Introduction**

- 53 Many applications require monitoring of discharge in rivers, both in the operational field (e.g.
- flood and drought warning systems, water resource management, hydroelectric production) and
- 55 in academic research (e.g. hydrological modelling, calculation of flux of sediment, nutrient or
- contaminant). Streamflow monitoring networks are very unevenly distributed around the world.
- 57 They are mainly located in developed countries, often managed by federal or governmental
- agencies and generally concern rivers with a drainage area greater than 100 km<sup>2</sup>. The United
- 59 States of America (USA) is certainly the best equipped country in the world with a network of
- 60 more than 8000 stations belonging to the National Streamflow Network (NSN) managed by the
- 61 United States Geological Survey (USGS) (Eberts et al. 2018). These stations cover drainage

areas ranging from 0.08 km<sup>2</sup> to 253000 km<sup>2</sup>. The median drainage area is 295 km<sup>2</sup>; 96.7% (resp.

- 71.7%) of the stations cover drainage areas larger than  $10 \text{ km}^2$  (resp.  $100 \text{ km}^2$ ). In contrast, the
- 64 southern countries have a severe lack of streamflow monitoring stations. Satellite observation
- 65 (e.g. SWOT) will make it possible to improve the situation for the world's major rivers, which
- are more than 100 m wide, or even 50 m wide in the best case, by providing hydrometric data at
   a maximum frequency of 21 days (Rodrigez et al., 2020). However, the issue of rivers covering
- 68 drainage areas of less than 100 km<sup>2</sup>, referred to as small rivers in this study, will not be improved
- by satellite observation in the next decade although they represent an incalculable number of
- watercourses. In addition, at this scale, observation has to be done at a high temporal resolution
- (sub-hourly) due to the dynamics of the hydrosystems, so in situ monitoring will remain the rule
- for a while. Recent studies, such as on land carbon budget to give just one example (Duvert,
- 73 2018; Botter, 2022), showed the need to increase the density of streamflow monitoring in small
- 74 rivers. The question is how to proceed, bearing in mind that current approaches cannot be
- applied because of the considerable resources (human, equipment) they involved. Therefore it is
   particularly important for the scientific community to contribute to the development of new
- 77 monitoring approaches, using parsimonious and reliable methodologies.
- 78 Techniques and methods for reference discharge measurement obtained at a specific time (so-
- called gauging), enabling to measure directly the discharge, have considerably evolved in the last
- 80 decades. It is now possible to measure reference discharge with a known level of uncertainty in a
- 81 wide range of conditions of river size, slope and hydrological conditions. In small rivers,
- impeller, electromagnetic and acoustic current meters as well as dilution methods are the most
   commonly tools used for low to medium flow conditions. For high flow conditions, the use of
- imagery like LSPIV (Muste et al., 2008) or STIV (Fujita et al., 2007) and portable surface
- velocity radar (Welber et al., 2006) has enabled measurements in situations never explored
- 86 before.
- 87 In contrast, streamflow monitoring require specific approaches compared to the reference
- discharge measurements. The conventional hydrometric approach still remains the most
- commonly used approach to date. It combines water level monitoring and the establishment of a
   stage-discharge (H-Q) rating curve allowing the water level time series to be posteriori converted
- to streamflow time series. It has incontestable advantages: i) the low cost and high accuracy of
- equipment for water level monitoring, ii) the quality of streamflow time series when reference
- discharge measurements are carried out regularly (roughly 10 times per year), iii) the availability
- 94 of methods for estimating uncertainties such as the Bayesian rating curve framework (Le Coz et
- al., 2014) or LOWESS regression (Coxon et al., 2015), see Kiang et al. (2018) for a review. On
- the other hand, the drawbacks of this method are: i) the operational costs due to the human
- resources involved, ii) the diversity of technical equipment required for the reference discharge
- 98 measurements, iii) the initial delay in the provision of streamflow time series as it might take
- 99 several years before establishing a reliable H-Q rating curve based on an extended range of
- 100 reference discharge measurements, iv) the exposure to hydro-meteorological risks for the staff
- 101 carrying out reference discharge measurements during floods, v) the sensitivity to hydraulic
- 102 control shifts, mainly caused by changes in bathymetry. Indeed, as soon as a flood significantly
- 103 modifies the geometry of the cross-section (deposition or erosion), the H-Q rating curve has to be
- 104 completely rebuilt with a new set of reference discharge measurements. In highly morphogenic
- rivers, it is even impossible to apply this approach as the H-Q rating curves change so often.

Since the 2000s, other approaches have gradually been developed. They can be grouped together 106 under the heading of velocimetric approaches insofar as they combine both the monitoring of the 107 water level (H) and the velocity (V) at high temporal resolution. A first attempt has been to 108 automate image-based discharge measurement techniques from one or more fixed cameras 109 (Hauet et al., 2008; Le Coz et al., 2010; Stumpf et al., 2016; Li et al., 2019). Water level may be 110 monitored by the camera itself or by an independent instrument (e.g. pressure sensor, radar, ultra 111 sound). Video sequences of a few seconds are recorded at high temporal resolution (e.g. every 5 112 to 30 minutes). Surface velocity fields are then calculated usually in real time on site to avoid the 113 need for extensive data transfer and storage. There exist commercial solutions for such 114 technology (e.g. Tenevia, Vortex-IO, Seba's Discharge Keeper, Xylem's Q-Cam) which are 115 116 either connected to the grid or autonomous in energy. Another velocimetric approach which has seen moderate growth over the last decade is the index velocity method. It was initially presented 117 by Levesque and Oberg (2012). This approach can substitute completely the conventional 118 hydrometric approach for the production of discharge time series (Kästner et al., 2018; 119 Gonçalves et al., 2023). It requires two relations: (i) a H-A<sub>wet</sub> relation for the calculation of the 120 wetted area (A<sub>wet</sub>) based on regular topographical surveys of the monitored cross-section; (ii) a 121 122 V-U<sub>mean</sub> relation for the calculation of the mean cross-section velocity U<sub>mean</sub> (so-called bulk velocity). The V-U<sub>mean</sub> relation, calibrated using a set of reference discharge measurements, can 123 be a simple-linear regression, a compound-linear regression or a multiple-linear regression 124 125 (Levesque and Oberg, 2012). Once the H-Awet and V-Umean relations are built, the calculation of discharge at any time step (t) can be done by multiplying the terms  $A_{wet}(t)$  and  $U_{mean}(t)$ . The 126 index velocity (V) can be monitored using different types of instruments (e.g. horizontally-127 oriented Acoustic Doppler Current Profiler, ultrasonic transit-time, surface velocity radar, 128 acoustic Doppler velocimeter), which makes this approach very flexible. However, the main 129 limitations of this approach are: (i) it still requires a large number of reference discharge 130 measurements, which implies both operating costs and human resources; (ii) velocity monitoring 131 is generally not as accurate as water level monitoring, which introduces noise in the calculated 132 discharges; (iii) it still needs regular survey of the bathymetry of the cross-section, to establish 133

- 134 and maintain the H-A<sub>wet</sub> relation.
- 135 The aim of this study is to produce continuous time series of discharge focusing on steep rivers
- 136 (slope typically higher than 1%), subject to frequent topographic changes due to morphogenic
- floods, where none of the above approaches are really suitable. The use of non-contact
- instrumentation is preferred in order to avoid problems of maintenance and destruction by flash
- 139 floods. Such conditions are common in mountainous regions of Mediterranean and tropical areas,
- where discharge may vary up to 3 or 4 orders of magnitude in a few hours. We propose to follow
- a velocimetric approach, similar to the index velocity method, using a local surface velocity
- monitored by a fixed radar ( $V_s$ ). We propose to establish a  $V_s$ - $U_{mean}$  relation based on reduced
- information, i.e. topographic surveys and automatic video recordings, which can be obtained
   outside flood periods for the former, and during flood periods for the latter. Specifically, we
- outside flood periods for the former, and during flood periods for the latter. Specifically, we decide to focus on the  $V_{s,max}$ -U<sub>mean</sub> relation between the maximum surface velocity and the bulk
- velocity. There are two reasons for this choice: (i) Chiu (1988, 1991) and Chiu and Said (1995)
- identified a linear relation between  $U_{mean}$  and the maximum velocity  $V_{max}$  in a river cross-section,
- 148 with this relation invariant with time and discharge (Chiu and Tung, 2002; Chiu and Chen,
- 149 2003). The existence of this linear relation was verified by Moramarco and Singh (2010) and
- Fulton et al. (2020) with observed data. (ii) The vertical axis on which  $V_{max}$  occurs is called the
- 151 "y axis".  $V_{s,max}$  is located in the same vertical axis as  $V_{max}$  as demonstrated by Chen and Chiu

- 152 (2004) and Fulton et al., (2020). In natural river sections controlled by slope and roughness, it
- seems reasonable to assume that  $V_{max}$  is located close to the surface and therefore  $V_{s,max}$  can be a seem of  $V_{max}$  can be a
- 154 good approximation of  $V_{max}$ .
- 155 A new dataset of observed data collected in a river of the southern French pre-Alps is used to
- apply this framework. The first objective of this study is to verify the existence of a linear  $V_{s,max}$ -
- 157 U<sub>mean</sub> relation using image-based surface velocity and discharge measurements derived from
- automatic video records and regular topographic surveys. Additionnaly, the resistance of this
- relation to morphological changes is tested. The second objective is to test if this linear  $V_{s,max}$ -U<sub>mean</sub> relation can be reasonably well predicted by theoretical models. Such models include: (i)
- $U_{\text{mean}}$  relation can be reasonably well predicted by theoretical models. Such models include: (i) the isovel model, initially developed by Maghrebi, (2006), which is a theoretical model based on
- an analogy from Biot-Savart's law of electromagnetism (Hayt, 1981) to calculate the distribution
- 163 of velocity within a cross-section, (ii) the Q-Commander software developed by the Sommer
- 164 company (Sommer, 2013). The third objective is to test the steadiness of the localisation of the
- 165 maximum surface velocity within the cross-section using image-based surface velocity
- measurements and theoretical models regardless of the existence of morphological changes. The
- 167 fourth objective is to evaluate the ability to produce streamflow times series using the framework
- defined by the index velocity method and the  $V_{s,max}$ - $U_{mean}$  relation predicted by the empirical
- 169 method calibrated with image-based results.

## 170 2 Materials and Methods

171 2.1 Site description and monitoring equipment

172 This study is based on data collected in the Galabre river which belongs to the Draix-Bléone

173 Observatory (https://oredraixbleone.inrae.fr/en/) and is part of the French research infrastructure

- 174 OZCAR (Gaillardet et al., 2018). The Galabre river is a tributary of the Bléone river. The
- Galabre catchment is presented in detail by Esteves et al. (2019) and Legout et al. (2021). Mean annual rainfall is respectively 958 mm at La Robine sur Galabre close to the outlet (alt. 750m
- annual rainfall is respectively 958 mm at La Robine sur Galabre close to the outlet (alt. 750m
  a.s.l) and 1046 mm at Ainac in the upstream part of the catchment (alt. 1145m a.s.l.). Erosion
- a.s.*i*) and 1040 mm at Amac in the upstream part of the catchment (att. 1145m a.s.*i*). Erosion and sediment transport processes are very active in this catchment due to the presence of patches
- of non-vegetated badlands (representing 9% of the total area), the general slope of the basin
- (mean slopes of 54, 19 and 6% for hillslopes, intermittent rivers and the main river, respectively)
- and the influence of Mediterranean rainfall and mountain thunderstorms (Esteves et al., 2019).
- 182 A conventional hydrometric station monitors streamflow at a 10-min time step at La Robine sur
- Galabre, at the outlet of the 20 km<sup>2</sup> catchment, since 2007 (Legout et al., 2021). The cross-
- 184 section is very stable as, in this reach, the river flows over limestone slabs and the local slope (3
- 185 %) is high enough to prevent sediment deposition. The station is equipped with a radar for water
- 186 level monitoring. A stage-discharge rating curve was established from 35 reference discharge
- 187 measurements using different gauging techniques (dilution, impeller current meter, 188 alextromagnetic surrent meter) applied between 2007 and 2014 (reacting form  $0.017 \text{ m}^3$
- electromagnetic current meter) applied between 2007 and 2014 (ranging from 0.017 m<sup>3</sup> s<sup>-1</sup> to 0.948 m<sup>3</sup> s<sup>-1</sup>) and an extrapolation performed by hydraulic modelling (HEC-RAS) (Esteves et al.,
- 190 2019).
- 191 A new station called RIPLE (River Platform for Monitoring Erosion) was installed in October
- 192 2018 on the Galabre river, 2.5 km downstream of La Robine sur Galabre. Nord et al. (2020)
- 193 presented the developpement of the RIPLE platform, an autonomous low-power instrument

194 platform for monitoring water and solid discharges in mesoscale rivers. The RIPLE station is

- equipped with a fixed surface velocity radar (so-called V radar), a water level radar (so-called H
- radar) and a video camera dedicated to Large Scale Particle Image Velocimetry (LSPIV) analysis
- as illustrated by the schematic diagram in Figure 1. A staff level gauge is also installed on the
- river bank. Both radars are installed on the same extension arm anchored to the vertical wall of
- the bridge on the downstream side, as shown in Figure 2. The sampling time step of the platform is 10 min. Water level and surface velocity data are remotely transmitted once a day to the lab in
- Grenoble. The RIPLE station is located in a gravel-bed river reach prone to frequent bathymetry
- 201 Grenoble. The RIPLE station is located in a graver-bed river reach profie to frequent bathyfile 202 changes
- 202 changes.
- 203 The H radar (CRUZOE manufactured by Paratronic) works on the time-of-flight principle. It
- points vertically below its position with a total opening angle of 12°. Each logged value is the
- average of three measuring cycles, each lasting 4 s and separated by 5 s. During each measuring
- 206 cycle, the instrument makes 16 measurements per second. The logged variable is called  $H_{rad}$  in
- 207 this study. The standard deviation (STD) is also logged simultaneously.
- 208 The V radar (RG-30 manufactured by Sommer) works on the Doppler principle. For more details
- about the radar Doppler technology, the readers can refer to the study presented by Fulton et al.
- (2020), Son et al. (2023) and Huang et al. (2023). The V radar points slightly further downstream
- at an angle of 32 degrees to the vertical and with a total opening angle of  $12^{\circ}$ , so that the centre
- of the zone targeted by the V radar is located 3.7 m further downstream for very low flow  $\frac{1}{2}$
- conditions (respectively 2.5 m further downstreal for a water depth of 2 m). Every measurement
   is time averaged over 30 records obtained at a frequency of 1 Hz. The logged variable is called
- 215 V<sub>rad</sub> in this study.
- The AXIS P1435-LE camera is mounted on a mast from the bridge deck, looking downstream.
- 217 The camera, which is triggered when the value of water level exceeds a threshold, records video
- at an interval of 30 min during storm events. It takes short videos (approximately 7 s) of the river
- scene at a rate of 30 frames per second. This configuration allows for effective utilization of
- 220 media storage, reduces energy consumption of the platform and ensures that only high flow
- conditions are captured for LSPIV analysis. The video sequences stored in a SD card of the
- 222 LSPIV camera are retrieved regularly during field visits.
- The LSPIV cross-section used for analysis and calculation is located slightly further downstream of the bridge. Indeed, the presence of a natural step formed by the bedrock under the upper part
- of the bridge creates a hydraulic jump and conditions that are particularly challenging for
- hydrometric monitoring. The river is more uniform downstream of the bridge, and therefore
- more appropriate to velocity exploration. The horizontal distance between the H radar and the
- "LSPIV cross-section" shown in Figure 2 is approximately 10 m. The slope of the river is of the
- order of 2% in this reach, which means that, assuming a slope of the free surface parallel to the
- slope of the bed, a drop in the water level of 0.2 m is applied to the value of  $H_{rad}$  to obtain the
- 231 corresponding value in the "LSPIV cross-section", so-called  $H_{LSPIV}$ .

Figure 1 – Conceptual sketch of a velocimetric station with the different instruments deployed including fixed surface velocity radar (V radar), water level radar (H radar), LSPIV camera and staff level gauge.

Figure 2 - a) photograph of the RIPLE platform on the Galabre River taken from downstream of the bridge and looking upstream, b) aerial view of the bridge housing the RIPLE platform and the river reach downstream of the bridge with the radars cross-section, the LSPIV cross-section, and the location of the instruments. The yellow ellipse indicates the approximative area targeted by the V radar in low flow conditions such as those shown in the image. The blue ellipse indicates the approximative area targeted by the V radar when the water depth is around 2 m.

243 2.2 Data control and curation

The period from October 2018 to May 2021 is considered in this study. For the upstream station at La Robine sur Galabre, data are regularly controlled before being publicly released through the online data platform of the Draix-Bléone observatory (https://bdoh.irstea.fr/DRAIX/nosdonnees?site=Galabre). The quality codes are presented in Table 1. The raw data produced by the H radar are often of good quality and directly validated.

For the downstream station, the same procedure of quality control is applied. Quality codes are assigned to processed data as presented in Table 1. Velocity data are often more spurious than water level data (Blake and Packman, 2008; Nord et al., 2014; Fulton et al., 2020; Rahman Khan et al. 2021). Customized filters based on statistical parameters have been designed for surface velocity data. The methodology is adapted from Blake and Packman (2008) and Nord et al. (2014). The order of filters follows the same sequence:

- Missing values (NaN): values are replaced by -9999 and quality code 'l' is
  assigned. Given the regular morphological changes in the river bed, some periods of
  missing data occur due to the presence of a gravel bar that formed temporarily below the
  H-V radars on the right bank of the river. This situation represents 34.2% of the total
  dataset and is rather more frequent from the end of 2020.
- 260 2. Repeat velocity error: Given natural flow variability and resolution of radar, more 261 than three repeated and consecutive values are unlikely. These are clone observations and 262 are replaced by -9999 with a quality code 'i'.
- 3. Spurious observations: A moving window average is used with a fixed window
  size of 4 steps (40 min). The observation is considered erroneous when difference
  between recorded and moving average at a time step is more than 30%. These are
  replaced by -9999 and quality code 'i' is assigned.
- Physical and configuration limit: The maximum surface velocity in natural river is
  limited to 7.0 m/s. The lower limit of 0.2 m/s is recommended by manufacturer. The
  observations exceeding maximum and below minimum are replaced by -9999 and quality
  code 'i' is assigned.
- 5. Signal to noise ratio (SNR): The radar manufacturer recommends a lower limit for
  the value of the quality. The data with a SNR value lower than 30 is replaced by quality
  code 'd'. The values are maintained since deleting these may lead to parting away of
  useful information during subsequent analysis.
- Kalid: All other remaining logged data is checked and quality code 'v' is
  assigned. This represents 51.2% of the total dataset and 77.8% of the dataset without
  missing data. Most of unvalidated data are associated with low velocities values, typically
  lower than 0.5 m/s.
- 279 280
- 281 282

283	Table 1 – Quality codes assigned to processed data										
	Sr.No.	Quality	Code	Value	Comment						
	1	Valid	v	raw data	observation found valid						
	2	Doubtful	d	raw data	unexpected observation but still physically acceptable						
	3	Estimate	е	reconstructed	reconstructed data (e.g. interpolation)						
	4	Lack	I	-9999	gap - missing observation (blank or NaN)						
284	5	Invalid	i	-9999	erroneous observation that has been deleted						
201											

- 286 2.3 Topographic surveys and detection of bathymetric shifts

As seen in Figure 2, the downstream station (RIPLE) is located in a gravel-bed river reach where

- the morphology is likely to change regularly due to active sediment transport processes.
  Different methods, i.e. total station, lasermeter, D-GPS, are used to carry out
- topographic/bathymetric surveys of the LSPIV cross-section as illustrated in Figure 2. Each time,
- three reference points are surveyed in order to convert all the data into the same local reference
- frame represented in Figures 1 and 2.

293 A first survey of the LSPIV cross-section was conducted in October 2018 when the station was installed. Regular surveys were then carried out during field visits (9 in total over the study 294 period). These data enable to build the H-Awet relation of the LSPIV cross-section after each new 295 bathymetric change. Plotting the H-V data provided by the H-V radars can help detect 296 bathymetric changes (Rahman Khan et al., 2021). Indeed, a sudden shift in the H-V scatter plot, 297 which often occurs during major floods, indicates a change in bathymetry and the need for a new 298 bathymetric survey of the LSPIV cross-section. Points that cause the deviation in the scatter plot 299 can reveal the exact timing of the morphological changes. By following this procedure, it is 300 possible to accurately track and identify the changes occurring in the bathymetry. The AreaComp 301 version 2.1 software (United States Geological Survey, 2021) was used to calculate the H-Awet 302 303 relations.

304 2.4 LSPIV analysis

Large scale particle image velocimetry (LSPIV) is a technique that performs image processing and pattern tracking to measure the velocity of a flowing fluid (Hauet et al., 2008; Muste et al., 2008; Le Coz et al., 2010). It works by analysing consecutive images taken at a fixed time interval and tracking the movement of visible patterns at the surface of the fluid thanks to a pattern-matching algorithm, with a likelihood criterion based on cross-correlation. In this study, the software Fudaa-LSPIV v1.8.2 (Le Coz et al. 2014) was used. Figure 3 illustrates the various steps involved in producing a surface velocity field and calculating discharge.

Step 1 – Image Extraction: A total of 2381 video sequences were recorded during the study period. However, 2024 video sequences were withdrawn due to improper camera trigger settings between 04/10/2018 and 03/07/2019. In addition, all video sequences recorded at night and with bad quality of tracers were omitted as they were not exploitable for the LSPIV. In the end, a total of 69 video sequences were selected for this study. Once video sequences were selected manually, images were extracted using default time step of 0.033 s. The value of the water level in the "LSPIV cross-section", H<sub>LSPIV</sub>, was also entered for each video sequence.

Step 2 – Orthorectification: the coordinates of 11 ground reference points marked on site at different locations using black and white paint were used for orthorectification. This step allows to calibrate the camera model, to correct distortion due to perspective and provides metric scale to images instead of pixels. A resolution of 0.02 m/pixel was assigned for good visualization of natural tracer.

324 Step 3 – LSPIV analysis: Pearce et al. (2020), evaluated application of various image

velocimetry algorithms, including the widely used LSPIV algorithm. They found that velocity

results are sensitive to the interrogation area (IA) parameter. Le Coz et al. (2010) recommended

that IA be sized enough to include enough tracers and small enough to be computationally

effective. Therefore, the value of IA was derived from a first test involving two video sequences covering a wide range of surface velocities, i.e. the video sequence corresponding to the highest

measured radar velocity and the video sequence corresponding to the lowest radar velocity. This

331 methodology assured the applicability of a single parameter choice for the entire range of video

sequences. The value of IA was set to 0.48 m. The spatial resolution of the grid used to perform

LSPIV calculation was 0.36 m in the Y direction and 0.66 m in the X direction. There were 40

points in the Y direction covering the width of the river at high flows and 30 points in the X

direction from X = 2 m to X = 17.65 m.

336 Step 4 – Post processing: Instantaneous velocities obtained for each pair of consecutive images

337 were used to calculate time-averaged results of surface velocity field over the whole video

sequence. This was carried out after applying filters on minimum and maximum correlation

coefficient and velocity. In this study, correlation range of 0.6-1.0 and minimum velocity of 0.5
 m/s were found to be the most suitable filters to remove spurious results and obtain the most

341 relevant surface velocity fields.

342 Step 5 – Discharge and  $V_{s,max}$ : The cross-section where the discharge is to be measured (so-

called "LSPIV cross-section") was imported. This transect was interpolated at a regular step of

0.1 m with calculation of the corresponding water depth at each new point. The search radius

was 1 m in the longitudinal direction and 0.2 m in the transverse direction. This means that the points of the grid that are within this search radius are weight-averaged by distance to produce

the velocity component perpendicular to the transect at each interpolated point of the transect.

Fudaa-LSPIV uses a velocity index ( $\alpha$ ), so-called depth-averaged to surface velocity ratio, to

transform surface velocity to depth-averaged velocity. Welber et al. (2016), Hauet et al. (2018)

confirmed the acceptability of default velocity index value of 0.85 on multiple sites under

different hydraulic configurations. The default value of 0.85 was used in this study since no

ADCP or current meter measurement was available to adjust the value of  $\alpha$ . Discharge was then

computed as the sum of the contributions of discharge per unit width over the whole interpolated transect. Finally, the maximum value of surface velocity (so-called  $V_{s,max LSPIV}$ ) as well as its

transect. Finally, the maximum value of surface velocity (so-called  $V_{s,max\_LSPIV}$ ) as well as its spatial coordinates were extracted by calculating the moving average over 8 points to smooth out

356 any erratic results.

Figure 3 – Main steps involved in producing surface velocity field and calculating discharge using Fudaa-LSPIV v1.8.2

## 359 2.5 The $V_{s,max\_LSPIV}$ - $U_{mean}$ relation

Four methods were initially identified to build the  $V_{s,max}$ - $U_{mean}$  relation : (i) the Entropy model; (ii) the Isovel model; (iii) a calibration using LSPIV measurements; (iv) the Q-Commander model. However, the application of the Entropy model was not concluding in our case and the results were excluded from the study. Given the importance of this approach in the literature, the Entropy model is still presented briefly below since part of its formalism has been retained for this study. The possible reasons why the application failed are also mentioned.

## 366 2.5.1 Entropy model

Chiu (1987, 1988), Chiu and Tung (2002), Chiu and Chen (2003) proposed a velocity
distribution equation based on the probability concept and the Shannon's information entropy
(Shannon, 1948). The velocity distribution at the "y axis", i.e. the axis of the cross-section on
which the maximum velocity V<sub>max</sub> occurs, is represented by:

- 371
- 372

$$u = \frac{V_{max}}{M} ln[1 + (e^M - 1)F(u)]$$
(1)

373 where u = velocity as a function of depth at the "y axis";  $V_{max}$  = maximum velocity at the "y

axis"; M = parameter of the probability distribution used to describe the velocity distribution; and  $F(u) = \int_0^u f(u) du$ , which represents the cumulative distribution function, or the probability of a randomly sampled point velocity that is less than or equal to u.

377 The probability distribution f(u), is resilient and is invariant with time and water level at a

channel cross section. M is constant at a channel cross section. Chiu (1987, 1988) identified a

linear relationship, function of the parameter M, between  $U_{mean}$  and  $V_{max}$  in a channel cross-

section.  $\emptyset$ , which is the ratio between U<sub>mean</sub> and V<sub>max</sub> is expressed by Chiu and Tung (2002), as follows:

382 
$$\phi = \frac{U_{mean}}{V_{max}} = \frac{e^M}{(e^M - 1)} - \frac{1}{M}$$
 (2)

In its original form, the method requires at least one complete distribution of velocity within the cross-section, obtained by ADCP or current meter for example. Since such data did not exist in our case, the original method as applied by Fulton et al. (2020) could not be applied. Alternatively, Farina et al. (2014) proposed derived procedures applicable to cases where only the surface velocity is available (either the complete surface velocity distribution or only the maximum surface velocity). These derived procedures were attempted in our case using the LSPIV measurements. However, the results were not satisfactory. It seems that the parametric

formula used to determine the position of the maximum velocity in the vertical initially proposed by Chiu and Tung (2002) was calibrated with data from large rivers and is not suitable for small rivers.

With reference to the formalism of the Entropy model, we introduce the ratio  $\phi_s$  between  $U_{mean}$ and  $V_{s,max}$  expressed as:

$$\phi_s = \frac{\upsilon_{mean}}{\nu_{s,max}} \tag{3}$$

2.5.2 Isovel model

Figure 4 - Section where u<sub>spm</sub> is calculated for each point inside the cross-section considering a desired mesh size.

The original motivation of the development of the Isovel model was to improve reference 399 discharge measurements by minimising the number of sampling steps during velocity gauging, if 400 possible to a single point velocity measurement. The model was initially developed by Maghrebi 401 (2003). This approach draws its inspiration from the Biot–Savart law (Hayt, 1981), which can be 402 used to calculate the intensity of a magnetic field generated at a point in space by an infinitely 403 long wire carrying a stationary and steady current. Maghrebi (2006) used this analogy to quantify 404 the impact of perimeter roughness on velocity inside the channel. In this method, the velocity of 405 any point inside the river cross-section depends on its distance (r) from the wetted perimeter 406 (Pw) and the constant related to the boundary roughness  $(c_1)$ .  $u_{spm}$  means the velocity of a single 407 point measurement. As in Figure 4, the incremental velocity of any point inside the cross-section 408 409  $du_{spm}$  is due to cross product between the function  $f(\mathbf{r})$ , an infinitesimal element of wetted perimeter **dp**, and c: 410

$$du_{spm} = f(r) \times c_1 \, \mathrm{dp} \tag{4}$$

412 f(r) is the dominant velocity function according to Kavousizadeh and Ahmadi (2018) and Ali and 413 Maghrebi (2023). The direction of the velocity is normal to the plane containing the vector of the 414 infinitesimal element of wetted perimeter (**dp**) and the vector drawn from the infinitesimal 415 element of wetted perimeter to the point where the velocity is calculated (**r**). Since vectors **r** and 416 **dp** are located in a plane normal to the main flow direction, the cross product of them is normal

417 to the plane of the section.

418
419 The velocity in the main flow direction can be obtained by integration along the wetted perimeter
420 as:

421

411

$$\boldsymbol{u_{spm}} = \int_0^{P_W} \boldsymbol{du_{spm}} = \int_0^{P_W} f(\boldsymbol{r}) \times c_1 \, \mathrm{d}\boldsymbol{p}$$
(5)

And the scalar of the velocity in a Cartesian coordinate system (x,y,z), as shown in Figure 4, is obtained as:

$$u_{spm}(\mathbf{y},\mathbf{z}) = \int_0^{P_W} f(r) c_1 dp \sin\theta = \int_0^{P_W} c_1 \sin\theta f(r) dp$$
(6)

As a result, points far from the perimeter will have higher values of  $u_{spm}$  than those which are located close to the perimeter.

- 430 Then, for the distance function f(r), Maghrebi (2006) considers power law of velocity
- distribution function (Chen, 1991) as follows:

432 
$$f(r) = u_*(c_2 r^{\frac{1}{m}})$$
 (7)

Where  $u_*$  is the shear velocity which comes from  $u_* = \sqrt{\tau_0/\rho}$  with  $\tau_0$  the boundary shear stress and  $\rho$  the mass density of fluid,  $c_2$  is the coefficient related to turbulent intensity, and m is an exponent ranging between 1/4 to 1/12 which depends on the intensity of the turbulence. Numerous experiments show that a value of m = 1/7 agrees well for turbulent velocity profiles in

smooth boundaries (Chen, 1991), (Wright and Parker, 2004).

438 Then, replacing Equation 7 in Equation 6 gives:

439 
$$u_{spm}(y,z) = \int_0^{P_W} c_1 u_* \left(c_2 \, r^{\frac{1}{m}}\right) \sin\theta \, dp \tag{8}$$

440 By considering  $c = c_1 c_2 u_*$  and m = 7, Equation 8 can be rewritten as:

$$u_{spm}(\mathbf{y},\mathbf{z}) = \int_0^{P_W} \mathbf{c} \left(r^{\frac{1}{7}}\right) \sin\theta \,\mathrm{d}\mathbf{p} \tag{9}$$

442

455

441

443 The bulk theoretical velocity  $U_{spm}$  is obtained by integrating  $u_{spm}$  over the channel section:

444 
$$U_{spm} = \frac{\int_{A} u_{spm}(y,z) \, dA}{A} = \frac{\int_{A} (\int_{0}^{Pw} c \, (r^{\frac{1}{7}}) \sin\theta) \, dA}{A} \tag{9}$$

Finally, dividing the theoretical point velocity to the theoretical bulk velocity provides with the dimensionless isovel coefficient ( $\eta$ ) at any point of the cross-section:

447 
$$\eta(y,z) = \frac{u_{spm}(y,z)}{U_{spm}}$$
(10)

In case of uniform roughness and shear velocity along the perimeter, the term c is cancelled and

Equation 10 only depends on r,  $\theta$  and dA. This assumption was made in this study as it was done

in the work of Kavousizadeh and Ahmadi (2018). This results in a parsimonious method for

451 calculating the velocity distribution within the channel cross-section as only bathymetric data are452 required.

In this study, the dimensionless isovel coefficient corresponding to the point with the highest surface velocity is called  $\eta_s$  and is defined as:

 $\eta_s = \frac{v_{s,max}}{v_{mean}} \tag{11}$ 

456 It is worth to note that  $\eta_s$  is the inverse of  $\phi_s$ . The accuracy of this method is affected by the

457 channel bed control, non-uniformity of the cross section, irregular flow directions and presence

458 of singularities. The choice of the cross-section is therefore crucial. This choice must follow the

common rules for gauging using the velocity-area method, i.e. reach of river as uniform aspossible, with quasi 1D velocities.

To the knowledge of the authors, this study is the first application of the Isovel model in irregular cross-sections as all other applications of this method has been done on wide regular sections.

For each video records analysed with Fudaa-LSPIV, the value of water level in the "LSPIV"

464 cross-section", i.e.  $H_{LSPIV}$ , as well as the appropriate bathymetry, were entered to apply the Isovel 465 model. This resulted in the value of  $\eta_s$ . The spatial coordinates of the point corresponding to  $\eta_s$ 466 were also extracted in order to give the position of the "y axis".  $U_{mean\_Isovel}$  was then calculated as 467 the product of  $V_{s,max\_LSPIV}$  by the value of  $\frac{1}{\eta_s}$ . Finally, the slope of the regression between all pairs

- 468 of  $(V_{s,max LSPIV}, U_{mean Isovel})$  was calculated.
- 469

## 2.5.3 Calibrated relation using LSPIV results

For each video records,  $U_{mean\_LSPIV}$  was calculated by dividing the value of discharge Q by  $A_{wet}$ 

in the "LSPIV cross-section". The value of discharge was obtained through the LSPIV analysis
as described in section 2.4. The value of A<sub>wet</sub> was derived from the H-A<sub>wet</sub> relation for the value

of  $H_{LSPIV}$ . Historical pairs of  $V_{s,max\_LSPIV}$  and  $U_{mean\_LSPIV}$  were then plotted and the slope of the linear regression forcing to go through the zero intercept was computed. This method is similar

- 474 linear regression forcing to go through the zero intercept was computed. This method is similar 475 to the preferred method used by Fulton et al. (2020) for computing the value of  $\phi$  with the 476 Entropy model. However, in the present case, the slope of the V<sub>s,max\_LSPIV</sub>-U<sub>mean\_LSPIV</sub> gives the
- 477 value of  $\phi_s$ .

478

2.5.4 Q-Commander

The Sommer company has developed the Q-Commander software in order to process velocity 479 measured with surface velocity radars (e.g. RG-30, RQ-30). This software gives the distribution 480 of the dimensionless k-factor throughout the cross-section. The k-factor is the ratio between the 481 bulk velocity and the measured local velocity at the surface. It is therefore analogous to the 482 inverse of n of the Isovel model. The documentation of the software (Sommer, 2013) states that 483 the value of the k-factor is usually in the range of 60 to 120% for suitable flow measurement 484 sites, depending on the shape of the profile, the actually measured water level, the position of the 485 radar sensor, and the roughness of the profile. As input, the software requires the profile of the 486 cross-section, the roughness of the river bed and the lateral position of the radar sensor in the 487 cross-section. Subsequently, the cross-section area and the k-factor are automatically calculated 488 for each defined water level value. The equations used in the model are not available, but the 489 model is based on the universal logarithmic law of the wall and considers the influence of the 490 complete cross-section (Sommer, 2013). In this study, the version 2.0.3.5 of the Q-commander 491 492 software was used. The conditions (i.e. profile of the cross-section, value of the water level) of each video records analysed with Fudaa-LSPIV were used as input, the roughness was set to 100 493 (gravel bed) and the position that gives the lowest k-factor value was sought in the cross-section. 494 Such a position corresponds to the "y axis" and the lowest value of the k-factor corresponds to 495  $\phi_s$ . U<sub>mean Commander</sub> was then calculated as the product of V<sub>s,max\_LSPIV</sub> by the lowest value of k-496 factor. Finally, the slope of the regression between all pairs of (V<sub>s,max\_LSPIV</sub>, U<sub>mean\_Commander</sub>) was 497 calculated. 498

499	2.6 Discharge time series calculation
500	2.6.1 Relation between $V_{rad}$ and $V_{s,max\_LSPIV}$
501 502 503 504 505 506 507 508 509	In this study, the index velocity is $V_{rad}$ , monitored from the downstream side of the bridge. In order to apply the theoretical framework of the index velocity method with the objective of deriving time series of discharge, a relation has to be built between $V_{rad}$ and $U_{mean}$ . At the moment, different methods have been presented to build a linear relation between $V_{s,max\_LSPIV}$ and $U_{mean}$ in the "LSPIV cross-section". A complementary relation has to be established between $V_{rad}$ measured from the downstream side of the bridge in the "radars cross-section" and $V_{s,max\_LSPIV}$ in the "LSPIV cross-section". For each video records analysed with Fudaa-LSPIV, the value of $V_{s,max\_LSPIV}$ was extracted and the synchronized value of $V_{rad}$ was also retrieved. Historical pairs of $V_{rad}$ and $V_{s,max\_LSPIV}$ were then plotted and a linear regression was computed.
510	2.6.2 Discharge algorithm
511 512 513	The procedure was designed to calculate continuously water discharge (Q) from the variables $H_{rad}$ and $V_{rad}$ monitored by the H-V radars at each time step (t). To accomplish this, the methodology can be summarised as follows:
514 515 516	1) The periods with stable bathymetry were identified from the analysis of the $H_{rad}$ - $V_{rad}$ data series and the corresponding H-A <sub>wet</sub> relations were calculated using the AreaComp version 2.1 software
517 518 519 520	2) At each time step, $H_{rad}(t)$ in the "radars cross section" was converted into $H_{LSPIV}(t)$ in the "LSPIV cross section" by applying a linear transformation that considers the slope and the distance between the "radars cross-section" and the "LSPIV cross-section" (reduction of 0.2 m in water level)
521 522	3) At each time step, $A_{wet}(t)$ in the "LSPIV cross section" was calculated using $H_{LSPIV}(t)$ and the corresponding H-A <sub>wet</sub> relation
523 524 525	4) At each time step, $V_{rad}(t)$ was transformed into $V_{s,max\_LSPIV}(t)$ using the $V_{rad}$ - $V_{s,max\_LSPIV}$ linear relation that enables to shift from the "radars cross section" to the "LSPIV cross section" (see section 2.6.1)
526 527 528	5) At each time step, $U_{mean}(t)$ was calculated using one of the $V_{s,max\_LSPIV}$ - $U_{mean}$ linear relations presented in section 2.5. In this study, the relation calibrated with LSPIV results was selected.
529	6) At each time step, $Q(t)$ was calculated as the product of $U_{mean}(t)$ by $A_{wet}(t)$ .
530	2.6.3 Uncertainty
531 532 533	An analysis of the uncertainty in the procedure of calculation of discharge time series was carried out. Given that $Q(t)$ is calculated as the product of $U_{mean}(t)$ by $A_{wet}(t)$ , and considering that the error sources related to $U_{mean}(t)$ and $A_{wet}(t)$ are independent, the squared relative standard

that the error sources related to  $U_{mean}(t)$  and  $A_{wet}(t)$  are independent, the squared relative standard uncertainty  $u'^2(Q)$  could be expressed following the Guide to the expression of the uncertainty in measurement (ISO/IEC 98-3, 2010) as the sum of the squared standard uncertainties of the error
 sources:

$$u'^{2}(Q) = u'^{2}(U_{mean}) + u'^{2}(A_{wet})$$
<sup>(12)</sup>

538 Considering that U<sub>mean</sub> is obtained from two independent linear relations applied consecutively,

539  $u'^2(U_{mean})$  is expressed as follows:

540 
$$u'^{2}(U_{mean}) = u'^{2}(V_{rad}) + u'^{2}\left(\left(V_{rad}, V_{s, \max\_LSPIV}\right)_{rating}\right) + u'^{2}\left(\left(V_{s, \max\_LSPIV}, U_{mean}\right)_{rating}\right)$$
(13)

- 541 Similarly, considering that A<sub>wet</sub> is obtained from a non-linear relation depending on the
- bathymetric profile of the "LSPIV cross-section" and the value of  $H_{LSPIV}$  which itself is derived from  $H_{rad}$  using the slope and the distance between the "radars cross-section" and the "LSPIV cross-section",  $u'^2(A_{wet})$  is expressed as follows:

545 
$$u'^{2}(A_{wet}) = u'^{2}(bathymetry) + u'^{2}(H_{rad}) + u'^{2}(slope)$$
(14)

- The standard uncertainties  $u'(V_{rad})$  and  $u'(H_{rad})$  are calculated as the standard relative errors of the variables  $V_{rad}$  and  $H_{rad}$  which are the standard deviations divided by the means. The standard uncertainties  $u'((V_{rad}, V_{s,max\_LSPIV})_{rating})$  and  $u'((V_{s,max\_LSPIV}, U_{mean})_{rating})$  are the residual standard errors of the linear regressions. The standard uncertainty u'(slope) is calculated as the standard uncertainty of an equiprobable rectangular distribution considering that the slope between the "radars cross-section" and the "LSPIV cross-section" can vary by 0.3% around the value of 2% used in this study. Finally, the standard uncertainty u'(bathymetry) is the most difficult to
- estimate. An assumption is made that the standard uncertainty in the bathymetric profile of the
- 554 "LSPIV cross-section" is 10%.
- 555 By following this simplified approach, it was possible to calculate a standard uncertainty on Q,
- 556 u'(Q), which is constant whatever the value of Q. The final uncertainty is expressed at the 95%
- confidence interval considering a normal distribution and using a coverage factor of 2.
- 558

## 559 **3 Results**

560 3.1 Detection of bathymetric shifts and related periods

561 Figure 5 shows the time series of  $V_{rad}$  and  $H_{rad}$  for the entire study period. As explained already in section 2.2, some periods of missing data are due to the presence of a gravel bar that formed 562 temporarily below the H-V radars. This affects the period from July 2019 to May 2021. Figure 5 563 also displays the time series of water level at La Robine station, the upstream historical station. 564 At each station, water level is expressed in a local coordinate system where the zero level 565 corresponds to the zero in the staff level gauge. It can be seen that at certain periods, the water 566 level at La Robine is higher than the water level at RIPLE, while at other periods it is the 567 opposite. This is due to bathymetric shifts that occured at the RIPLE station during certain 568 floods, whereas bathymetric shifts are very unlikely at La Robine station because the river is set 569 over the bedrock. 570

Figure 6a shows the scatter plot of V<sub>rad</sub> versus H<sub>rad</sub> for the entire study period. Six periods with 571 distinct relations between V<sub>rad</sub> and H<sub>rad</sub> were identified manually. The temporal limits of these 572 periods were extracted from the time-stamping of the couples of points (H<sub>rad</sub>, V<sub>rad</sub>). It is worth 573 mentioning that, even in the absence of the V<sub>rad</sub> time series as it is the case for many hydrometric 574 stations, it would have been possible to identify the bathymetric changes using an automatic 575 shift detection algorithm such as the method presented recently by Darienzo et al. (2021). 576 However, the method used in this study allows a more accurate time stamping of the bathymetric 577 shifts. The end of period 1 was identified to 01/02/2019 10:00 (UTC), the end of period 2 to 578 579 23/10/2019 18:00 (UTC), the end of period 3 to 03/11/2019 04:30 (UTC), the end of period 4 to 21/12/2019 04:50 (UTC), the end of period 5 to 22/01/2021 17:50 (UTC). The six periods are 580 represented in Figure 5 using different colours. The vertical dotted lines in Figure 5 indicate the 581 dates of the topographical surveys carried out at the RIPLE station. There is one campaign per 582 period, with the exception of period 3. The surveyed cross-section profiles associated with each 583 period (except period 3) are shown in Figure 6b. The topographic results confirm that the cross-584 section profiles are significantly different from each other: the change between period 1 and 585 586 period 2 is characterized by an increase in bed elevation of the order of 20 cm in the centre-right

of the river channel due to deposition of sediment. The changes between period 2 and period 3

and between period 3 and period 4 remain unknown. As period 3 lasted only 11 days, it was not

possible to carry out a bathymetric survey during this short period. In fact, during autumn,

significant rainfall events can be frequent on soils that are already very moist, likely to produce repeated morphogenic floods (Esteves et al., 2019). Nevertheless, the change between period 2

repeated morphogenic floods (Esteves et al., 2019). Nevertheless, the change between period 2 and period 4 shows an increase in bed elevation over a large part of the left-hand of the cross-

section. The change between period 4 and period 5 is marked by a decrease in bed elevation of

the order of 50 cm over the width of the river channel due to erosion processes. The change

between period 5 and period 6 is marked by a reorganisation of the shape of the cross-section

596 with a very slight tendency towards sedimentation.

It can be seen that the changes of period occurred during flood events. The change between 597 period 1 and period 2 occurred during the first significant flood of the study (01/02/2019), where 598 the maximum radar velocity reached 3.5 m/s. The change between period 2 and period 3 599 occurred during a period where data were missing at the RIPLE station due to a power failure. 600 However, the data from La Robine station shows that the flood that produced the bathymetric 601 shift (23/10/2019) is of the same order of magnitude as that of the 01/02/2019. The change 602 between period 3 and period 4 occurred during a major flood (03/11/2019) of the study period 603 with maximum radar velocity of 3.5 m/s. The change between period 4 and period 5 occurred at 604 the end of a significant flood (21/12/2019) with maximum radar velocity of 3 m/s. The change 605 between period 5 and period 6 occurred during a small flood (22/01/2021) where the maximum 606 607 radar velocity reached 1.4 m/s. Although the transitions between these periods are generally caused by floods, not all significant floods cause a change in bathymetry. For instance, the events 608 of 02/03/2020, 04/06/2020 and 10/05/2021 did not produce significant changes in bathymetry 609 whereas they were characterized by significant radar velocities (maximum of 2.0 m/s, 1.5 m/s 610 and 2.1 m/s respectively). The factors controlling these changes in bathymetry are not well 611 known yet even though they are assumed to be linked to bedload transport, and more specifically 612 613 to the processes of deposition and remobilisation of gravels. On the other hand, it is likely that some bathymetric changes have been missed. In fact, there is still some dispersion in the H<sub>rad</sub> -614 V<sub>rad</sub> relations for the different separated periods. A more detailed identification, still based on the 615 analysis of the relations between V<sub>rad</sub> and H<sub>rad</sub> or based on the application of an automatic shift 616 617 detection method (Darienzo et al., 2021) would be possible but it would lead to more sub-periods and we would face to the problem of lack of bathymetric data. The proposed breakdown is 618 therefore a compromise between the identification of major bathymetric shifts and the 619 availability of topographic data. It is recognized in this study that there remains a significant 620 degree of uncertainty in the bathymetric profiles within the six separate periods. This is taken 621 into account in the uncertainty analysis. 622

Figure 6c shows the H-A<sub>wet</sub> relations for periods 1 to 6 (except period 3). The result exhibits a significant change in the H-A<sub>wet</sub> relation between period 4 and 5 due to the important digging of the river section during the 21/12/2019 flood event. The other bathymetric changes have a more limited impact on the H-A<sub>wet</sub> relations. The results presented in this section confirm the effectiveness of the method proposed for detection of bathymetric changes. Regular control of the H<sub>rad</sub> - V<sub>rad</sub> scatter plot, coupled with bathymetric survey campaigns, enable to identify major changes in bathymetry and attribute corresponding cross-sectional profiles (i.e. H-A<sub>wet</sub> relations).

Figure 5 – Time series of  $H_{rad}$  (colour data, bottom series, left axis) and  $V_{rad}$  (colour data, top series, right axis) at the RIPLE station. Positioning of video sequence recordings on the time series of  $V_{rad}$  (black circles). Time series of  $H_{rad}$  (black +, left axis) at the Robine station. The vertical dotted lines indicate the dates of the topographical surveys at the RIPLE station.

#### 640 3.2 LSPIV results

The results of LSPIV analysis are summarized in Table 2. The maximum discharge of 30.76 m<sup>3</sup>/s was computed during period 5 for the video taken the 02/03/2020 at 12:43 (UTC) with a value of  $V_{s,max\_LSPIV}$  of 4.37 m/s and a value of  $U_{mean\_LSPIV}$  of 2.86 m/s. The lowest discharge of 0.81 m<sup>3</sup>/s was computed during period 2 for the video taken the 15/10/2019 at 12:21 (UTC) with a value of  $V_{s,max\_LSPIV}$  of 1.02 m/s and a value of  $U_{mean\_LSPIV}$  of 0.71 m/s. Table 2 also gives the values of  $V_{rad}$  and  $H_{LSPIV}$  at the time steps corresponding to the video recordings.  $H_{LSPIV}$  is derived from  $H_{rad}$  according to the method described in the section 2.1.

648

649Table 2 – Results of LSPIV analyses carried out on video sequences recorded at the RIPLE station (Q: flow discharge,  $A_{wet}$ : wetted area,650 $U_{mean\_LSPIV}$ : mean cross-sectional velocity,  $V_{s,max\_LSPIV}$ : maximum surface velocity, y axis: lateral position of  $V_{s,max}$ ,  $\phi_s$ : ratio between  $U_{mean}$ 

and V<sub>s,max</sub>). Extraction of radar data (H<sub>LSPIV</sub> and V<sub>rad</sub>) at time steps corresponding to the video recordings. Results of the Isovel model for

- 3.3 The V<sub>s,max\_LSPIV</sub>-U<sub>mean</sub> relation in the "LSPIV section"
  - 3.3.1 Calibrated relation using LSPIV results

658 Based on data presented in Table 2, the mean cross-section velocity calculated with LSPIV results (U<sub>mean LSPIV</sub>) was plotted against the maximum surface velocity (V<sub>s.max LSPIV</sub>) in Figure 7 659 for each bathymetric period (except period 3). Linear regressions forcing to go through the zero 660 intercept were calculated between the two variables. The statistic results of the linear regressions 661 are presented in Table 3. Significant coefficients of determination (between 0.798 and 0.947) are 662 obtained for all periods. The values of the slope of these different regressions are then compared. 663 664 They range between 0.652 (period 4) and 0.755 (period 1). The interval of confidence of these slopes are also calculated. The assumption to be tested is the resistance of the  $V_{s,max}$  LSPIV-665 U<sub>mean LSPIV</sub> relation to bathymetric shifts. From a strictly statistical point of view, this assumption 666 is not validated here since the 95% confidence intervals of the different regressions do not 667 completely overlap. However, taking into account the relatively small number of points for 668 certain periods (e.g. 6 and 7 observations for periods 1 and 4 respectively) and the uncertainties 669 associated with the LSPIV method for the estimation of V<sub>s,max LSPIV</sub> and U<sub>mean LSPIV</sub> (uncertainties 670 in the image analysis method and in the bathymetry for the calculation of  $U_{mean LSPIV}$ , it seems 671 reasonable to conclude that the differences between the periods are sufficiently small so that the 672 periods can be combined together to calculate an overall regression. Figure 7 shows the linear 673 relation between V<sub>s.max LSPIV</sub> and U<sub>mean LSPIV</sub> for all periods combined together. Tha data of 674 Figure 7 are also reproduced in Figure 8 for intercomparison with the results of the Isovel model 675 and the Q-Commander model. The slope of the global regression is 0.686 and its 95% interval 676 confidence is  $\pm 0.011$  (Table 3). In conclusion, there seems to be a proportionality between 677 V<sub>s,max LSPIV</sub> and U<sub>mean LSPIV</sub>. Moreover this linear relation appears to be independent of 678 bathymetric shifts with a single stable and robust slope, which would represent an intrinsic 679

680 property of the cross-section.

682 683	Figure 7 – Relation between $U_{mean\_LSPIV}$ and $V_{s,max\_LSPIV}$ for each bathymetric period (except period 3). A linear regression forcing to go through the zero intercept is fitted for each bathymetric period and for all periods combined together (black line).

 710
 Figure 8 - Relation between Umean and Vs,max\_LSPTV for all the conditions reported in Table 2. Umean is obtained by three methods: LSPTV

 711
 results, Isovel model and Q-Commander model. A linear regression forcing to go through the zero intercept is fitted for each approach.

 712
 The 95% confidence interval associated with the linear regression for the LSPTV case is shown in grey.

713 3.3.2 Isovel model

As seen in Table 2, the value of  $\frac{1}{\eta_s}$  ranges between 0.54 and 0.64, with an average of 0.61 and a standard deviation of 0.02. Figure 8 represents U<sub>mean</sub> calculated by the Isovel model (U<sub>mean\_Isovel</sub>) versus V<sub>s,max\_LSPIV</sub> derived from the LSPIV analysis for the 69 conditions of Table 2. The linear regression forcing to go through the zero intercept gives a slope of 0.616. This value is 10% lower than the slope of the calibrated regression using LSPIV but it can be considered as an acceptable result given that the Isovel method as applied in this study only requires bathymetric and water level information as input.

721 3.3.3 Q-Commander

As seen in Table 2, the value of the k-factor<sub>min</sub> ranges between 0.49 and 0.70, with an average of 0.64 and a standard deviation of 0.04. Figure 8 represents  $U_{mean}$  calculated by the Q-Commander

- software ( $U_{mean\_Commander}$ ) versus  $V_{s,max\_LSPIV}$  for the 69 conditions of Table 2. The linear
- regression forcing to go through the zero intercept gives a slope of 0.69. This value is of the
- same order of magnitude as the slope of the calibrated relation using LSPIV results. Q-
- 727 Commander is therefore the tool that produces the best prediction of the  $V_{s,max\_LSPIV}$ - $U_{mean\_LSPIV}$
- relation. Q-Commander is potentially an effective tool to be used for future applications.
- However, given that Q-Commander is a commercial software whose code is covered by a patent, the equations used in the model are not available. It is therefore important to continue working
- with methods such as the Isovel model or the Entropy model to understand which factors control
- the linear relation between  $V_{s,max}$  and  $U_{mean}$ .
- 733 3.4 Position of the "y axis"

734 Figure 9 exhibits the position of the "y axis" for all the conditions reported in Table 2 based on LSPIV results. The results are grouped by bathymetric period. The cross-sectional profiles at the 735 "LSPIV section" for each bathymetric period are also displayed. Figure 10a shows the box plots 736 of the "y axis" position for each bathymetric period. The mean value of the position of the "y 737 738 axis" is 12.7 m (standard deviation of 1.8 m), 14.2 m (standard deviation of 0.2 m), 13.9 m (standard deviation of 0.5 m), 14.0 m (standard deviation of 0.9 m), 13.6 m (standard deviation 739 of 0.8 m) for period 1, 2, 4, 5, and 6 respectively. The position of the "y axis" is relatively 740 constant for periods 2 to 6. The maximum relative difference is 2% compared to the average of 741 742 the 4 periods, which is 13.9 m. The maximum relative difference is also 2% compared to the river at bank-full discharge, which is approximately 13.8 m. The standard deviation values for 743 periods 2 to 6 are all lower than 1 m. For period 1, the results are more scattered. The average 744 position of the "y axis" for period 1 is 1.2 m lower than the average value of periods 2 to 6. This 745 represents a relative difference of 8.6% compared to the average of periods 2 to 6. Period 1 746 includes 3 of the 5 smallest discharge values in Table 2. Such discharges are associated with low 747 water depths, as seen in Figure 9, and "y axis" positions that are located both furthest to the left 748 and right sides of the dataset. This may be due to the poorer quality of the LSPIV analyses for 749 low flow conditions and also to the fact that period 1 includes only six observations. Apart from 750 these few outliers, the position of the "y axis" can be considered stable in spite of the 751 bathymetric changes. 752

In Figure 10b, the data from the different bathymetric periods are grouped together and box plots 753 of the position of the "y axis" are represented for the three methods used in this study (LSPIV, 754 Isovel, and Q-Commander). Based on LSPIV results, the mean value of the "y axis" position is 755 13.8 m and the median is 14 m. For the Isovel model, the mean value of the "v axis" position is 756 12.8 m, the median is 13 m and the standard deviation is 1 m. For Q-Commander, the mean 757 value of the "v axis" position is 12.3 m, the median is 12 m and the standard deviation is 1.3 m. 758 The Isovel model and the Q-Commander software predict the average position of the "y axis" 759 respectively 1 m and 1.5 m closer to the right bank than the LSPIV method. This represents a 760 lateral shift of 7% and 11% respectively, considering the width of the river at bank-full 761 discharge, compared to the mean value of the LSPIV method. The standard deviation of the "y 762 axis" for these two methods is of the same order of magnitude as for the LSPIV results (0.9%). 763

764

Figure 9 – Cross-sectional profiles at the "LSPIV section" for each bathymetric period (except period 3) and location of the "y axis",
 which corresponds to the point of maximum surface velocity, for all the conditions reported in Table 2 based on LSPIV results.

In conclusion, the results show that the position of the "y axis" is relatively stable despite strong
bathymetric changes. On the other hand, the theoretical methods (Isovel and Q-Commander)
predict satisfactorily the mean position of the "y axis" compared to the LSPIV results even
though more data is still needed to verify these assertions.

771

#### 3.5 Calculation of discharge time series

#### 3.5.1 Calibrated relation between $V_{rad}$ and $V_{s,max\_LSPIV}$

As described in section 2.6.2, a relation needs to be established between  $V_{rad}$  measured in the 780 "radars section" and V<sub>s.max LSPIV</sub> obtained in the "LSPIV section" before V<sub>s.max LSPIV</sub> can be 781 transformed into U<sub>mean</sub>. Figure 11 presents the scatter plot of V<sub>s.max LSPIV</sub> versus V<sub>rad</sub>. Two groups 782 of periods were distinguished: periods 1 to 2 on one hand, periods 4 to 6 on the other hand. 783 Figure 11 also shows the linear regression fitted for each group of periods as well as their 95% 784 confidence intervals. The coefficient of determination is high for each of the linear regressions, 785 with R<sup>2</sup>=0.9015 for periods 1 to 2 and R<sup>2</sup>=0.8111 for periods 4 to 6. The reasons for this change 786 in the linear relation are not entirely clear. It seems to be linked to a shift in the morphological 787 788 behaviour between the "radars section" and the "LSPIV section". There may have been a localised and temporary scouring of the riverbed in the vicinity of the bridge where the radars are 789 installed caused by the hydraulic jump in the upper part of the bridge. 790

Figure 11 – Relations between V<sub>s,max LSPIV</sub> in the "LSPIV section" and V<sub>rad</sub> in the "radars section" based on the results reported in Table 2
 for two different groups of periods. A linear regression is fitted for each group of periods. The 95% confidence intervals associated with
 the linear regressions are shown in grey.

795

#### 796 **4 Discussion**

- 797 4.1 Evaluation of the method
- 798

# 4.1.1 Comparison with the historical station at La Robine

The discharge algorithm was applied to the data at RIPLE for the period from October 2018 to 799 May 2021, except period 3 (from 23/10/2019 to 03/11/2019) due to the absence of bathymetric 800 data. The discharge time series at RIPLE, expressed as specific discharge of the drainage area (in 801  $m^{3}/s/km^{2}$ ), are shown in Appendix 1. The discharge time series at La Robine are also represented 802 in Appendix 1 as they provide the only comparative data for assessing the method presented in 803 this study. The Galabre catchment at la Robine station drains a surface of 20 km<sup>2</sup> compared with 804 a surface of 34 km<sup>2</sup> at the RIPLE station. This corresponds to a 41% increase in the drained area 805 of the catchment from La Robine station to RIPLE station. Therefore, a very good match 806 between the data of the 2 stations cannot be expected, even in the case of perfectly accurate data, 807 808 because of the hydrological processes involved (spatial distribution of rainfall, heterogeneity of soils properties, land cover, and infiltration, role of the alluvial water table) and the phenomenon 809

of flood wave propagation. In general, the data seem to match up well. Table 4 presents the

statistics of the comparison between the specific discharge at the two stations for all the time

steps of the study period, except when data is missing at one of the stations. Both stations have

the same sampling period (e.g. 10 min). Results are obtained by comparing data of the two

stations at the same time step. The time lag associated with the transfer of water from upstream

to downstream is neglected in this comparison. The time lag between peak discharge at the two stations during floods is short, generally on the order of 10 to 20 min and possibly up to 30-40

min for small floods in spring and summer. Outside the floods, there is no need to consider a

time lag as the regime is considered permanent. Anyway, the data were compared with and

819 without a time lag, but there was no gain in the results when a time lag was considered.

821 Table 4 – Statistic results of the comparison between the specific discharge at La Robine and RIPLE stations for all the data of the study.

_	all data	Vrad > 0.7 m/s	Vrad < 0.7 m/s
Nash-Sutcliffe efficiency (NSE)	0.877	0.863	0.580
Log Nash-Sutcliffe efficiency (logNSE)	0.248	0.738	-0.084
Percent Bias (PBIAS)	4.5	2.9	8.7

822

Three statistical results are given in Table 4: the Nash-Sutcliffe efficiency (NSE), the log Nash-Sutcliffe efficiency (logNSE), and the percent bias (PBIAS). The NSE provides information about the deviation of the specific discharge at RIPLE compared to the specific discharge at La Robine. Applying the NSE to the logarithm of discharges (logNSE) enables to assess the behaviour of the prediction at low flow discharges. PBIAS provides information on the existence of a simulation bias (negative or positive), expressed as a %, between the two variables.

The data are considered as a whole (all data) and then divided into two groups according to the 829 value of the fixed velocity radar:  $V_{rad} > 0.7$  m/s and  $V_{rad} < 0.7$  m/s. The values of NSE are good 830 (i.e. in the range 0.86-0.88) for "all data" and the " $V_{rad} > 0.7$  m/s" group and less good (0.58) for 831 the " $V_{rad} < 0.7$  m/s" group. The logNSE value is reasonably good (0.738) for the " $V_{rad} > 0.7$ 832 m/s" group, but much worse (0.248) for "all data", and poor (-0.084) for the " $V_{rad} < 0.7$  m/s" 833 group. The PBIAS value is the lower (2.9%) for the " $V_{rad} > 0.7$  m/s" group, intermediate (4.5%) 834 for "all data", and the higher (8.7%) for the " $V_{rad} < 0.7 \text{ m/s}$ " group. These results show that the 835 comparison between specific discharges at the two stations is generally acceptable for "all data". 836 This comparison is better when  $V_{rad}$  is above 0.7 m/s. In contrast, below this velocity, specific 837 discharges at RIPLE calculated using the approach presented in this study are significantly 838 different from specific discharges at La Robine station calculated using the stage-discharge 839

rating curve, and have an overall tendency to underestimate.

The literature frequently states that surface velocity radars do not perform well in the low-

velocity range (Welber et al., 2016; Fulton et al., 2020; Rahman Khan et al., 2021; Son et al.,

843 2023), even though manufacturers claim that instrument sensitivity and resolution are good even

at low velocities. In fact, the environmental conditions encountered for low velocities make

measurements less reliable. Sources of error in this velocity range (typically below 0.7 m/s)

include (i) wind, which has a more detrimental effect than at higher velocities; (ii) the higher

847 distance between the sensor and the free surface compared to high flow conditions, which

<sup>820</sup> 

increases the sampled area and thus the variability of the measurement; and (iii) the diversity of hydraulic micro-controls, which can occur at low water levels due to the exposition of boulders.

850 851

Figure 12 – Specific discharge at the RIPLE station versus specific discharge at La Robine station for all the study period.

Figure 12 shows the same data as in Appendix 1 but in the form of a scatter plot of specific 852 discharges at the two stations. First of all, the regression between the two variables was 853 calculated. It gives a slope equal to unity, an intercept of almost zero, and a coefficient of 854 determination of 0.88. This confirms the good general agreement between the two variables and 855 the general absence of bias. However, the two variables are better correlated for higher values 856 than for lower values. This finding is supported by the results of Table 5 which presents the 857 percentages of values of specific discharge at RIPLE that belong to the ranges  $\pm 25\%$ ,  $\pm 50\%$  and 858  $\pm$  100% of the corresponding values at La Robine. Similarly, the lines at  $\pm$  25% of the 1:1 line 859 are shown in Figure 12. In Table 5, the data are considered as a whole (all data) and then three 860 subsets are considered according to the value of the fixed velocity radar:  $V_{rad} > 0.7$  m/s,  $V_{rad} > 1$ 861 m/s, and  $V_{rad} > 1.5$  m/s. When "all data" are considered, only 15.7% of the specific discharges 862 calculated at RIPLE belong to the range  $\pm 25\%$  of the corresponding specific discharges at La 863 Robine. On the other hand, when considering the subsets for which the value of  $V_{rad}$  is greater 864 than 0.7, 1 and 1.5 m/s, respectively 30.6, 38.4 and 45.6% of the specific discharges calculated at 865 RIPLE fall within the range  $\pm 25\%$  of the corresponding specific discharges at La Robine. These 866 percentages increase significantly when the intervals at  $\pm$  50% and  $\pm$  100% of corresponding 867 specific flows at La Robine are considered. This corroborates the fact that the results are worse at 868

- low radar velocities (i.e. < 0.7 m/s) and better at higher radar velocities. This velocimetric
- 870 method is therefore rather reserved to medium to high flow conditions.
- 871

# Table 5 – Percentages of values of specific discharge at RIPLE within ± 25%, ± 50% and ± 100% of values of specific discharge at La Robine.

	all data	V <sub>rad</sub> > 0.7 m/s	$V_{rad} > 1 m/s$	$V_{rad}$ > 1.5 m/s
number of observations	27103	7421	3383	842
$(Q_{spe})_{RIPLE} \in [0.75 \text{ x} (Q_{spe})_{La Robine}; 1.25 \text{ x} (Q_{spe})_{La Robine}]$	15.7%	30.6%	38.4%	45.6%
$(Q_{spe})_{RIPLE} \in [0.5 \text{ x} (Q_{spe})_{La Robine}; 1.5 \text{ x} (Q_{spe})_{La Robine}]$	29.8%	61.1%	77.7%	79.0%
(Q <sub>spe</sub> ) <sub>RIPLE</sub> ε [0 x (Q <sub>spe</sub> ) <sub>La Robine</sub> ; 2 x (Q <sub>spe</sub> ) <sub>La Robine</sub> ]	89.0%	95.0%	94.6%	93.0%

874

To conclude, the comparison of specific discharges at the two stations needs to be put into 875 perspective. First, the quality of the observed discharges at La Robine is not perfect, especially at 876 high flow conditions, since few direct discharge measurements were available to build the stage-877 discharge rating curve. Second, it should be remembered that there is a 41% increase in the 878 drained area between the 2 stations which means that the discharges at the two stations have to 879 be rescaled to be compared. This is far from ideal, but there was no real alternative in this study. 880 Therefore, it is still necessary to make comparisons of this type at other stations where reference 881 data is available, in order to assess the velocimetric method presented in this study rigorously. 882 Nevertheless, the results of this study show that the approach presented in this study is able to 883 produce valuable continuous discharge time series during floods and more generally in medium 884 to high flow conditions, despite the very frequent occurrence of bathymetric changes, given a 885 limited investment of time and people in the field. 886

887

888 4.1

4.1.2 Uncertainty analysis

The results of the simplified uncertainty analysis applied to the velocimetric method are 889 presented in Table 6. This table gives the relative error (in %) of each terms of uncertainty 890 891 considered in this study. The dominant uncertainty terms are the two linear relations applied consecutively to transform V<sub>rad</sub> into U<sub>mean</sub>, the bathymetry of the "LSPIV cross-section" and the 892 slope between the "radars cross-section" and the "LSPIV cross-section". Their relative error 893 894 range between 7.1% and 12.6%. The relative uncertainty on Q which is calculated as the root square of the sum of the squares of the different terms of Table 6 is 20%. The four dominant 895 terms of uncertainty listed above represent 83.2% of the uncertainty on Q and 98% of the relative 896 897 uncertainty on Q considering the 6 sources shown in the Table 6.

<sup>899</sup> Table 6 - Relative error (in %) of each terms of uncertainty considered in this study when applying the velocimetric method..

		u'(V <sub>rad</sub> )	u'(V <sub>rad,</sub> V <sub>s,max</sub> ) <sub>rating</sub>	u'(V <sub>s,max,</sub> U <sub>mean</sub> ) <sub>rating</sub>	u'(bathymetry)	u'(H <sub>rad</sub> )	u'(slope)
	uncertainty (%)	4	12.6	7.1	10	0.01	8.7
	relative weight of each	0.4	22.0	15.6	17.0	0.0	17.6
	uncertainty source (%)	9.4	52.0	15.0	17.2	0.0	17.0

900

907

This uncertainty analysis is simplified insofar as the uncertainty is considered to be constant whatever the discharge value. Referring to the previous section, it makes sense to follow this simplified analysis for situations where radar velocities are greater than 0.7 m/s, which corresponds to high flow conditions in this study. On the other hand, this simplified analysis does not really make sense for situations involving low radar velocities and low water levels. In such case, the uncertainty is largely underestimated.

908Figure 13 – Time series of specific discharge at the RIPLE station calculated using the approach presented in this study and at La Robine909calculated using the stage-discharge rating curve for the period from 01/03/2020 to 07/03/2020. The 95% confidence intervals are shown910in pink for data at RIPLE and in grey for data at La Robine. The values of specific discharge measured directly at RIPLE by the LSPIV911method for the conditions reported in Table 2 are also shown.

The 95% confidence interval of Q is calculated as  $\pm$  twice the value of the relative uncertainty on Q. Figure 13 exhibits the time series of specific discharge calculated using the approach presented in this study at the RIPLE station for the period from 01/03/2020 to 07/03/2020. On the same figure, the time series of specific discharge calculated at La Robine station using the

stage-discharge rating curve is displayed. For this latter station, the relative uncertainty on Q

considered by Navratil et al. (2011) in their global uncertainty analysis of suspended sediment

monitoring was as high as 20%. Finally, the values of specific discharge calculated by the LSPIV

method for the conditions reported in Table 2 (direct LSPIV measurements) are also shown in

Figure 13. It can be checked that the values of specific discharge measured directly at RIPLE by

the LSPIV method are within the confidence interval of the time series of specific discharge at
 RIPLE calculated using the approach presented in this study. Furthermore, it can be seen that the

data of the two stations overlap during the two successive floods, except during the first phase of

the rise of the first flood. At the end of the first flood and outside flood periods, the agreement

between the data at the two stations decreases. This observation supports the previous conclusion

which hinders the application of the method to low flow conditions.

927

4.2 Limitations and perspectives for improving the method

929 The method presented in this study makes it possible to produce reliable streamflow time series

- in a river prone to bathymetric shifts when no other method is available. As a result, the method
- has serious advantages to offer. However, the choice of the section to be instrumented must
- remain that of a hydrometer, as the conditions to be met are those for current meter gauging, i.e.
- reach of river as uniform as possible with quasi 1D velocities. Furthermore, it should be borne in mind that the method proposed in this study has yet to be validated with reference data in
- different environments. It should also be mentioned that this method does not allow a qualitative
- estimation discharge in low flow conditions, i.e. when radar velocities are below 0.7 m/s. This
- can pose problems for rivers located in areas of low slope. The method is also less effective for
- higher than bank-full discharges, as the position of the "y axis" is likely to change when flood
- 939 plain is inundated.
- In terms of uncertainty, we should recognize that our framework for computing the uncertainty is
- too simplistic, and has to be improved. It is clear that the relative error is largely underestimated
- for radar velocities lower than 0.7 m/s. However, it is important to bear in mind, that the idea that
- supports this research is to increase the spatial density of streamflow stations in the future,
- particularly in small rivers where it is impossible with current ressources to install more
- 945 conventional hydrometric station (H-Q). In the end, it might be acceptable to have greater
- 946 uncertainty on discharge estimation if, at the same time, the number of streamflow monitoring
- points increases spatially.
- The perspective of this research would be to apply the method presented in this study in
- ungauged rivers and possibly in the absence of LSPIV discharge measurements. Indeed, the
- analysis of video sequences with the LSPIV method requires both time and expertise, which
- could hamper the multiplication of new stations of this type. It would be possible to automate the
- 952 LSPIV method, but this would require a great deal of effort and the method would still have
- limitations in certain light conditions, as it is a passive method.
- 954 Our perspective is rather to try to be parsimonious and favours active instruments (i.e. radar or
- LiDAR). To do this, we propose in the future to position the H and V radars directly in the hydraulically suitable choosen section. In this study, this would have meant placing the radars
- directly above the "LSPIV cross section" using cables for instance, instead of placing them on
- the bridge ten meters upstream. This would eliminate two sources of error: the relation between
- $H_{rad}$  to  $H_{LSPIV}$  and the relation between  $V_{rad}$  and  $V_{s,max}$  LSPIV. Moreover, we propose to install the
- V radar directly at the "y axis", assuming that the position of the "y axis" does not vary over
- time, except when the flood plain is inundated. By doing so, the relative uncertainty on Q would
- drop to 12.9% as two of the dominant terms of uncertainty would be removed in Table 6.
- Different approaches can be considered for positioning the V radar at the "y axis" in the
- hydraulically suitable choosen section and assessing the the  $U_{mean}/V_{max}$  ratio. Fulton et al. (2020)
- propose to use at least one highly-resolved velocity gauging obtained by ADCP or current meter
- to identify the position of the "y axis" in the cross section and apply the entropy method for the
- vertical velocity profile at the "y axis" to predict also the  $U_{mean}/V_{max}$  ratio. Alternatively, if
- several highly-resolved velocity gaugings are available, Fulton et al. (2020) propose to calibrate the  $U_{mean}/V_{max}$  ratio with the historical pairs of  $U_{mean}$  and  $V_{max}$ . They mention that this second
- method is optimal. It also enables to improve the accuracy of the position of the "y axis" and
- therefore that of the V radar to be installed at that position. However, this approach still requires

- a lot of human ressources and expertise in the field for highly-resolved velocity gaugings in
- different flow conditions. Moreover, there remains a doubt: it is not clear how Fulton et al.
- 974 (2020) calculate  $U_{mean}$  from  $V_{rad}$  when the relation is established between the  $V_{max}$  and  $U_{mean}$ .

With the aim of being as parsimonious as possible while maintaining the quality of the estimates, 975 we have tested in this study the possibility of predicting the position of the "y axis" and the ratio 976 between V<sub>s.max</sub> and U<sub>mean</sub> using theoretical methods, i.e. the Isovel model and the Q-Commander 977 model. The results are promising, as these theoretical methods predict quite well the location of 978 979 the "y axis" and the  $U_{mean}/V_{s,max}$  ratio based on limited information, i.e. the bathymetry of the cross-section and the bed roughness. These models still need to be evaluated in a larger number 980 of rivers and environments where reference data are available. For the Isovel model, the results 981 could certainly be further improved by considering a non-uniform roughness coefficient and by 982 adjusting the exponent of the power law, set to 7 in this study. The impact on the quality of the 983 discharge estimates should also be assessed when applying the "y axis" and the  $U_{mean}/V_{s,max}$  ratio 984 predicted by these theoretical models. To realize this, it is necessary to have independent data of 985 986 quality for the reference discharges.

Finally, one way of improving the method presented here would be to automate the detection of

changes in the  $H_{rad}$  -  $V_{rad}$  scatter plot due to changes in the bathymetry by using machine-

learning algorithms for example, and also to try to automate bathymetric surveys. (Gourley,

2017; Li et al., 2019; Stumpf et al., 2016) proposed methods to automate topographic surveys

based on LiDAR and stereophotogrammetry, at least after the floods when the water level

decreased sufficiently to expose to the air a large part of the cross-section. Such methods should

be tested in future studies.

## 994 **5 Conclusions**

The application of the conventional method (stage-discharge rating curve) for monitoring of

streamflow is not appropriate, or even not feasible, in rivers prone to frequent topographic shifts.

<sup>997</sup> This study proposes an effective and robust framework based on the index velocity method

combined with non-contact instruments in order to provide continuous time series of streamflow in such rivers. The approach, which relies on water level and surface velocity radar monitoring,

LSPIV discharge measurement and bathymetry surveys, is tested using a dataset of 2.5 years in a

river of the southern French pre-Alps. By plotting the  $H_{rad} - V_{rad}$  scatter plot, the location in time

1002 of the bathymetric changes are easily detected - they all occur during floods - and six

1003 bathymetric periods are defined. For each bathymetric period, a relation between the water level

and the wetted area of the cross-sectional profiles is built based on bathymetric surveys. A linear and proportional relation is then sought between the maximum surface velocity in the "LSPIV

- 1006 cross-section' called  $V_{s,max}$  LSPIV and the cross-sectional velocity  $U_{mean}$  LSPIV. The values of
- $V_{s,max LSPIV}$  are extracted for 69 video sequences recorded during floods.  $U_{mean}$  is obtained based
- 1008 on three different methods: (i) LSPIV discharge measurement; (ii) the Isovel model; (iii) the Q-
- 1009 Commander software developed by the Sommer company. The  $U_{mean}/V_{s,max\_LSPIV}$  ratio is
- respectively 0.686, 0.616 and 0.692 for the three methods listed previoulsy. Isovel and Q-
- 1011 Commander methods correctly predict the  $U_{mean}/V_{s,max\_LSPIV}$  ratio compared to the method
- 1012 calibrated with LSPIV discharge measurements (within a range of less than 10%), while they
- 1013 only rely on bathymetric, bed roughness and water level information as input. These are

- 1014 therefore parsimonious methods that could prove useful in the future in the absence of highly
- 1015 resolved velocity gauging.

The location of the maximum velocity in the cross-section is also investigated in the study. The analysis of the LSPIV measurements show that the position of the "y axis" is relatively constant for all bathymetric periods and to a lesser extent when period 1 is also included, in spite of strong bathymetric changes. When the Isovel and Q-Commander models are applied, the mean value of the "y axis" represents a lateral shift to the right bank of 7% and 11% respectively, considering the width of the river at bank-full discharge, compared to the mean value obtained with the LSPIV measurements. These methods confirm the stability of the position of the "y axis" in

1023 presence of bathymetric changes.

Finally, discharge is calculated at each time step as the product of the cross-sectional velocity and the wetted area, to produce a time series of streamflow for the entire study period. The

results are compared in terms of specific discharge with the data collected at an historical station

1027 located 2.5 km further upstream on the same river and presenting a stable H-Q rating curve. Data

1028 comparison is good when  $V_{rad}$  is above 0.7 m/s (NSE of 0.863, logNSE of 0.738, PBIAS of

1029 2.9%) but much less good when  $V_{rad}$  is below 0.7 m/s (NSE of 0.580, logNSE of -0.084, PBIAS 1030 of 8.7%). The quality of the estimates increases as  $V_{rad}$  increases, since respectively 61.1% and

1031 79% of the estimates are within the range  $\pm$  50% of the specific discharges at the historical

1032 station when  $V_{rad}$  is greater than 0.7 m/s and 1.5 m/s.

- 1037 CE01-0019-01 (DEAR project). This research was also supported by ANR through the
- 1038 "Investment for Future Excellency Equipment" project CRITEX with the reference ANR-11-
- 1039 EQPX-0011 and project TERRA FORMA with the reference ANR-21-ESRE-0014. The
- 1040 deployment of the RIPLE platform in the field was supported by the Labex OSUG@2020 (grant
- no. ANR10 LABX56) and the Institut National des Sciences de l'Univers (grant no.
- 1042 INSU/CNRS). The maintenance of the RIPLE platform and La Robine station was carried out by
- 1043 the technical service of the IGE.
- 1044

## 1045 Open Research

- 1046 The data used to produce the results in this study are made available through two public
- 1047 repositories: one for the data of the RIPLE station (Nord, 2024) and another one for the data of the
- 1048 upstream station at La Robine sur Galabre (https://bdoh.irstea.fr/DRAIX/station/GALABRE). Please
- 1049 reach out to the corresponding author for further information.
