30 **Abstract**

31 A common viewpoint across the Earth science community is that global soil moisture
32 estimates from satellite L-band (1.4 GHz) measurements represent moisture only in the
33 shallow soil layers (0-5 cm) and are of limited value for studying global terrestrial
34 ecosystems because plants use water from deeper rootzones. Here, we argue that such
35 a viewpoint is flawed for two reasons. First, microwave soil emission theory and
36 statistical considerations of vertically correlated soil moisture information together
37 indicate that L-band measurements are typically representative of soil moisture within at
38 least the top 15-25 cm, or 3-5 times deeper than commonly thought. Second, in
39 reviewing isotopic tracer field studies of plant water uptake, we find a global prevalence
40 of vegetation that primarily draws moisture from these upper soil layers. This is
41 especially true for grasslands and croplands covering more than a third of global
42 vegetated surfaces. While shrub and tree species tend to draw deeper soil moisture,
43 these plants often still preferentially or seasonally draw water from the upper soil layers.
44 Therefore, L-band satellite soil moisture estimates are more relevant to global

45 vegetation water uptake than commonly appreciated, and we encourage their
46 application across terrestrial hydrophere and biosphere studies.

47

48 **1. Introduction**

49 Global soil moisture retrievals from microwave satellites are now widely used across the
50 Earth science community to study various topics related to the global climate system
51 and its water, carbon, and energy cycles. While soil moisture in the unsaturated zone
52 stores only 0.005% of Earth's water by volume (Bras, 1990), its position at the interface
53 of the land and the atmosphere is of high value for understanding these global cycles
54 (Koster and Suarez, 2001; McColl et al., 2017). As such, satellite-based soil moisture
55 estimates are increasingly being used in studies of land-atmosphere interactions,
56 numerical weather prediction, plant function and stress, and land surface response to
57 climate change (Akbar et al., 2020; Dong et al., 2020; Feldman et al., 2018b, 2022;
58 Konings et al., 2017; Purdy et al., 2018; Santanello et al., 2019; Short Gianotti et al.,
59 2020; Taylor et al., 2012; Tuttle and Salvucci, 2016).

60

61 However, a viewpoint has spread that microwave satellite soil moisture is of limited use
62 for studying vegetated landscapes because it only perceives the surface layer of deep
63 rootzones. A major contributor to this viewpoint is the history of the microwave remote
64 sensing community generally offering a simplified view of a shallow observing depth of
65 satellite-based retrievals. For example, the Soil Moisture Active Passive (SMAP) and
66 Soil Moisture and Ocean Salinity (SMOS) L-band satellite missions are often described
67 as producing estimates of soil moisture within the top 5 cm of soil (Entekhabi et al.,
68 2010; Kerr et al., 2010). Similarly, the Advanced Microwave Scanning Radiometer
69 (AMSR) satellite series and the Advanced Scatterometer (ASCAT) (at higher C- and X-
70 band frequencies) are thought to observe only the top 2 cm of soil. Other contributors to
71 this viewpoint include the prevalent use of the top-most in-situ sensors for assessing
72 satellite soil moisture products, and a common intuition that the maximum rooting depth
73 defines the relevant water uptake profile.

74

75 According to this viewpoint, if roots supply plants from soil layers down to maximum
76 rooting depths that are meters below the top 5 cm, then satellite soil moisture estimates
77 have little value for the global study of terrestrial water, carbon, and energy fluxes, given
78 that these fluxes can rely heavily on plant use of soil moisture (Jasechko et al., 2013;
79 Katul et al., 2012). As a result, many researchers avoid the use of these microwave
80 satellite soil moisture products, instead often favoring rootzone moisture products from
81 model reanalysis or precipitation-based wetness indices. We avoid calling attention to
82 specific references, but argue that such a viewpoint is widely held and is stated across
83 the peer-reviewed literature. If satellite soil moisture retrievals were to hold more
84 information about the rootzone, they would be considered more desirable than
85 reanalysis products for some land-atmosphere and ecological applications; they are
86 observations independent of model-prescribed linkages with other land surface
87 variables and provide direct information about plant water use and evapotranspiration
88 (Dong and Crow, 2019).

89

90 In fact, recent studies do not support the idea that microwave satellites are limited to
91 seeing only a shallow (0-5 cm) surface soil layer. The same L-band microwaves used to
92 retrieve surface soil moisture have been previously used to detect subsurface geologic
93 features in drylands beyond depths of one meter (Farr et al., 1986; Paillou et al., 2010).
94 Even if soil moisture satellites only observed the upper soil layers, surface and rootzone
95 moisture dynamics are almost always hydraulically connected and correlated (Akbar et
96 al., 2018; Ford et al., 2014; Qiu et al., 2014). This is because rootzone moisture is
97 driven by surface forcing and has strong spatiotemporal memory resulting in similar soil
98 moisture dynamics in the upper surface and deeper soil layers (Albergel et al., 2008;
99 McColl et al., 2017). Hydraulic redistribution by plants can also further couple the
100 surface and deeper soil layers (Nadezhina et al., 2010). As a result, the vertical depth
101 of representation, or support scale, of L-band satellite surface soil moisture has been
102 shown to be deeper than 5 cm (Akbar et al., 2018; Short Gianotti et al., 2019). Both
103 surface and deeper soil layer support scales consequently have similar information
104 content in explaining evapotranspiration fluxes and moisture thresholds between
105 evaporative regimes (Dong et al., 2022; Qiu et al., 2016). Satellite surface soil moisture
106 retrievals are thus recognized as a means to improve the characterization of rootzone
107 soil moisture and evapotranspiration in model assimilation frameworks (Kumar et al.,
108 2009; Purdy et al., 2018; Reichle et al., 2019).

109 Furthermore, a common emphasis on the fact that maximum rooting depths can extend
110 plant water uptake meters into the soil (Nepstad et al., 1994) neglects that active water
111 uptake is rarely uniform across the rooting profile. Specifically, global observations and
112 optimally modeled rooting profiles indicate that most plants preferentially draw water
113 from the upper soil layers to take advantage of these layers' pulse water and nutrient
114 availability (Collins and Bras, 2007; Jackson et al., 1996; Nippert and Holdo, 2015).
115 Even for deeper-rooted vegetation, high sensitivity to upper-layer soil moisture is also
116 found based on findings of decreasing rooting biomass and root hydraulic conductance
117 with depth (Nippert et al., 2012; Werner et al., 2021). Therefore, to learn about nominal
118 plant water use and evapotranspiration, rootzone soil moisture products may not always
119 need to integrate moisture dynamics down to the maximum rooting depth.
120

121 This perspective article evaluates the literature to determine (1) whether L-band satellite
122 surface soil moisture products capture soil moisture dynamics deeper than 5 cm and (2)
123 to what extent the vertical soil depth representation of satellite retrievals is relevant for
124 global vegetation water uptake and evapotranspiration.

125 **2. Satellite Soil Moisture's Effective Sensing Depth**

126 The true vertical support of remote sensing-based soil moisture retrievals is dependent
127 on both (1) the microwave emission properties of the soil column and (2) the vertical
128 autocorrelation of typical soil moisture profiles and their dynamics (Njoku and
129 Entekhabi, 1996; Short Gianotti et al., 2019). Both principles result in decay of soil
130 moisture representation with depth (i.e., exponential distribution). Furthermore, these
131 principles trade off in dominance from dry to wet conditions (Fig. 1).
132
133
134

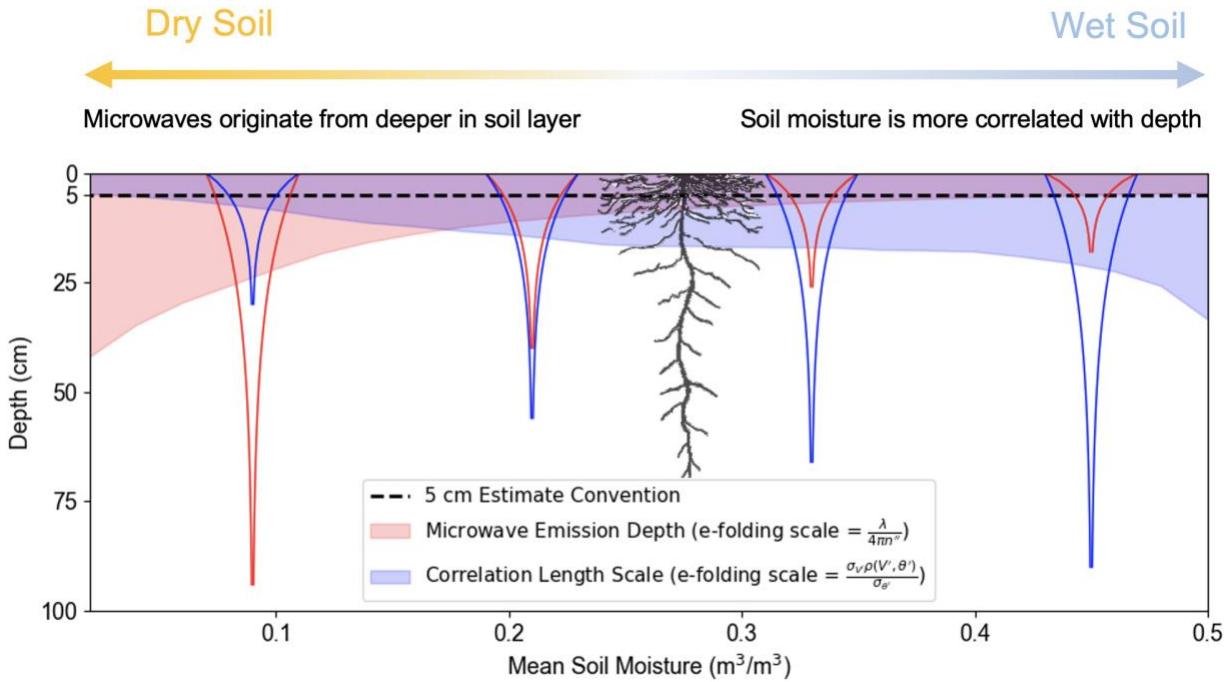

135 For drier soils, L-band satellites directly detect soil moisture in a deeper soil column
136 because microwave emission originates from deeper soil layers (Fig. 1). Specifically,
137 modeling microwave emission from a soil layer that is assumed to be a homogenous,
138 dielectric medium reveals that soil emission depth increases with aridity and vertically
139 decays approximately exponentially (Njoku and Entekhabi, 1996; Njoku and Kong,
140 1977). Therefore, despite drier periods resulting in less coupling between surface and
141 deeper layer soil moisture, satellites directly sample deeper into the soil column, often
142 well below 5 cm (Fig. 1).

143
144 For wetter soils, despite shallower soil emission depths from an electromagnetic
145 perspective, surface soil moisture has a greater hydraulic connectivity with deeper soil
146 layers (Fig. 1). This is because soil moisture is a storage variable with strong
147 spatiotemporal memory (McColl et al., 2017). As a result, satellite soil moisture from L-
148 band satellites holds statistical information about the soil moisture magnitudes and
149 variations deeper than 5 cm into the soil column, especially under wetter conditions
150 (Akbar et al., 2018; Short Gianotti et al., 2019). Such vertical autocorrelation information
151 decays approximately exponentially with depth, similarly to microwave soil emission.

152
153 Combining these electromagnetic and statistical considerations shows that, under a
154 wide range of soil moisture conditions, L-band satellites effectively sample soil moisture
155 dynamics deeper than 5 cm - realistically the top 15 to 25 cm (Fig. 1). This deeper
156 "effective sensing depth" results from electromagnetic and statistical considerations of
157 satellite-based soil moisture trading off in their dominance of vertical soil representation
158 from dry to wet conditions. In principle, the combined support scale of the satellite-
159 based soil moisture dynamics is at least the deeper of the two considerations, the full
160 depth of which is under investigation. Deeper layers between 25 to 100 cm are still
161 integrated but contribute progressively less to the signal with depth (Fig. 1). By contrast,
162 reanalysis rootzone moisture products often assess the uniform, column-averaged soil
163 moisture typically between 0 and 100 cm and/or discretized portions of this range.

164
165 Note that, in the case of drier soils, the microwave emission depth directly observes the
166 magnitude and time variations of deeper layer soil moisture. However, in wetter
167 conditions, only the soil moisture magnitude and variations in the upper soil layers
168 nearer to 5 cm are directly observed by L-band satellite sensors (Fig. 1). Nevertheless,
169 the typically high hydraulic connectivity between shallow and deeper layers in these
170 wetter conditions allows indirect observation of the soil moisture magnitude and
171 variations in the deeper layers.

172

173
 174 Figure 1. Effective sensing depth of microwave satellite soil moisture based on
 175 consideration of both L-band (1.4 GHz) microwave soil emission physics and vertical
 176 hydraulic connectivity of soil moisture. Satellite effective sensing depths of soil moisture
 177 range between 15 cm to over 25 cm, 3-5 times deeper than commonly thought, while
 178 integrating some deeper soil information. Effective sensing depths (shading) are e-
 179 folding scales determined from distributions (solid lines) of microwave soil emission and
 180 soil moisture information with depth. Microwave emission depth e-folding scale (red
 181 shading) and example emission profiles (red solid lines) are computed based on the soil
 182 emission model in Njoku and Entekhabi, (1996). Note that changes in soil texture have
 183 minimal influence on microwave emission depths compared to variations in soil
 184 moisture (not shown). E-folding vertical correlation length scales (blue shading) are
 185 computed by averaging global vertical length scale estimates, obtained with permission
 186 from Short Gianotti et al., (2019), binned based on mean annual soil moisture.
 187 Corresponding example profiles of degree of hydraulic connectivity with the surface
 188 (blue solid lines) are estimated from these averaged e-folding length scales. For
 189 equation details, see Appendix A. The displayed root profile image, adapted with
 190 permission from Nippert and Holdo, (2015), has a commonly-observed structure of
 191 decreasing root biomass with depth. The exact dimensions vary globally.

192
 193 **3. Revised View of Plant Water Uptake Depths**
 194 A common viewpoint across the Earth science community is that rootzones are
 195 (qualitatively) “deep,” which strongly argues against using a 0-5-cm or even a 0-20-cm
 196 soil moisture dataset to study vegetated landscapes. Indeed, maximum rooting depths
 197 often extend to 1-2-m and, at times, tens of meters below the surface depending on
 198 climate and surface topography (Fan et al., 2017; Nepstad et al., 1994; H. J. Schenk
 199 and Jackson, 2002; Tumber-Dávila et al., 2022). Existence of deep roots indicates
 200 adaptation to plant water stress, where access to deeper, less variable water sources

201 allows plants to continue transpiring and survive under severe water-limitation (Stocker
202 et al., 2021). However, in the context of nominal plant water uptake, such a perspective
203 can result in over-emphasis of the maximum rooting depth and neglect of the nature of
204 typical rooting profiles and their relevance to the global water cycle. Specifically, global
205 rooting profiles are typically concentrated in the upper soil layers and decrease in root
206 density with depth (Jackson et al., 1996). For example, some estimates indicate that
207 90% of global vegetation has more than half of their roots in the top 30 cm of soil (J. H.
208 Schenk and Jackson, 2002).

209
210 Shallow preferential soil water uptake and deeper roots can exist concurrently - the
211 existence of a deep maximum rooting depth does not imply low plant utilization of
212 shallow soil moisture. The deepest roots are indeed important for survival under
213 seasonal or severe water limitation. However, the frequency and volumetric proportion
214 of use of these deeper water stores is small, often much less than 10% of annual plant
215 water uptake (McCormick et al., 2021; Miguez-Macho and Fan, 2021). This lower
216 contribution of water uptake from the deeper layers is, in part, because there are
217 hydraulic limitations in transporting water over long vertical distances from deeper roots,
218 with high radial and axial resistances in roots that can increase with depth (Jones, 2014;
219 Landsberg and Fowkes, 1978; Nippert et al., 2012). Additionally, essential limiting
220 nutrients are typically highly concentrated in the upper soil layers due to decaying
221 organic matter, which prevents sole plant reliance on deeper moisture sources
222 (Jobbágy and Jackson, 2001). This motivates strategies like hydraulic redistribution
223 where plants actively move water via the roots to upper soil layers for easier uptake of
224 nutrients under dry conditions (Cardon et al., 2013). As such, the maximum rooting
225 depth is often of limited importance for evaluating nominal plant water uptake
226 throughout the year (Nippert and Holdo, 2015). This is true even in water-limited
227 ecosystems (Nippert and Holdo, 2015), where rainfall infiltration is often shallow (<30
228 cm) and plants must rely on this more frequently wetted shallow zone for survival (Scott
229 and Biedermaier, 2019).

230
231 Additionally, due to root suberization and woody root development that prevents root
232 water uptake, the rooting distribution does not necessarily match the actual vertical
233 profile of root water uptake (Kramer and Boyer, 1995). Instead, isotopic tracers can be
234 used to estimate the true range of primary water uptake, commonly called the functional
235 rooting profile (Dawson and Pate, 1996; Ehleringer and Dawson, 1992). Within the limits
236 imposed by isotopic mixing model uncertainties (Case et al., 2020; Ogle et al., 2004),
237 isotopic tracer methods can determine water uptake profiles and/or ranges more
238 relevant to the water cycle than knowledge of the rooting profile alone.

239
240 Therefore, instead of rooting profile information, we have collated isotopic tracer studies
241 that determine the vertical range of roots contributing the most to xylem water within
242 plants (Fig. 2). Values displayed in Fig. 2 reflect the primary zones of water uptake over
243 most of the year indicated by each reviewed study. In our web search of peer-reviewed
244 literature, our keywords included "stable", "isotope," "tracer," "plant," "root," "water
245 uptake," and "soil." We only sampled studies that (a) explicitly stated or displayed the
246 primary depths of water uptake (avoiding subjective judgment of results), (b) assessed

247 naturally occurring plants under nominal conditions (avoiding experimental
248 manipulation, extreme stress, and laboratory experiments), and (c) evaluated plant
249 species with an unobstructed rootzone (avoiding riparian, coastal, and shallow bedrock
250 environments). We additionally searched citations within studies that initially met our
251 criteria using these same keywords. Our search resulted in 45 references that met our
252 criteria (Fig. 2 and Table S1).

253

254 We find that grass and crop species across global climates typically extract water from
255 the upper soil layers (0-30 cm) over most of the year, with preferential uptake of water
256 nearer to the surface (Figs. 2A and 2B). For grass species, 95% of the studies found
257 grasses primarily use water from at least the top 50 cm with 65% of studies explicitly
258 finding increased proportional uptake in the top-most soil layers (Fig. 2A). All sampled
259 crop species either primarily use soil water within the top 25 cm or preferentially draw
260 water from the upper soil layers with decreasing water use with depth (Fig. 2B). All crop
261 studies that found water use extending deeper than 50 cm also found proportionally
262 higher water use in the upper soil layers. 88% of these same studies also found the
263 primary plant water uptake zone transitioned temporarily to the upper soil layers (see
264 diamond symbols in Fig. 2B).

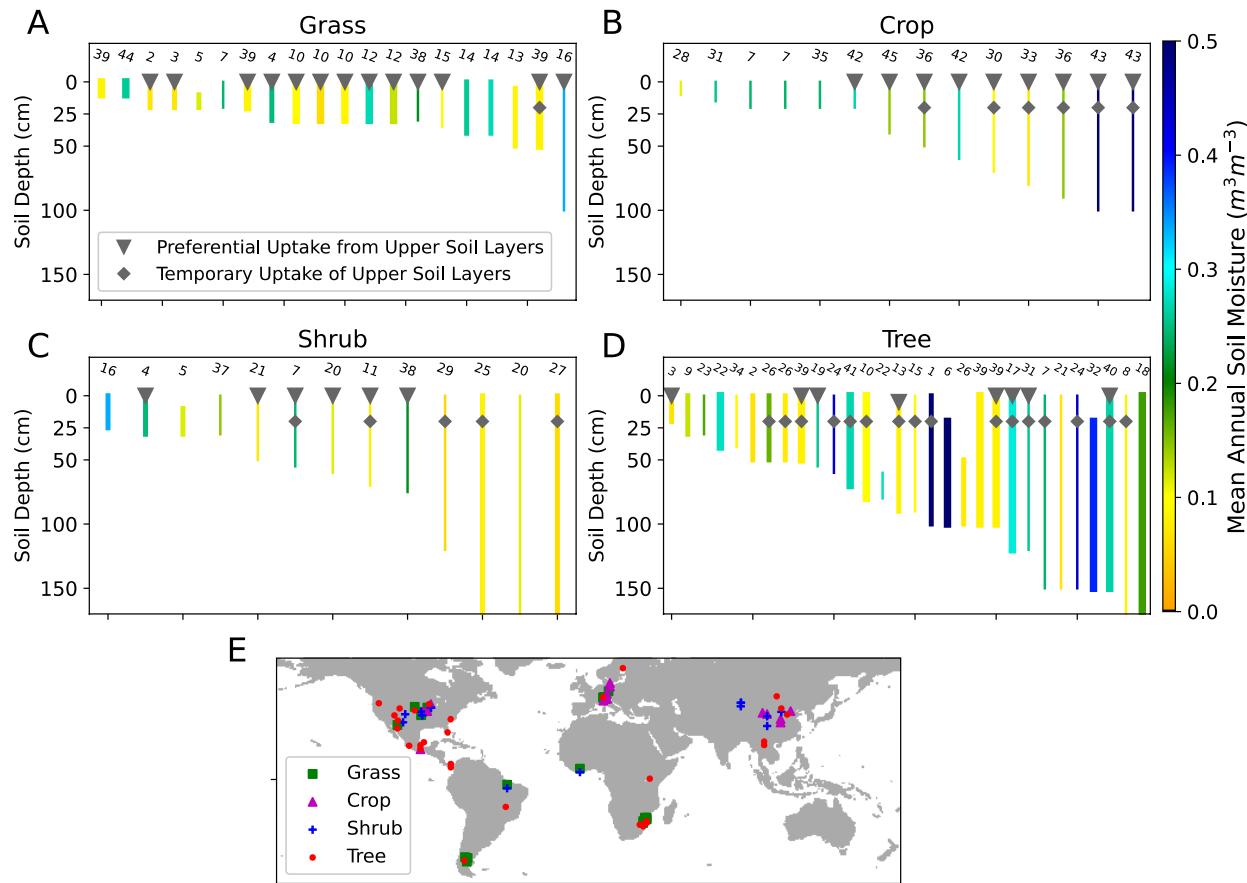

265

266 Shrub and tree species show a larger vertical range of water uptake, with water uptake
267 commonly extending to well below 50 cm (Figs. 2C and 2D) often related to root-niche
268 separation under competition with grasses (Case et al., 2020). However, even in these
269 deeper water uptake cases, 89% of shrub isotopic studies and 67% of tree isotopic
270 studies found either proportionally higher water uptake from the upper soil layers or the
271 primary water use zone transitioned temporarily to the upper soil layers. Absence of
272 triangle and diamond symbols indicate that the study did not mention either
273 phenomenon, not that the phenomenon does not exist. Therefore, these percentages
274 that indicate preferential or temporary uptake of upper soil layer moisture are lower
275 bounds.

276

277 We acknowledge potential biases in our search. For example, a greater proportion of
278 studies in the midlatitudes arises due to abundant field research facilities in Asia,
279 Europe, and North America as well as a lack of field measurements in the tropics
280 (Schimel et al., 2015). More studies also take place in semi-arid and sub-humid
281 environments because of their higher proportion of global land cover (about 70% of land
282 surfaces receive <1,000 mm of annual rainfall according to Global Precipitation
283 Measurement rainfall (Huffman, 2015)). While our search yielded few tropical forest
284 studies, we expect these regions may have deeper functional rooting profiles similarly to
285 those found in Fig. 2D (Ichii et al., 2007). However, we argue that this search provided a
286 representative distribution of species across grass, crop, shrub, and tree categories and
287 across global moisture availability gradients.

288

289
290 Figure 2. Primary root water uptake profiles (or functional rooting profile) based on field
291 stable isotope tracer studies for species binned in (A) grass, (B) crop, (C) shrub, and (D)
292 tree categories based on Table S1. The triangle symbol means the study found
293 preferential water uptake nearer to the surface and decreasing uptake with depth. The
294 diamond symbol means that while the study found uptake to 50 cm soil depths or below,
295 root water uptake switched primarily to the upper soil layers (<~30cm) temporarily
296 during the year. Placement of the diamond symbol at 20 cm is arbitrary. Thickness of
297 the line indicates number of species studied in the given reference. The number above
298 the plotlines is the reference index (see Table S1). Mean annual SMAP soil moisture is
299 displayed for each field site using the nearest 36 km pixel. (E) Locations of the isotopic
300 field measurements.

301
302 **4. Recommendations**
303 Our findings convey that satellite L-band radiometry captures global soil moisture
304 dynamics at least as deep as the top 15-25 cm of soil (Fig. 1), which is more than three
305 times deeper than commonly stated as well as more relevant for evaluating plant
306 function than commonly appreciated. L-band satellite soil moisture estimates appear
307 optimal for studying most grasslands and croplands, which cover more than a third of
308 global vegetated surfaces. This proportion is higher when including non-vegetated
309 surfaces, given that bare surfaces are also dominated by upper soil layer processes
310 (i.e., bare soil evaporation). Grass and crop water use also decreases with depth, much

311 like the decreasing L-band satellite soil moisture representation with depth (Fig. 1).
312 Therefore, soil moisture datasets that integrate rootzone dynamics between 0-100 cm
313 and deeper may in fact be less useful than L-band soil moisture for representing plant-
314 relevant soil moisture dynamics in grass and croplands. This is because soil moisture
315 products representing the 0-100 cm layer will integrate subdued moisture dynamics in
316 deeper layers not relevant to the functional rooting profile concentrated in the upper soil
317 layers. Additionally, even woody plant species that exhibit deeper root water uptake
318 (shrubs and trees; see Fig. 2) frequently draw water nearer to the surface preferentially
319 or temporarily within a given season. L-band soil moisture observations are still useful
320 for these scenarios at least during certain times of the year, and will increase in utility if
321 global functional root profiles become shallower under global change (Hauser et al.,
322 2020).

323
324 Given these considerations, our findings indicate a wider applicability of satellite soil
325 moisture for the study of global climate. This encourages broader, more confident use of
326 satellite soil moisture for the study of soil moisture's impact on the terrestrial net carbon
327 balance, water movement in the soil-plant-atmosphere continuum, land-atmosphere
328 coupling, and crop yield forecasting (Akbar et al., 2020; Dong et al., 2020; Feldman et
329 al., 2022, 2018b; Konings et al., 2017; Purdy et al., 2018; Santanello et al., 2019; Short
330 Gianotti et al., 2020; Taylor et al., 2012; Tuttle and Salvucci, 2016).

331
332 While our assessment indicates wide applicability of L-band satellite soil moisture, we
333 stress that deeper-layer (0-100 cm and beyond) soil moisture products based on the
334 assimilation of L-band observations (i.e., SMAP L4 rootzone soil moisture; Reichle et
335 al., 2019) are likely more optimal for the study of soil moisture memory in the context of
336 land-atmosphere interactions, the study of deeper-rooted vegetation function under
337 water-stress conditions, the study of infiltration and drainage fluxes, and the initialization
338 of dynamical seasonal forecasts. Our findings here also indicate that reanalysis
339 rootzone soil moisture products are needed for the study of many mixed (i.e., savanna)
340 and forested landscapes.

341
342 Furthermore, we argue that there is no single soil moisture product that will globally
343 integrate the soil moisture layers relevant to plant water uptake and thus terrestrial
344 water, carbon, and energy exchanges. Instead, the optimal soil moisture product
345 changes in time and space. For studies of water, carbon, and energy exchanges at
346 landscape scales, we encourage first understanding the typical root water uptake
347 patterns for plant species in the study region and then carefully selecting a soil moisture
348 dataset. Potentially, multiple products and their synergistic use are needed depending
349 on the complexity of root water uptake scenarios.

350
351 For example, for herbaceous ecosystems including most croplands, grasslands, and
352 savannas with sparse tree cover, the L-band soil moisture products will likely optimally
353 integrate the relevant rootzone moisture information. These observations will
354 additionally be optimal for the study of mostly bare surface supplied mainly by soil
355 evaporation. Alternatively, in scenarios where prevalent deeper-rooted shrubs and trees
356 are mixed with a shallow-rooted understory, datasets representing a uniform distribution

357 of integrated soil moisture across the top 1-2 meters of soil (i.e., model reanalysis
358 rootzone soil moisture products) may be optimal (Reichle et al., 2019). P-band (0.4
359 GHz) soil moisture remote sensing applications may be more useful for these scenarios
360 as well with potentially twice as deep of effective sensing depths than at L-band
361 (Konings et al., 2014). Finally, in scenarios where root water uptake extends well below
362 one meter for consistent or transient use of deep moisture or groundwater (McCormick
363 et al., 2021; Miguez-Macho and Fan, 2021), care must be taken in determining when
364 this uptake occurs. Such scenarios may occur in tropical rainforests where L-band
365 satellite soil moisture retrievals are suboptimal due to vegetation multiple-scattering of
366 microwaves (Feldman et al., 2018a; Kurum et al., 2011). Satellite-based terrestrial water
367 storage variations (i.e., GRACE and GRACE-FO) may be useful to study these cases
368 and can be used in tandem with reanalysis rootzone products (Rodell and Famiglietti,
369 2001).

370

371 In summary, we urge the community to consider using L-band soil moisture
372 observations for applications involving vegetated landscapes. The value of satellite-
373 based soil moisture beyond only a shallow (0-5 cm) surface layer emphasizes the
374 urgent need to maintain continuity of L-band satellite remote sensing missions.

375

376 **Appendix A**

377 The e-folding depth of microwave emission used to estimate surface soil moisture can
378 be modeled by:

379
$$L_{Emission} = \frac{\lambda}{4\pi n''} \quad (\text{Eq. A1})$$

380 where λ is the emission wavelength (Njoku and Kong, 1977). n'' is the imaginary part of
381 the refractive index, which is the square root of the dielectric constant. The dielectric
382 constant is a function largely of soil moisture and soil texture (i.e., clay fraction). $L_{Emission}$
383 is the e-folding scale that represents the emission depth of microwaves. Measurements
384 of these microwaves are used to estimate satellite soil moisture.

385

386 The e-folding vertical correlation length scale of soil moisture dynamics can be
387 computed by:

388
$$L_{Correlation} = \frac{\sigma_V' \rho(V', \theta_s')}{\sigma_{\theta_s'}} \quad (\text{Eq. A2})$$

389 where V is the total volume soil moisture in the column, θ_s is the surface soil moisture, ρ
390 is correlation, and σ is standard deviation (Short Gianotti et al., 2019). Prime
391 superscripts indicate the time derivative. $L_{Correlation}$ is a correlation length scale, or the e-
392 folding scale, that captures the decay of surface soil moisture's correlation with the total
393 column soil moisture. $L_{Correlation}$ is thus the effective depth to which the surface soil
394 moisture (here, being measured at least at a 5 cm depth) holds information about the
395 total soil column moisture. Similar theoretical arguments allow interpretation of $L_{Correlation}$
396 to be a support scale of the soil moisture magnitude and time dynamics (Akbar et al.,
397 2018).

398

399 While Eq. A2 is an exact solution, total column volumetric moisture is not widely
400 available to estimate $L_{Correlation}$ globally. Thus, Short Gianotti et al. (2019) estimate
401 $L_{Correlation}$ using information about the variance of surface hydrologic fluxes (rainfall

402 minus surface hydrologic losses) as well as surface soil moisture variance and
403 autocorrelation (their equation 28). GPM rainfall retrievals and SMAP soil moisture
404 retrievals are used together to globally estimate $L_{\text{Correlation}}$, which are used in Fig. 1.
405

406 **Acknowledgements**

407 Andrew F. Feldman's research was supported by an appointment to the NASA
408 Postdoctoral Program at the NASA Goddard Space Flight Center, administered by Oak
409 Ridge Associated Universities under contract with NASA. The authors with MIT
410 affiliation, Rolf H. Reichle, and Wade T. Crow were supported by the NASA SMAP
411 mission. The authors thank Alexandra Konings for helpful comments that improved the
412 manuscript.

413

414 **Author Contributions**

415 A.F.F. conceived of the study, performed the analysis, and drafted the manuscript. D.E.
416 and A.F.F. led the study. D.J.S.G., J.D., R.A., W.T.C, and D.E. provided guidance and
417 edits on the presentation of satellite sensing depth estimates. J.B.N., S.J.T.D, N.M.H.,
418 F.E.R., and R.L.S. provided guidance and edits on presentation of isotopic tracer
419 studies and rooting depth information. K.A.M., R.H.R., A.C., J.J., and B.P. provided
420 guidance on all components and, in particular, in framing the perspective in the context
421 of their respective fields. All authors contributed substantial textual edits.
