Abstract

Previous simulations have suggested that O+ outflow plays a role in driving the sawtooth oscillations. This study investigates the role of O+ by identifying the differences in ionospheric outflow between sawtooth and non-sawtooth storms using 11 years of FAST/Time of flight Energy Angle Mass Spectrograph (TEAMS) ion composition data from 1996 through 2007 during storms driven by coronal mass ejections (CMEs). We find that the storm's initial phase shows larger O+ outflow during non-sawtooth storms, and the main and recovery phases revealed differences in the location of ionospheric outflow. On the pre-midnight sector, a larger O+ outflow was observed during the main phase of sawtooth storms, while non-sawtooth storms exhibited stronger O+ outflow during the recovery phase. On the dayside, the peak outflow shifts significantly towards dawn during sawtooth storms. This strong dawnside sector outflow during sawtooth storms warrants consideration.

12 **Key Points:**

- 13 • The intensity and location of O⁺ outflow during storms are different in storms with
14 and without sawtooth oscillations.
- 15 • The peak dayside outflow is significantly shifted towards dawn during storms with
16 sawtooth observations.
- 17 • The nightside picture is mixed; the pre-midnight O⁺ outflow is higher in the main
18 phase but lower in the recovery phase of sawtooth storms.

Abstract

Previous simulations have suggested that O^+ outflow plays a role in driving the sawtooth oscillations. This study investigates the role of O^+ by identifying the differences in ionospheric outflow between sawtooth and non-sawtooth storms using 11 years of FAST/Time of flight Energy Angle Mass Spectrograph (TEAMS) ion composition data from 1996 through 2007 during storms driven by coronal mass ejections (CMEs). We find that the storm's initial phase shows larger O^+ outflow during non-sawtooth storms, and the main and recovery phases revealed differences in the location of ionospheric outflow. On the pre-midnight sector, a larger O^+ outflow was observed during the main phase of sawtooth storms, while non-sawtooth storms exhibited stronger O^+ outflow during the recovery phase. On the dayside, the peak outflow shifts significantly towards dawn during sawtooth storms. This strong dawnside sector outflow during sawtooth storms warrants consideration.

Plain Language Summary

A sawtooth event is a convection mode in Earth's magnetosphere, which transports solar wind plasma and energy into the inner magnetosphere and ionosphere. Despite three decades since their discovery, the mechanism behind sawtooth oscillations remains uncertain. One theory suggests that O^+ outflow induces sawtooth oscillations through an internal feedback mechanism. In line with this theory, some simulations have generated sawtooth oscillations under steady geomagnetic conditions. Furthermore, previous observations indicate that some, but not all, geomagnetic storms exhibit sawtooth oscillations. This study utilizes data from the FAST/TEAMS instrument (1996-2007) and compares O^+ outflow variations during geomagnetic storms with and without sawtooth oscillations. Findings indicate that during the storms' initial phase, sawtooth storms produce less O^+ outflow than non-sawtooth storms. Additionally, non-sawtooth storms exhibit higher O^+ outflow in the dayside during the main phase and in the pre-midnight sector during the recovery phase, challenging the key role of O^+ outflow in driving the feedback mechanism. However, observing large O^+ outflow in the dawnside sector of sawtooth events suggests more investigation is needed.

1 Introduction

When the interplanetary magnetic field (IMF) is southward, magnetotail reconnection brings solar wind plasma and energy into the inner magnetosphere and ionosphere via three different modes: Steady Magnetospheric Convection mode (SMC), magnetic substorms, and the comparatively less-explored phenomenon of sawtooth events. In SMC, the magnetosphere does not accumulate solar wind energy but redirects it from the dayside to the nightside by a nearly balanced reconnection rate on both sides (Sergeev et al., 1996; DeJong et al., 2008). Conversely, during the magnetospheric substorm, the magnetosphere acts as an energy reservoir, storing solar wind energy in the tail lobes and then releasing it into the inner magnetosphere and ionosphere. For an isolated substorm, the process of loading/unloading energy is localized near midnight in magnetic local time (MLT) (Russell & McPherron, 1973; Hones Jr. et al., 1984). In some cases, this loading/unloading energy occurs over a wider MLT region, during a longer time period, and quasi periodically with more than two oscillations. This mode is termed a global sawtooth event (Reeves et al., 2002; Henderson, 2004). The reason for the magnetosphere's preference for one mode over the other in response to the solar wind energy input is still unknown.

Global sawtooth events, identified as quasi-periodic, large-amplitude oscillations in energetic particles at geosynchronous orbit (Belian & Cayton, 1989; Borovsky et al., 1993) with a periodicity of 2–4 hours (Cai & Clauer, 2009), derive their name from the saw blade-like characteristics of particle injections marked by a gradual decrease (growth

69 phase) followed by a sharp increase (onset) (Belian et al., 1995). These energetic par-
70 ticle flux oscillations are correlated with magnetic field changes in the tail, at geostation-
71 ary orbit, and ground stations, as well as changes in the auroral electrojet index, auro-
72 ral precipitation, and polar cap indices (Huang et al., 2003; Kitamura et al., 2005; Cai
73 et al., 2006; Henderson et al., 2006; Huang & Cai, 2009; Troshichev & Janzhura, 2009).
74 These observations suggested that the sawtooth mode is generated by an internal mag-
75 netospheric instability (Huang, 2011); however, there are studies that claim sawtooth events
76 are generated by external parameters in solar wind drivers (Lee et al., 2004, 2006; Cai
77 & Clauer, 2013). Cai and Clauer (2009, 2013) compiled a comprehensive list of sawtooth
78 events spanning from 1996 to 2007, encompassing a total of 126 events. Cai et al. (2011),
79 through extensive statistical analysis, examined the relationship between sawtooth events
80 and geomagnetic storms and found that a substantial majority, 94.6%, of sawtooth events
81 occurred during geomagnetic storms.

82 During geomagnetic storms, the O^+ density and pressure and its occurrence fre-
83 quency in the plasma sheet and lobe are enhanced (Kistler et al., 2006, 2010; Liao et al.,
84 2010). The ionosphere is the main source of O^+ ions in the magnetosphere (Shelley et
85 al., 1972; Sharp et al., 1974), predominantly from two regions: the dayside cusp and the
86 nightside auroral region (Yau & André, 1997) and the increase of O^+ outflow during storms
87 has been reported from both sources e.g. (Yau et al., 1988; Cully et al., 2003; Nowrouzi
88 et al., 2023). Cusp-origin O^+ flows along the open field lines to the lobe and enters the
89 plasma sheet during reconnection in the tail. The field lines in the nightside auroral re-
90 gions are directly connected to the plasma sheet. The occurrence of sawtooth events dur-
91 ing storms, when O^+ is enhanced, suggests that the cause of substorms may be related
92 to the O^+ .

93 Brambles et al. (2011) incorporated ionospheric O^+ fluence into the multifluid Lyon-
94 Fedder-Mobarry (LFM) model (Lyon et al., 2004) and demonstrated that strong O^+ flu-
95 ence can generate sawtooth events in simulations. Ouellette et al. (2013) investigated
96 the mechanism for driving the events and introduced a hypothesis for the periodicity of
97 sawtooth events: the periodic loading and unloading of O^+ ions through ionospheric out-
98 flow into the plasma sheet changes the reconnection rate within the magnetotail current
99 sheet. These variations in reconnection rate lead to distinct magnetic field configuration
100 changes in the tail, releasing an O^+ -rich plasmoid and sending particle precipitation and
101 Alfvénic waves towards the ionosphere, which drives more outflow for the subsequent saw-
102 tooth in the cycle. This mechanism suggests that it is nightside O^+ outflow that is re-
103 sponsible. Using simulation Brambles et al. (2013) found that for an event driven by cor-
104 onal mass ejections (CME) with steady solar wind conditions, nightside O^+ fluence was
105 required to generate the sawtooth oscillations. In contrast, sawtooth events driven by
106 streaming interaction regions (SIR) could be driven without O^+ fluence. Using a physics-
107 based model, Varney et al. (2016) simulated a sawtooth event under steady solar wind
108 conditions and found that the cases that developed sawtooth oscillations had strong out-
109 flow in the midnight auroral region. Zhang et al. (2020) investigated whether cusp out-
110 flow could also drive sawtooth oscillations. They found that while only 10% of dayside
111 cusp O^+ outflow reached the plasma sheet, it was sufficient to induce sawtooth oscilla-
112 tions. Finally, Wang et al. (2022) showed that kinetic reconnection in the magnetotail
113 can reproduce the periodic loading and unloading of the magnetic flux in the magneto-
114 sphere even without ionospheric outflow. Thus, from the simulation results, sawtooth
115 oscillations can be driven by either nightside or dayside outflow or from strong driving,
116 independent of outflow.

117 The magnetotail observations also do not give a clear picture. Liao et al. (2014)
118 investigated and compared the composition of the plasma sheet during sawtooth events
119 and isolated storm-time substorms. While the O^+/H^+ ratio was higher on average dur-
120 ing the sawtooth substorms, there were substorms with a high O^+/H^+ ratio for no saw-
121 tooth events, as well as sawtooth substorms with a low O^+/H^+ ratio.

122 Regarding the source of the O⁺ nightside aurora outflow vs. dayside cusp outflow
 123 during the sawtooth substorms, an observational study showed that the cusp is the pre-
 124 dominant source of O⁺ ions in the 15-20 Re plasma sheet where sawtooth events driven
 125 by SIRs and CMEs (Lund et al., 2018). This is where the near-Earth neutral line is typ-
 126 ically located, therefore, where the plasma sheet composition would potentially affect re-
 127 connection.

128 Therefore, neither the simulations nor the observations have been conclusive on the
 129 role of O⁺ in driving sawtooth oscillations. However, another aspect that might help to
 130 clarify the role of O⁺ is to determine how the ion outflow varies in intensity and loca-
 131 tion between storms with sawtooth oscillations and storms without. Since global saw-
 132 tooth oscillations occur during some, but not all geomagnetic storms (Borovsky, 2004),
 133 it is worthwhile to investigate the variation of ionospheric O⁺ outflow during CME storms,
 134 comparing those with sawtooth events to those without sawtooth events. If either day-
 135 side or nightside O⁺ outflow is involved in triggering sawtooth events, we would expect
 136 significant differences in the outflow characteristics for these two types of events. Since
 137 most of the sawtooth teeth occur in the main and recovery phases (Cai et al., 2011), the
 138 outflow characteristics are investigated during different storm phases.

139 2 Data and Methodology

140 To examine the role of ionospheric O⁺ outflow in driving sawtooth events, this study
 141 measures the averaged ionospheric O⁺ and H⁺ outflow during geomagnetic storms and
 142 compares the outflow during sawtooth storms (i.e., storms with sawtooth oscillations)
 143 with the outflow during non-sawtooth storms. For this purpose, we will use the list of
 144 all CME storms with clear main and recovery phases and with a minimum value of Dis-
 145 turbance storm time index (Dst) less than $-50nT$, from 1996 to 2007, published in Nowrouzi
 146 et al. (2023). This list contains information about the time of the initial, main, and re-
 147 covery phases, as well as the solar wind driver for each storm. Our process involved cross-
 148 referencing each storm from this list with the corresponding period in this list of saw-
 149 tooth events from 1996-2007, (Cai & Clauer, 2009, 2013). If a storm in the first list in-
 150 volves a sawtooth event in the second list, we label the storm as a sawtooth storm; oth-
 151 erwise, it is labeled as a non-sawtooth storm.

152 Since simulations such as (Brambles et al., 2013) and (Varney et al., 2016), find
 153 that ionospheric O⁺ outflow is only needed during storms with steady solar wind con-
 154 ditions to drive the sawtooth mode, this study is limited to the geomagnetic storms which
 155 are driven by CMEs. Also, to reduce the effect of the storm's intensity on this sawtooth/non-
 156 sawtooth comparison, this statistical analysis only examines moderate storms with $-150nT \leq$
 157 $Dst_{minimum} \leq -50nT$. In Figure 1, the minimum Dst of all CME moderate storms
 158 used in this study are plotted. The red and blue circles represent the sawtooth and non-
 159 sawtooth storms, respectively. The orange line shows the smoothed daily average of F10.7,
 160 the solar radio flux at 10.7 cm as an indicator of solar activity, during solar cycle 23, which
 161 spans from 1996 to 2008. It is observed that sawtooth events during moderate CME storms
 162 are observed in all the solar cycle's phases, however they are more common in the so-
 163 lar cycle's maximum phase with $180s.f.u. < F10.7$ (or less common during the mini-
 164 mum phase with $F10.7 < 180s.f.u.$). In Figure 1, the moderate CME storms include
 165 158 sawtooth injections. In total, there are identified 4 teeth during the initial phase,
 166 88 teeth during the storm main phase, 52 teeth during the early recovery phase, and 14
 167 teeth during the long recovery phase.

168 The Fast Auroral Snapshot Explorer (FAST) spacecraft was launched in August 1996
 169 to advance the study of auroral acceleration physics and magnetosphere-ionosphere cou-
 170 pling. FAST was placed into an elliptical polar orbit characterized by a period of 133
 171 minutes, an inclination angle of 83°, a perigee altitude of approximately 350 km, and an
 172 apogee altitude of roughly 4175 km (Carlson et al., 1998). On the FAST spacecraft, the

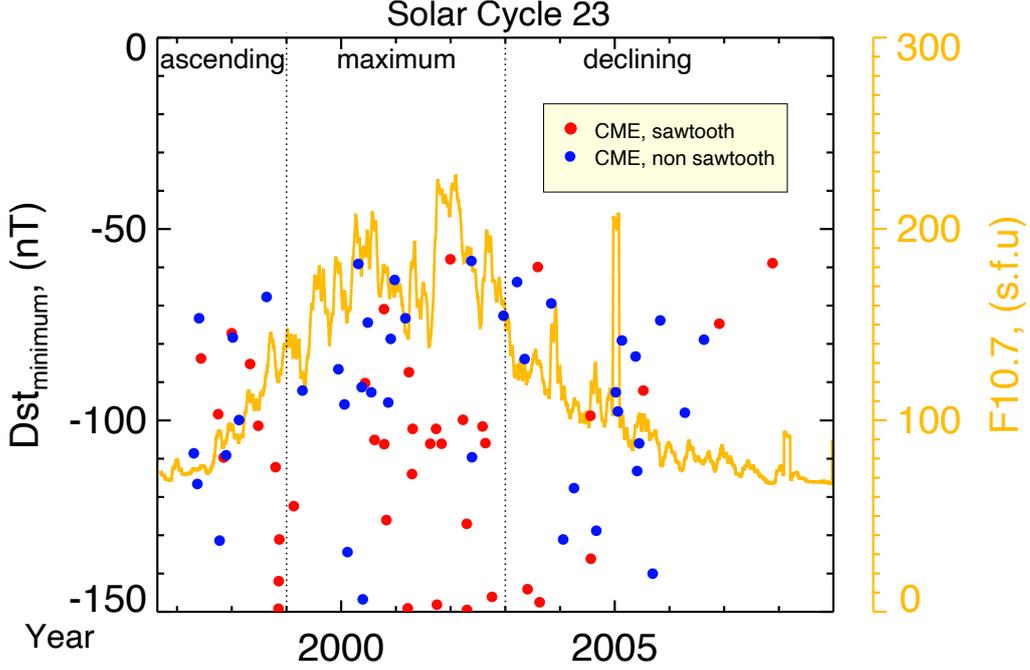

Figure 1. The scatter plot of the minimum Dst for CME sawtooth storms (red) and CME non-sawtooth storms (blue). The orange line shows the F10.7 indices for the 23rd solar cycle.

173 TEAMS instrument measured the 3-D distribution functions of particle species H^+ , O^+ ,
 174 He^+ and He^{++} , (Klumpar et al., 2001). This study employs the recently recalibrated
 175 TEAMS L2 data ¹ to calculate the ionospheric outflow flux of O^+ and H^+ ions with the
 176 following equation.

$$\Phi(m) = 2\pi \int_{E=10eV}^{E_{cutoff}} dE \int j(m, E, \alpha) |\sin(\alpha) \sin(\Delta\alpha) \cos(\alpha) \cos(\Delta\alpha)| d\alpha \quad (1)$$

177 In equation 1, the variables α , $\Delta\alpha$, E , and $j(m, E, \alpha)$ represent the pitch angle in
 178 the center of the bin, half-width of the pitch angle bin which is 11.25° , energy, and en-
 179 ergy flux in the center of the bin for the species m , respectively. To exclude contribu-
 180 tions from the magnetosphere and ram plasma within ionospheric outflow measurements,
 181 the energy flux is integrated over the energy range from $10eV$ to the dynamic cutoff en-
 182 ergy, as described in detail by Hatch et al. (2020); Zhao et al. (2020); and Nowrouzi et
 183 al. (2023). This study utilizes data collected between 1500 km and 4200 km altitude of
 184 the northern and southern hemispheres. The net flux is normalized by mapping it to 300
 185 km by using the IGRF model. Using the described methodology, the O^+ and H^+ out-
 186 flow fluxes acquired from the northern and southern hemispheres are combined and cal-
 187 culated for the list's pre-storm and storm phase intervals.

188 Subsequently, the outflow rate (fluence) of O^+ and H^+ are quantified. The ion species
 189 fluence is determined by multiplying the averaged outflow flux and the surface area:

¹ most of the recalibrations were detailed in the Appendix section of Nowrouzi (2022)

$$fluence_{jk} = \left(\frac{\sum_{i=0}^{n_{jk}-1} flux_i}{n_{jk}} \right) \times A_{jk} \quad (2)$$

190 Where A_{jk} is the area covered by bin jk at a mapped altitude of 300 km and n_{jk} is the
 191 number of samples in that bin. Outflow fluxes are grouped into storm phases for both
 192 sawtooth and non-sawtooth storms

193 Figures 2 and 3 display the mapped net outflow fluxes of O^+ and H^+ in the polar
 194 region, respectively. The data in Figure 2 are divided into the three storm phases (ini-
 195 tial, main, and recovery) in the three columns. The top panel illustrates the outflow flux
 196 along the spacecraft trajectory for Invariant Latitude (ILAT) values greater than 50° from
 197 all CME-driven storms during each storm phase. The black circles in these figures are
 198 spaced in 10° ILAT increments from all CME-driven storms during each storm phase.
 199 In the next panels, the data space is binned within the range of $50^\circ < ILAT < 90^\circ$
 200 and $0 < MLT < 24$ into 40° ILAT bins, each with a width of 1° and 24 Magnetic Lo-
 201 cal Time (MLT) bins, each with a time width of 1 hour. Subsequently, the average ion
 202 outflow flux within each MLT-ILAT bin is calculated and assigned to that bin in the large
 203 dials. The number of measurements in each MLT-ILAT bin is presented in the smaller
 204 dials, plotted on the top of each big dial. The second panel illustrates the average out-
 205 flow flux for all CME storms, which is shown in the trajectory panel. Then, the data plot-
 206 ted in the trajectory panel were divided into two groups, the sawtooth and non-sawtooth
 207 storms, and the averaged outflow flux of each group is plotted in the third and fourth
 208 panels.

209 3 Data Analysis and Discussion

210 In Figures 2 and 3, the lack of data samples in a few MLT-ILAT bins with lower
 211 latitudes (indicated in gray) limits the analysis of outflow fluxes to $60^\circ < ILAT < 90^\circ$.
 212 A visual comparison of the third and fourth panels shows that during the initial phase (left
 213 column), the O^+ and H^+ outflow fluxes in $70^\circ < ILAT < 80^\circ$ are stronger during non-
 214 sawtooth storms than during sawtooth storms. In the main phase, the different locations
 215 of the dominant outflow between sawtooth and non-sawtooth storms are considerable.
 216 During sawtooth storms, the peak outflow is observed in the dawn region, between 3 MLT
 217 and 8 MLT, mostly between 70° and 60° ILAT, while for non-sawtooth storms, the peak
 218 is closer to noon, spanning from 7 MLT to 13 MLT and between 80° and 65° ILAT. Dur-
 219 ing the recovery phase, both sawtooth and non-sawtooth storms display the dayside cusp
 220 outflow from 7 MLT to 14 MLT, while the sawtooth storms show an additional large O^+
 221 outflow on the dawnside from 2 MLT to 6 MLT, not observed in non-sawtooth storms.
 222 On the nightside, the high O^+ outflow in non-sawtooth storms shows a $\sim 5^\circ$ equator-
 223 ward shift of latitudinal location in sawtooth storms.

224 To quantitatively compare the outflow fluxes between sawtooth and non-sawtooth
 225 CME storms, the fluence of averaged outflow fluxes in each MLT-ILAT bin is calculated
 226 from equation 2, summed into three-hour MLT bins over the ILAT range from $60^\circ <$
 227 $ILAT < 90^\circ$ and displayed in Figure 4. From left to right: the O^+ fluence, the H^+ flu-
 228 ence, and the ratio fluences of O^+/H^+ are plotted as a function of MLT for the initial
 229 phase at the top, the main phase in the middle and the recovery phase at the bottom.
 230 The red and blue lines indicate outflow fluences during sawtooth and non-sawtooth storms,
 231 respectively. The error bars denote the standard deviation (SD).

232 In the initial phase, non-sawtooth storms show higher O^+ and H^+ outflow fluences
 233 than sawtooth storms in all MLT sectors, except before midnight, where sawtooth and
 234 non-sawtooth fluences are comparable in both O^+ and H^+ plots. The O^+ outflow flu-
 235 ence is up to 10 times larger in non-sawtooth storms than in sawtooth storms in some
 236 MLT sectors. This observation aligns with previous observational studies indicating a
 237 correlation between sawtooth events and solar wind, for instance, a study suggesting that

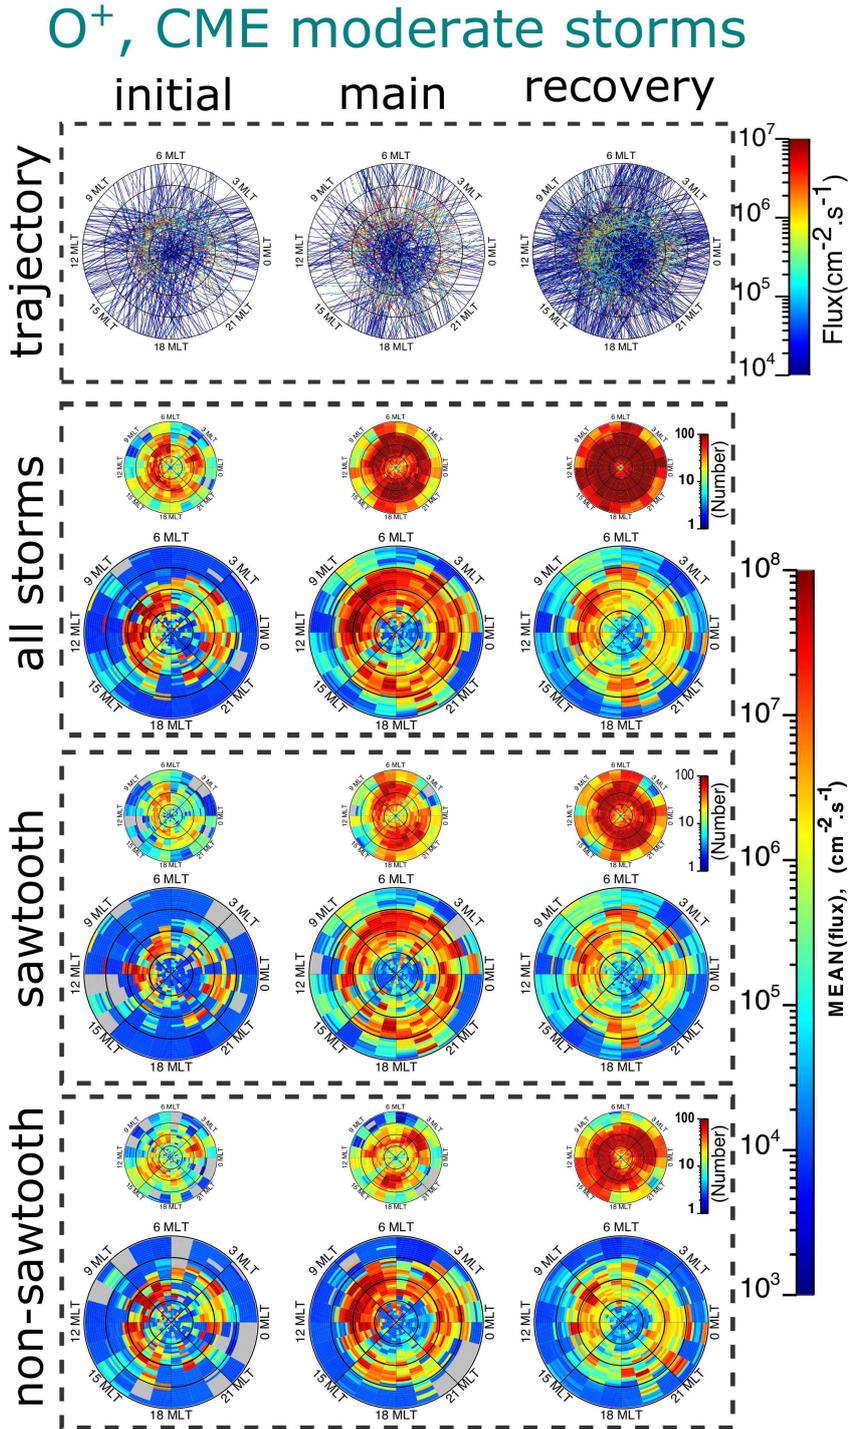

Figure 2. The top panel shows mapped O⁺ outflow flux along the FAST trajectories for all moderate CME storms. Horizontally, columns display data during the initial, main, and recovery phases. The average of the first panel data is illustrated in the second panel. The third and fourth panels represent the averaged O⁺ outflow flux from sawtooth storms and non-sawtooth storms, respectively. The big dials indicate the averaged outflow and the small dials show the number of data points in each bin.

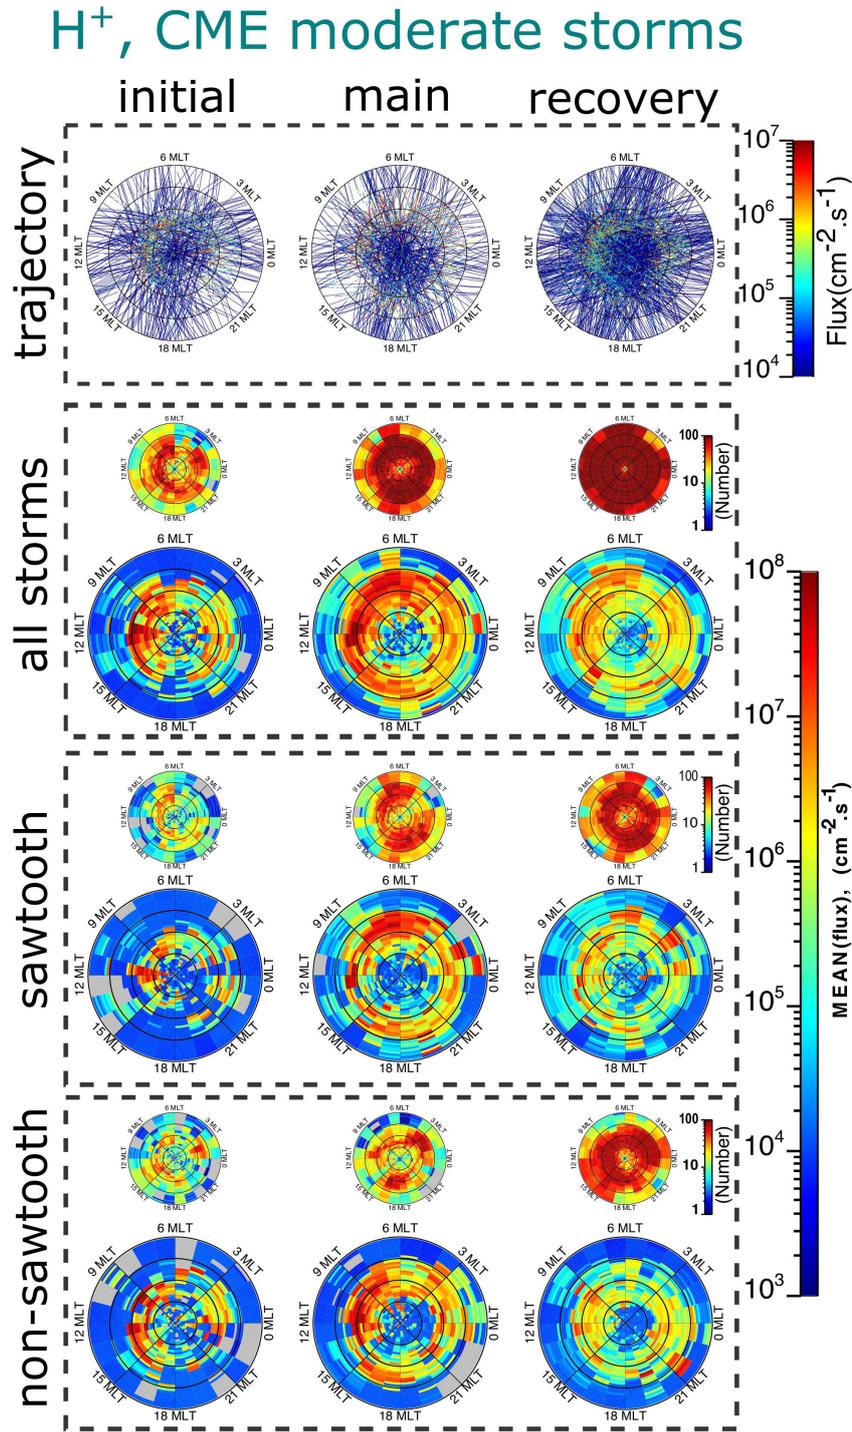

Figure 3. The mapped H⁺ outflow flux in the polar region. The format is the same as in Figure 2.

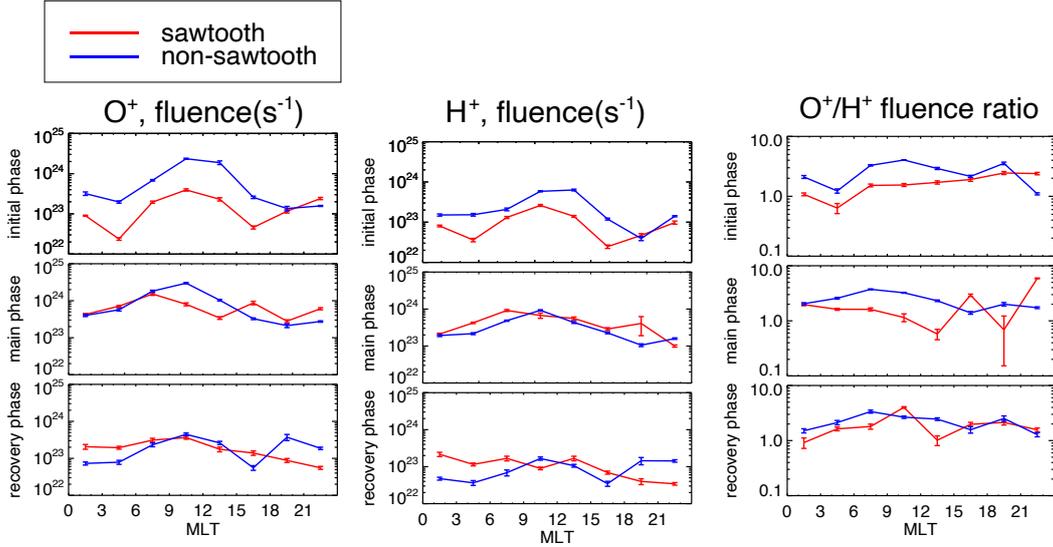

Figure 4. From left to right, the panels illustrate the O^+ and H^+ fluences and their ratio. Top to bottom, the panels display the mapped outflow flux fluences during the initial, main, and recovery phases as a function of MLT for sawtooth storms in red and non-sawtooth storms in blue.

238 sawtooth events do not occur when solar wind magnetic flux is higher than a threshold
 239 (Cai & Clauer, 2013).

240 During the main phase, the O^+ outflow fluence at noon is higher in non-sawtooth
 241 storms than in sawtooth storms, but, as noted above, the peak O^+ outflow is shifted to-
 242 ward dawn in sawtooth storms. During the recovery phase, the outflow on the dayside
 243 is comparable. This suggests that it is not significantly higher dayside O^+ outflow that
 244 is driving sawtooth events. However, it is possible that the enhanced dawnside outflow
 245 can populate the plasma sheet better than the outflow closer to noon, and so it has a
 246 greater effect.

247 Although during the main phase, sawtooth events display larger O^+ outflow be-
 248 fore midnight than non-sawtooth events, during the recovery phase, this pattern is ob-
 249 served in the after-midnight MLT sectors. Before midnight, non-sawtooth storms show
 250 about 5 times higher O^+ outflow fluence than sawtooth storms. While enhanced night-
 251 side outflow could help to drive sawtooth events during the main phase, this observa-
 252 tion argues against it being a cause during the recovery phase.

253 The observations for H^+ outflow fluence during storm phases are similar to the O^+
 254 outflow fluence; however, the difference between sawtooth and non-sawtooth is weaker
 255 in the outflow fluence of H^+ than in the outflow fluence of O^+ . In the ratio plot on the
 256 right, a higher O^+/H^+ is observed mainly during non-sawtooth storms than during saw-
 257 tooth storms. However, the notable exceptions in the pre-midnight MLT sectors are con-
 258 siderable.

259 4 Summary and Conclusions

260 This paper performed a statistical analysis on 11 years of FAST/TEAMS charged
 261 particle data from 1996 through 2007, focusing on CME-driven moderate storms. The

objective of the study was to explore any observational evidence showing differences in ionospheric outflow between sawtooth and non-sawtooth storms that support the role of O^+ outflow in driving sawtooth oscillations. The observations indicate that the location of high ionospheric outflow differs between sawtooth and non-sawtooth events. This study reveals that:

1- In the initial phase, the non-sawtooth storms generate larger O^+ outflow than sawtooth storms in most MLT sectors. Since the initial phase outflow would be the first to reach the plasma sheet during a storm, this suggests that, at least in the early phase of a storm, the cusp outflow is not important in triggering the sawtooth oscillations or may even suggest that the initial phase outflow from the cusp, if anything, suppresses sawtooth oscillations.

2- During the main and recovery phase, the O^+ outflow fluence in the nightside region is higher in sawtooth storms than in non-sawtooth storms during the pre-midnight sector of the main phase and the post-midnight sector of the recovery phase and significantly lower during the post-midnight sector of the recovery phase.

3- During the main and recovery phases, while the outflow at noon is lower during sawtooth storms, the peak of the O^+ outflow is shifted toward the dawn sector in sawtooth storms. This suggests that while the levels of peak O^+ outflow are comparable between sawtooth and non-sawtooth storms, their spatial distribution differs. Consequently, this difference in location may help with access to the plasma sheet.

In summary, there are significant differences in the outflow patterns between storms with sawtooth oscillations and storms without. However, the observations do not unambiguously support one model over another, with differences observed both on the dayside and the nightside. The most compelling difference is that the location of the peak dayside outflow is shifted significantly towards dawn in the sawtooth storms, and we suggest exploring the impacts of this difference in future simulations.

12 **Key Points:**

- 13 • The intensity and location of O⁺ outflow during storms are different in storms with
14 and without sawtooth oscillations.
- 15 • The peak dayside outflow is significantly shifted towards dawn during storms with
16 sawtooth observations.
- 17 • The nightside picture is mixed; the pre-midnight O⁺ outflow is higher in the main
18 phase but lower in the recovery phase of sawtooth storms.

Abstract

Previous simulations have suggested that O^+ outflow plays a role in driving the sawtooth oscillations. This study investigates the role of O^+ by identifying the differences in ionospheric outflow between sawtooth and non-sawtooth storms using 11 years of FAST/Time of flight Energy Angle Mass Spectrograph (TEAMS) ion composition data from 1996 through 2007 during storms driven by coronal mass ejections (CMEs). We find that the storm's initial phase shows larger O^+ outflow during non-sawtooth storms, and the main and recovery phases revealed differences in the location of ionospheric outflow. On the pre-midnight sector, a larger O^+ outflow was observed during the main phase of sawtooth storms, while non-sawtooth storms exhibited stronger O^+ outflow during the recovery phase. On the dayside, the peak outflow shifts significantly towards dawn during sawtooth storms. This strong dawnside sector outflow during sawtooth storms warrants consideration.

Plain Language Summary

A sawtooth event is a convection mode in Earth's magnetosphere, which transports solar wind plasma and energy into the inner magnetosphere and ionosphere. Despite three decades since their discovery, the mechanism behind sawtooth oscillations remains uncertain. One theory suggests that O^+ outflow induces sawtooth oscillations through an internal feedback mechanism. In line with this theory, some simulations have generated sawtooth oscillations under steady geomagnetic conditions. Furthermore, previous observations indicate that some, but not all, geomagnetic storms exhibit sawtooth oscillations. This study utilizes data from the FAST/TEAMS instrument (1996-2007) and compares O^+ outflow variations during geomagnetic storms with and without sawtooth oscillations. Findings indicate that during the storms' initial phase, sawtooth storms produce less O^+ outflow than non-sawtooth storms. Additionally, non-sawtooth storms exhibit higher O^+ outflow in the dayside during the main phase and in the pre-midnight sector during the recovery phase, challenging the key role of O^+ outflow in driving the feedback mechanism. However, observing large O^+ outflow in the dawnside sector of sawtooth events suggests more investigation is needed.

1 Introduction

When the interplanetary magnetic field (IMF) is southward, magnetotail reconnection brings solar wind plasma and energy into the inner magnetosphere and ionosphere via three different modes: Steady Magnetospheric Convection mode (SMC), magnetic substorms, and the comparatively less-explored phenomenon of sawtooth events. In SMC, the magnetosphere does not accumulate solar wind energy but redirects it from the dayside to the nightside by a nearly balanced reconnection rate on both sides (Sergeev et al., 1996; DeJong et al., 2008). Conversely, during the magnetospheric substorm, the magnetosphere acts as an energy reservoir, storing solar wind energy in the tail lobes and then releasing it into the inner magnetosphere and ionosphere. For an isolated substorm, the process of loading/unloading energy is localized near midnight in magnetic local time (MLT) (Russell & McPherron, 1973; Hones Jr. et al., 1984). In some cases, this loading/unloading energy occurs over a wider MLT region, during a longer time period, and quasi periodically with more than two oscillations. This mode is termed a global sawtooth event (Reeves et al., 2002; Henderson, 2004). The reason for the magnetosphere's preference for one mode over the other in response to the solar wind energy input is still unknown.

Global sawtooth events, identified as quasi-periodic, large-amplitude oscillations in energetic particles at geosynchronous orbit (Belian & Cayton, 1989; Borovsky et al., 1993) with a periodicity of 2–4 hours (Cai & Clauer, 2009), derive their name from the saw blade-like characteristics of particle injections marked by a gradual decrease (growth

69 phase) followed by a sharp increase (onset) (Belian et al., 1995). These energetic par-
 70 ticle flux oscillations are correlated with magnetic field changes in the tail, at geostation-
 71 ary orbit, and ground stations, as well as changes in the auroral electrojet index, auro-
 72 ral precipitation, and polar cap indices (Huang et al., 2003; Kitamura et al., 2005; Cai
 73 et al., 2006; Henderson et al., 2006; Huang & Cai, 2009; Troshichev & Janzhura, 2009).
 74 These observations suggested that the sawtooth mode is generated by an internal mag-
 75 netospheric instability (Huang, 2011); however, there are studies that claim sawtooth events
 76 are generated by external parameters in solar wind drivers (Lee et al., 2004, 2006; Cai
 77 & Clauer, 2013). Cai and Clauer (2009, 2013) compiled a comprehensive list of sawtooth
 78 events spanning from 1996 to 2007, encompassing a total of 126 events. Cai et al. (2011),
 79 through extensive statistical analysis, examined the relationship between sawtooth events
 80 and geomagnetic storms and found that a substantial majority, 94.6%, of sawtooth events
 81 occurred during geomagnetic storms.

82 During geomagnetic storms, the O^+ density and pressure and its occurrence fre-
 83 quency in the plasma sheet and lobe are enhanced (Kistler et al., 2006, 2010; Liao et al.,
 84 2010). The ionosphere is the main source of O^+ ions in the magnetosphere (Shelley et
 85 al., 1972; Sharp et al., 1974), predominantly from two regions: the dayside cusp and the
 86 nightside auroral region (Yau & André, 1997) and the increase of O^+ outflow during storms
 87 has been reported from both sources e.g. (Yau et al., 1988; Cully et al., 2003; Nowrouzi
 88 et al., 2023). Cusp-origin O^+ flows along the open field lines to the lobe and enters the
 89 plasma sheet during reconnection in the tail. The field lines in the nightside auroral re-
 90 gions are directly connected to the plasma sheet. The occurrence of sawtooth events dur-
 91 ing storms, when O^+ is enhanced, suggests that the cause of substorms may be related
 92 to the O^+ .

93 Brambles et al. (2011) incorporated ionospheric O^+ fluence into the multifluid Lyon-
 94 Fedder-Mobarry (LFM) model (Lyon et al., 2004) and demonstrated that strong O^+ flu-
 95 ence can generate sawtooth events in simulations. Ouellette et al. (2013) investigated
 96 the mechanism for driving the events and introduced a hypothesis for the periodicity of
 97 sawtooth events: the periodic loading and unloading of O^+ ions through ionospheric out-
 98 flow into the plasma sheet changes the reconnection rate within the magnetotail current
 99 sheet. These variations in reconnection rate lead to distinct magnetic field configuration
 100 changes in the tail, releasing an O^+ -rich plasmoid and sending particle precipitation and
 101 Alfvénic waves towards the ionosphere, which drives more outflow for the subsequent saw-
 102 tooth in the cycle. This mechanism suggests that it is nightside O^+ outflow that is re-
 103 sponsible. Using simulation Brambles et al. (2013) found that for an event driven by cor-
 104 onal mass ejections (CME) with steady solar wind conditions, nightside O^+ fluence was
 105 required to generate the sawtooth oscillations. In contrast, sawtooth events driven by
 106 streaming interaction regions (SIR) could be driven without O^+ fluence. Using a physics-
 107 based model, Varney et al. (2016) simulated a sawtooth event under steady solar wind
 108 conditions and found that the cases that developed sawtooth oscillations had strong out-
 109 flow in the midnight auroral region. Zhang et al. (2020) investigated whether cusp out-
 110 flow could also drive sawtooth oscillations. They found that while only 10% of dayside
 111 cusp O^+ outflow reached the plasma sheet, it was sufficient to induce sawtooth oscilla-
 112 tions. Finally, Wang et al. (2022) showed that kinetic reconnection in the magnetotail
 113 can reproduce the periodic loading and unloading of the magnetic flux in the magneto-
 114 sphere even without ionospheric outflow. Thus, from the simulation results, sawtooth
 115 oscillations can be driven by either nightside or dayside outflow or from strong driving,
 116 independent of outflow.

117 The magnetotail observations also do not give a clear picture. Liao et al. (2014)
 118 investigated and compared the composition of the plasma sheet during sawtooth events
 119 and isolated storm-time substorms. While the O^+/H^+ ratio was higher on average dur-
 120 ing the sawtooth substorms, there were substorms with a high O^+/H^+ ratio for no saw-
 121 tooth events, as well as sawtooth substorms with a low O^+/H^+ ratio.

122 Regarding the source of the O^+ nightside aurora outflow vs. dayside cusp outflow
 123 during the sawtooth substorms, an observational study showed that the cusp is the pre-
 124 dominant source of O^+ ions in the 15-20 Re plasma sheet where sawtooth events driven
 125 by SIRs and CMEs (Lund et al., 2018). This is where the near-Earth neutral line is typ-
 126 ically located, therefore, where the plasma sheet composition would potentially affect re-
 127 connection.

128 Therefore, neither the simulations nor the observations have been conclusive on the
 129 role of O^+ in driving sawtooth oscillations. However, another aspect that might help to
 130 clarify the role of O^+ is to determine how the ion outflow varies in intensity and loca-
 131 tion between storms with sawtooth oscillations and storms without. Since global saw-
 132 tooth oscillations occur during some, but not all geomagnetic storms (Borovsky, 2004),
 133 it is worthwhile to investigate the variation of ionospheric O^+ outflow during CME storms,
 134 comparing those with sawtooth events to those without sawtooth events. If either day-
 135 side or nightside O^+ outflow is involved in triggering sawtooth events, we would expect
 136 significant differences in the outflow characteristics for these two types of events. Since
 137 most of the sawtooth teeth occur in the main and recovery phases (Cai et al., 2011), the
 138 outflow characteristics are investigated during different storm phases.

139 2 Data and Methodology

140 To examine the role of ionospheric O^+ outflow in driving sawtooth events, this study
 141 measures the averaged ionospheric O^+ and H^+ outflow during geomagnetic storms and
 142 compares the outflow during sawtooth storms (i.e., storms with sawtooth oscillations)
 143 with the outflow during non-sawtooth storms. For this purpose, we will use the list of
 144 all CME storms with clear main and recovery phases and with a minimum value of Dis-
 145 turbance storm time index (Dst) less than $-50nT$, from 1996 to 2007, published in Nowrouzi
 146 et al. (2023). This list contains information about the time of the initial, main, and re-
 147 covery phases, as well as the solar wind driver for each storm. Our process involved cross-
 148 referencing each storm from this list with the corresponding period in this list of saw-
 149 tooth events from 1996-2007, (Cai & Clauer, 2009, 2013). If a storm in the first list in-
 150 volves a sawtooth event in the second list, we label the storm as a sawtooth storm; oth-
 151 erwise, it is labeled as a non-sawtooth storm.

152 Since simulations such as (Brambles et al., 2013) and (Varney et al., 2016), find
 153 that ionospheric O^+ outflow is only needed during storms with steady solar wind con-
 154 ditions to drive the sawtooth mode, this study is limited to the geomagnetic storms which
 155 are driven by CMEs. Also, to reduce the effect of the storm's intensity on this sawtooth/non-
 156 sawtooth comparison, this statistical analysis only examines moderate storms with $-150nT \leq$
 157 $Dst_{minimum} \leq -50nT$. In Figure 1, the minimum Dst of all CME moderate storms
 158 used in this study are plotted. The red and blue circles represent the sawtooth and non-
 159 sawtooth storms, respectively. The orange line shows the smoothed daily average of F10.7,
 160 the solar radio flux at 10.7 cm as an indicator of solar activity, during solar cycle 23, which
 161 spans from 1996 to 2008. It is observed that sawtooth events during moderate CME storms
 162 are observed in all the solar cycle's phases, however they are more common in the so-
 163 lar cycle's maximum phase with $180s.f.u. < F10.7$ (or less common during the mini-
 164 mum phase with $F10.7 < 180s.f.u.$). In Figure 1, the moderate CME storms include
 165 158 sawtooth injections. In total, there are identified 4 teeth during the initial phase,
 166 88 teeth during the storm main phase, 52 teeth during the early recovery phase, and 14
 167 teeth during the long recovery phase.

168 The Fast Auroral Snapshot Explorer (FAST) spacecraft was launched in August 1996
 169 to advance the study of auroral acceleration physics and magnetosphere-ionosphere cou-
 170 pling. FAST was placed into an elliptical polar orbit characterized by a period of 133
 171 minutes, an inclination angle of 83° , a perigee altitude of approximately 350 km, and an
 172 apogee altitude of roughly 4175 km (Carlson et al., 1998). On the FAST spacecraft, the

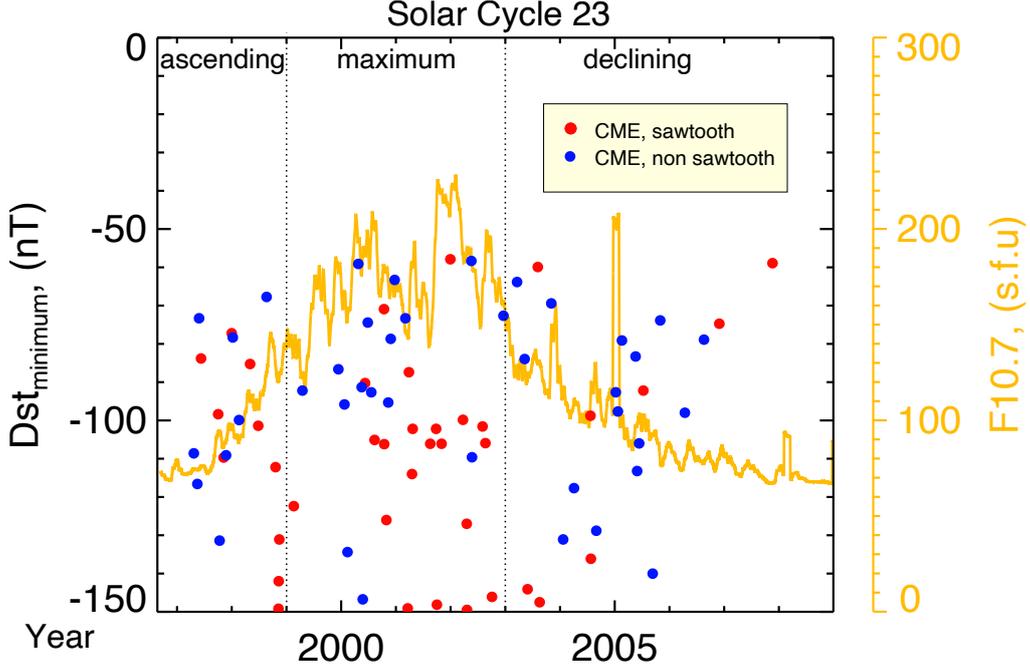

Figure 1. The scatter plot of the minimum Dst for CME sawtooth storms (red) and CME non-sawtooth storms (blue). The orange line shows the F10.7 indices for the 23rd solar cycle.

173 TEAMS instrument measured the 3-D distribution functions of particle species H^+ , O^+ ,
 174 He^+ and He^{++} , (Klumpar et al., 2001). This study employs the recently recalibrated
 175 TEAMS L2 data ¹ to calculate the ionospheric outflow flux of O^+ and H^+ ions with the
 176 following equation.

$$\Phi(m) = 2\pi \int_{E=10eV}^{E_{cutoff}} dE \int j(m, E, \alpha) |\sin(\alpha) \sin(\Delta\alpha) \cos(\alpha) \cos(\Delta\alpha)| d\alpha \quad (1)$$

177 In equation 1, the variables α , $\Delta\alpha$, E , and $j(m, E, \alpha)$ represent the pitch angle in
 178 the center of the bin, half-width of the pitch angle bin which is 11.25° , energy, and en-
 179 ergy flux in the center of the bin for the species m , respectively. To exclude contribu-
 180 tions from the magnetosphere and ram plasma within ionospheric outflow measurements,
 181 the energy flux is integrated over the energy range from $10eV$ to the dynamic cutoff en-
 182 ergy, as described in detail by Hatch et al. (2020); Zhao et al. (2020); and Nowrouzi et
 183 al. (2023). This study utilizes data collected between 1500 km and 4200 km altitude of
 184 the northern and southern hemispheres. The net flux is normalized by mapping it to 300
 185 km by using the IGRF model. Using the described methodology, the O^+ and H^+ out-
 186 flow fluxes acquired from the northern and southern hemispheres are combined and cal-
 187 culated for the list's pre-storm and storm phase intervals.

188 Subsequently, the outflow rate (fluence) of O^+ and H^+ are quantified. The ion species
 189 fluence is determined by multiplying the averaged outflow flux and the surface area:

¹ most of the recalibrations were detailed in the Appendix section of Nowrouzi (2022)

$$fluence_{jk} = \left(\frac{\sum_{i=0}^{n_{jk}-1} flux_i}{n_{jk}} \right) \times A_{jk} \quad (2)$$

190 Where A_{jk} is the area covered by bin jk at a mapped altitude of 300 km and n_{jk} is the
 191 number of samples in that bin. Outflow fluxes are grouped into storm phases for both
 192 sawtooth and non-sawtooth storms

193 Figures 2 and 3 display the mapped net outflow fluxes of O^+ and H^+ in the polar
 194 region, respectively. The data in Figure 2 are divided into the three storm phases (ini-
 195 tial, main, and recovery) in the three columns. The top panel illustrates the outflow flux
 196 along the spacecraft trajectory for Invariant Latitude (ILAT) values greater than 50° from
 197 all CME-driven storms during each storm phase. The black circles in these figures are
 198 spaced in 10° ILAT increments from all CME-driven storms during each storm phase.
 199 In the next panels, the data space is binned within the range of $50^\circ < ILAT < 90^\circ$
 200 and $0 < MLT < 24$ into 40° ILAT bins, each with a width of 1° and 24 Magnetic Lo-
 201 cal Time (MLT) bins, each with a time width of 1 hour. Subsequently, the average ion
 202 outflow flux within each MLT-ILAT bin is calculated and assigned to that bin in the large
 203 dials. The number of measurements in each MLT-ILAT bin is presented in the smaller
 204 dials, plotted on the top of each big dial. The second panel illustrates the average out-
 205 flow flux for all CME storms, which is shown in the trajectory panel. Then, the data plot-
 206 ted in the trajectory panel were divided into two groups, the sawtooth and non-sawtooth
 207 storms, and the averaged outflow flux of each group is plotted in the third and fourth
 208 panels.

209 3 Data Analysis and Discussion

210 In Figures 2 and 3, the lack of data samples in a few MLT-ILAT bins with lower
 211 latitudes (indicated in gray) limits the analysis of outflow fluxes to $60^\circ < ILAT < 90^\circ$.
 212 A visual comparison of the third and fourth panels shows that during the initial phase (left
 213 column), the O^+ and H^+ outflow fluxes in $70^\circ < ILAT < 80^\circ$ are stronger during non-
 214 sawtooth storms than during sawtooth storms. In the main phase, the different locations
 215 of the dominant outflow between sawtooth and non-sawtooth storms are considerable.
 216 During sawtooth storms, the peak outflow is observed in the dawn region, between 3 MLT
 217 and 8 MLT, mostly between 70° and 60° ILAT, while for non-sawtooth storms, the peak
 218 is closer to noon, spanning from 7 MLT to 13 MLT and between 80° and 65° ILAT. Dur-
 219 ing the recovery phase, both sawtooth and non-sawtooth storms display the dayside cusp
 220 outflow from 7 MLT to 14 MLT, while the sawtooth storms show an additional large O^+
 221 outflow on the dawnside from 2 MLT to 6 MLT, not observed in non-sawtooth storms.
 222 On the nightside, the high O^+ outflow in non-sawtooth storms shows a $\sim 5^\circ$ equator-
 223 ward shift of latitudinal location in sawtooth storms.

224 To quantitatively compare the outflow fluxes between sawtooth and non-sawtooth
 225 CME storms, the fluence of averaged outflow fluxes in each MLT-ILAT bin is calculated
 226 from equation 2, summed into three-hour MLT bins over the ILAT range from $60^\circ <$
 227 $ILAT < 90^\circ$ and displayed in Figure 4. From left to right: the O^+ fluence, the H^+ flu-
 228 ence, and the ratio fluences of O^+/H^+ are plotted as a function of MLT for the initial
 229 phase at the top, the main phase in the middle and the recovery phase at the bottom.
 230 The red and blue lines indicate outflow fluences during sawtooth and non-sawtooth storms,
 231 respectively. The error bars denote the standard deviation (SD).

232 In the initial phase, non-sawtooth storms show higher O^+ and H^+ outflow fluences
 233 than sawtooth storms in all MLT sectors, except before midnight, where sawtooth and
 234 non-sawtooth fluences are comparable in both O^+ and H^+ plots. The O^+ outflow flu-
 235 ence is up to 10 times larger in non-sawtooth storms than in sawtooth storms in some
 236 MLT sectors. This observation aligns with previous observational studies indicating a
 237 correlation between sawtooth events and solar wind, for instance, a study suggesting that

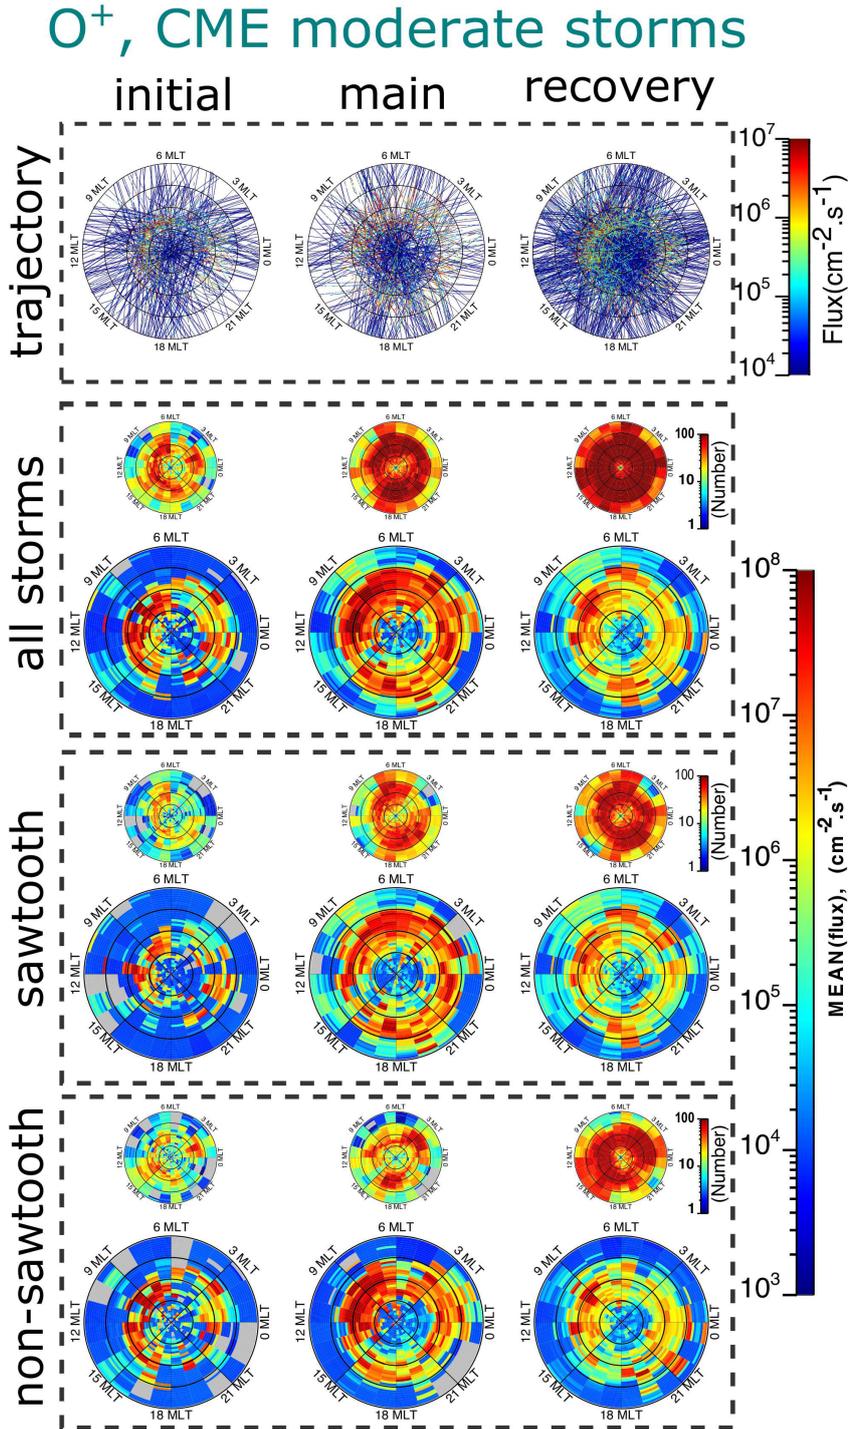

Figure 2. The top panel shows mapped O⁺ outflow flux along the FAST trajectories for all moderate CME storms. Horizontally, columns display data during the initial, main, and recovery phases. The average of the first panel data is illustrated in the second panel. The third and fourth panels represent the averaged O⁺ outflow flux from sawtooth storms and non-sawtooth storms, respectively. The big dials indicate the averaged outflow and the small dials show the number of data points in each bin.

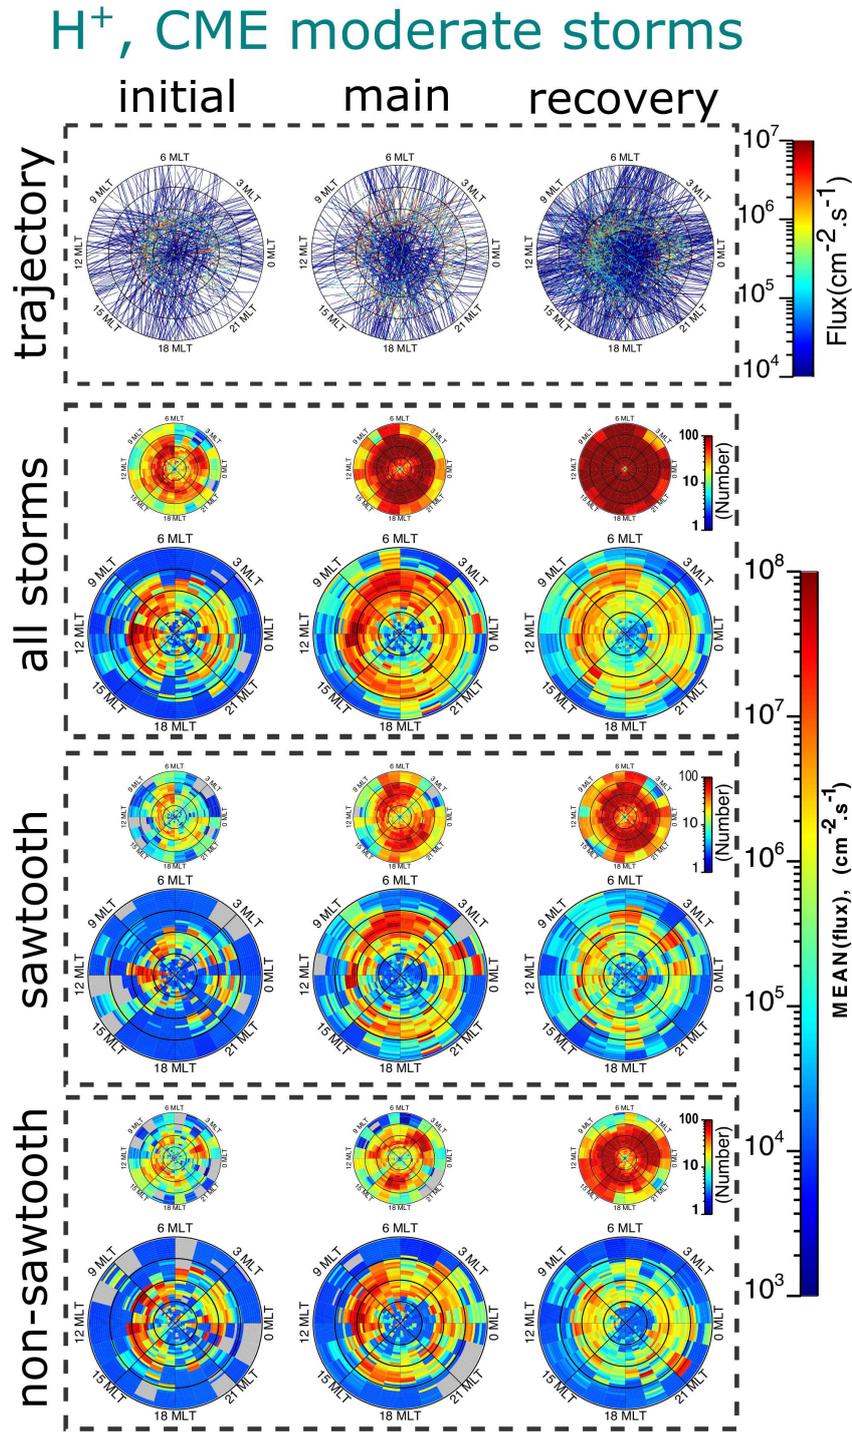

Figure 3. The mapped H⁺ outflow flux in the polar region. The format is the same as in Figure 2.

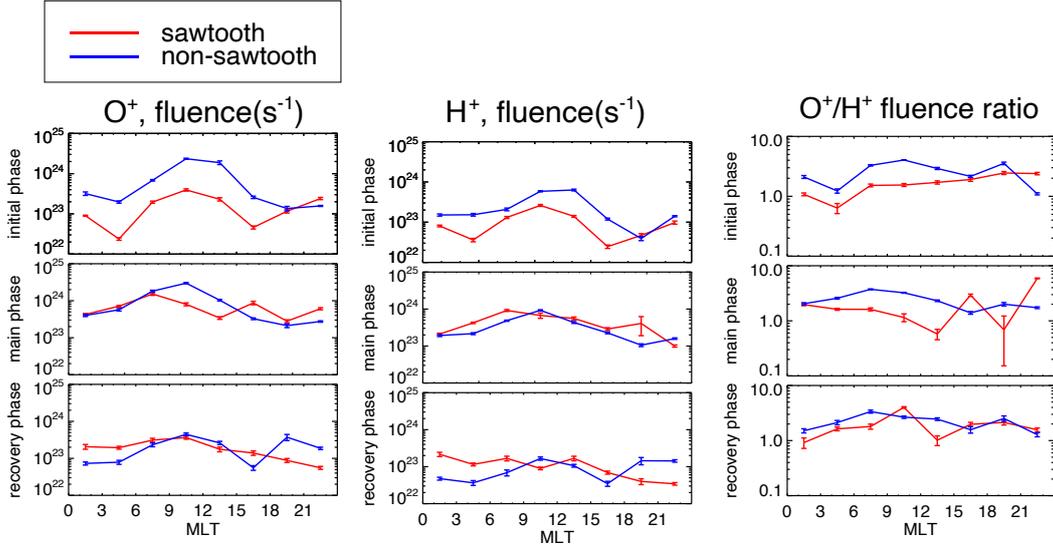

Figure 4. From left to right, the panels illustrate the O⁺ and H⁺ fluences and their ratio. Top to bottom, the panels display the mapped outflow flux fluences during the initial, main, and recovery phases as a function of MLT for sawtooth storms in red and non-sawtooth storms in blue.

238 sawtooth events do not occur when solar wind magnetic flux is higher than a threshold
 239 (Cai & Clauer, 2013).

240 During the main phase, the O⁺ outflow fluence at noon is higher in non-sawtooth
 241 storms than in sawtooth storms, but, as noted above, the peak O⁺ outflow is shifted to-
 242 ward dawn in sawtooth storms. During the recovery phase, the outflow on the dayside
 243 is comparable. This suggests that it is not significantly higher dayside O⁺ outflow that
 244 is driving sawtooth events. However, it is possible that the enhanced dawnside outflow
 245 can populate the plasma sheet better than the outflow closer to noon, and so it has a
 246 greater effect.

247 Although during the main phase, sawtooth events display larger O⁺ outflow be-
 248 fore midnight than non-sawtooth events, during the recovery phase, this pattern is ob-
 249 served in the after-midnight MLT sectors. Before midnight, non-sawtooth storms show
 250 about 5 times higher O⁺ outflow fluence than sawtooth storms. While enhanced night-
 251 side outflow could help to drive sawtooth events during the main phase, this observa-
 252 tion argues against it being a cause during the recovery phase.

253 The observations for H⁺ outflow fluence during storm phases are similar to the O⁺
 254 outflow fluence; however, the difference between sawtooth and non-sawtooth is weaker
 255 in the outflow fluence of H⁺ than in the outflow fluence of O⁺. In the ratio plot on the
 256 right, a higher O⁺/H⁺ is observed mainly during non-sawtooth storms than during saw-
 257 tooth storms. However, the notable exceptions in the pre-midnight MLT sectors are con-
 258 siderable.

259 4 Summary and Conclusions

260 This paper performed a statistical analysis on 11 years of FAST/TEAMS charged
 261 particle data from 1996 through 2007, focusing on CME-driven moderate storms. The

objective of the study was to explore any observational evidence showing differences in ionospheric outflow between sawtooth and non-sawtooth storms that support the role of O^+ outflow in driving sawtooth oscillations. The observations indicate that the location of high ionospheric outflow differs between sawtooth and non-sawtooth events. This study reveals that:

1- In the initial phase, the non-sawtooth storms generate larger O^+ outflow than sawtooth storms in most MLT sectors. Since the initial phase outflow would be the first to reach the plasma sheet during a storm, this suggests that, at least in the early phase of a storm, the cusp outflow is not important in triggering the sawtooth oscillations or may even suggest that the initial phase outflow from the cusp, if anything, suppresses sawtooth oscillations.

2- During the main and recovery phase, the O^+ outflow fluence in the nightside region is higher in sawtooth storms than in non-sawtooth storms during the pre-midnight sector of the main phase and the post-midnight sector of the recovery phase and significantly lower during the post-midnight sector of the recovery phase.

3- During the main and recovery phases, while the outflow at noon is lower during sawtooth storms, the peak of the O^+ outflow is shifted toward the dawn sector in sawtooth storms. This suggests that while the levels of peak O^+ outflow are comparable between sawtooth and non-sawtooth storms, their spatial distribution differs. Consequently, this difference in location may help with access to the plasma sheet.

In summary, there are significant differences in the outflow patterns between storms with sawtooth oscillations and storms without. However, the observations do not unambiguously support one model over another, with differences observed both on the dayside and the nightside. The most compelling difference is that the location of the peak dayside outflow is shifted significantly towards dawn in the sawtooth storms, and we suggest exploring the impacts of this difference in future simulations.
