24

Abstract

Vortex streets formed in the stratocumulus-capped wake of mountainous islands are the atmospheric analogues of the classic Kármán vortex street observed in laboratory flows past bluff bodies. The quantitative analysis of these mesoscale unsteady atmospheric flows has been hampered by the lack of satellite wind retrievals of sufficiently high spatial and temporal resolution. Taking advantage of the cutting-edge Advanced Baseline Imager, we derived km-scale cloud-motion winds at 5-minute frequency for a vortex street in the lee of Guadalupe Island imaged by Geostationary Operational Environmental Satellite-16. Combined with Moderate Resolution Imaging Spectroradiometer data, the geostationary imagery also provided accurate stereo cloud-top heights. The time series of geostationary winds, supplemented with snapshots of ocean surface winds from the Advanced Scatterometer, allowed us to capture the wake oscillations and measure vortex shedding dynamics. The retrievals revealed a markedly asymmetric vortex decay, with cyclonic eddies having larger peak vorticities than anticyclonic eddies at the same downstream location. Drawing on the vast knowledge accumulated about laboratory bluff body flows, we argue that the asymmetric island wake arises due to the combined effects of Earth's rotation and Guadalupe's non-axisymmetric shape resembling an inclined flat plate at low angle of attack. The asymmetric vortex decay implies a three-dimensional wake structure, where centrifugal or elliptical instabilities selectively destabilize anticyclonic eddies by introducing edge-mode or core-mode vertical perturbations to the clockwise-rotating vortex tubes.

1 Introduction

Flow past a circular cylinder is a classic problem in fluid dynamics. In an unstratified fluid and nonrotating reference frame, the wake pattern is determined solely by the Reynolds number Re. For $Re > {\sim}50$, vortices with alternate senses of rotation are shed from alternate sides of the cylinder. As these counterrotating vortices are advected downstream, they form a vortex street of two rows arranged in a staggered configuration as illustrated in Figure 1. For $Re < {\sim}190$, vortex shedding is strictly periodic and two dimensional with no vertical (spanwise) variations in the flow. For ${\sim}190 < Re < {\sim}260$, however, vortex shedding transitions from a laminar regime to a three-dimensional regime as streamwise and transverse vorticity structures develop in addition to the primary spanwise vortices. At higher Re, the fine-scale three dimensionality of the wake becomes increasingly disordered, but quasiperiodic coherent vortex shedding is observed even in highly turbulent laboratory flows with Re of the order of 10^6 (Williamson, 1996).

Although vortex streets were first photographed by Henri Bénard during his laboratory investigations of vortex spacing (Bénard, 1908a, 1908b), much to his chagrin the phenomenon became associated almost exclusively with Theodore von Kármán, who made two important contributions to the relevant aerodynamic knowledge (von Kármán, 1911, 1912; von Kármán & Rubach, 1912). One, he connected the momentum carried by the vortex system with wake drag. Two, he performed linear stability analysis of a simplified model comprising an infinite train of point vortices embedded in an inviscid fluid and showed that all vortex configurations are unstable, except for one specific staggered configuration with an aspect ratio—distance between vortex rows divided by inter-vortex spacing in one row—of $H/L = 0.281$, which is neutrally stable. Measurements of vortex streets in viscous fluids later found that the actual aspect ratio hardly ever assumes this theoretical value, but rather it increases with downstream distance due to turbulent diffusion, varying from 0.15 to 0.45 and also having a slight dependence on Re (Bénard, 1926a,

69   1926b, 1927; Matsui, 1981). Nevertheless, the vortex pattern sketched in Figure 1 is now
70   universally referred to as the Kármán vortex street in recognition of Kármán's fundamental
71   theoretical insights.

72   Visible band satellite images often show spectacular trains of vortices in the cloudy wake
73   of mountainous islands, which bear a striking resemblance to patterns observed behind cylinders
74   in low Reynolds number (Re < ~300) laboratory flows—see the fluid motion albums of Samimy
75   et al. (2003) and Van Dyke (1982). These atmospheric vortex streets consist of mesoscale eddies
76   in a well-mixed boundary layer capped by a temperature inversion and are made visible by
77   streaklines in stratocumulus clouds acting as tracer. The eddies span the entire boundary layer as
78   revealed by their sea surface imprints in Synthetic Aperture Radar (SAR) images (Li et al., 2000,
79   2008). As such, atmospheric vortex streets differ from their laboratory cousins in several important
80   aspects. First and foremost, they develop in a stratified atmosphere on a rotating Earth, which
81   necessitates the introduction of the Froude number Fr and the Rossby number Ro as additional
82   control parameters besides Re. Furthermore, the height to width aspect ratio and the sidewall slope
83   of relatively flat—and often not even axisymmetric—islands are much smaller than those of long
84   cylinders used as obstacles in the laboratory. Finally, while experimental setups go to great lengths
85   to ensure low-turbulence, steady, and uniform upstream flow, such ideal conditions are never
86   achieved in the atmosphere even in the most stable meteorological situations.

87   Whether atmospheric vortex streets are close physical analogues of laboratory ones or there
88   is only a superficial morphological similarity between these two systems depends ultimately on
89   the nature of the respective dynamical instabilities, vorticity generation and vortex shedding
90   mechanisms responsible for their formation. Although this topic is beyond the scope of our
91   observational study, we note that significant advances have been made in the understanding of
92   laboratory wake dynamics thanks to sophisticated experiments, direct numerical simulations, and
93   the introduction of new theoretical concepts such as global or local and absolute or convective
94   instability. The modern view of the phenomenon describes the onset of vortex shedding at the
95   critical Re = ~50 as a self-excited limit-cycle oscillation (Hopf bifurcation) with the periodic vortex
96   street in the near wake being the saturated end product of a time-amplified global instability
97   (Provansal et al., 1987; Provansal, 2006; Williamson, 1996).

98   Since Bénard and Kármán's pioneering work a century ago, hundreds of papers have been
99   published on laboratory wake vortices behind bluff bodies (reviewed partly by the excellent two-
100 volume monograph of Zdravkovich, 1997). In contrast, their atmospheric counterparts have
101 attracted considerably less attention due mainly to observational limitations—numerical modeling
102 studies are not surveyed in our paper. Although island vortex streets have been photographed from
103 a number of spacecraft, only the geometric aspect ratio and the vortex shedding frequency have so
104 far been estimated from satellite imagery (Chopra, 1973; Chopra & Hubert, 1965; Hubert &
105 Krueger, 1962; Jensen & Agee, 1978; Lyons & Fujita, 1968; Thomson et al., 1977; Tsuchiya,
106 1969; Zimmerman, 1969). The most comprehensive past study is that of Young and Zawislak
107 (2006), which derived aspect ratio statistics for 30 vortex streets based on Moderate Resolution
108 Imaging Spectroradiometer (MODIS) images. They found that the aspect ratio of atmospheric
109 vortex streets does follow geometric similarity theories but, much like in laboratory flows, it differs
110 considerably from Kármán's analytical prediction. The measured values were larger, with a mean

111 of 0.42 and a 95% confidence interval of 0.36–0.47 for island vortex streets having a straight
112 centerline.

113   The spaceborne measurement of atmospheric vortex street dynamics however has been out
114 of reach, because the spatial and temporal resolution of operational satellite wind products is still
115 too coarse to retrieve the small-scale wake flow. Existing cloud-motion wind algorithms are based
116 on 1–5 km pixel resolution imagery acquired every 10–100 minutes and use a large tracking box
117 of 26×26–72×72 km^2 (Horváth et al., 2017). Higher temporal and higher spatial resolution
118 sampling is needed to advance the understanding of atmospheric processes in turbulent
119 environments, as highlighted by a review of current remote sensing capabilities (Geerts et al.,
120 2018). Recently developed research-quality wind datasets now offer enhanced resolutions capable
121 of resolving the vortex street wind field. For example, Horváth (2013) demonstrated that 4.4-km
122 resolution stereo cloud-motion winds from the Multiangle Imaging SpectroRadiometer (MISR)
123 could successfully capture the flow and vorticity field of a vortex street in the lee of Jan Mayen
124 Island. Ocean surface winds from the Advanced Scatterometer (ASCAT) resampled on a 6.25-km
125 grid were also shown to well represent the finer details of island wakes including those of a
126 Madeira vortex street, in good agreement with near-coincident 4.4-km cloud-level MISR winds
127 (Nunalee et al., 2015; Vogelzang, 2016; Vogelzang et al., 2017).

128   The current paper reports on the latest improvements in satellite retrievals of small-scale
129 geophysical flows enabled by the enhanced capabilities of the Advanced Baseline Imager (ABI)
130 onboard the Geostationary Operational Environmental Satellite-R (GOES-R) series (Schmit et al.,
131 2017). The ABI provides visible band imagery at a spatial and temporal resolution of 0.5 km and
132 5 minutes over the continental United States (CONUS) scan sector, which includes Guadalupe
133 Island off Baja California. The operational GOES-R wind product contains 7.5-km resolution
134 cloud-motion vectors every 15 minutes (Bresky et al., 2012; Daniels et al., 2010). Internally,
135 however, the algorithm also computes 2.5-km resolution local motion vectors by the nested
136 tracking of 5×5-pixel sub-scenes. Our study takes advantage of these local motion vectors, whose
137 frequency we have also increased to 5 minutes, to investigate an atmospheric Kármán vortex street
138 observed by GOES-16 in the lee of Guadalupe on 9 May 2018. We also exploit a novel MODIS–
139 GOES joint wind product that offers accurate stereo cloud-top heights and semi-independent wind
140 validation data (Carr et al., 2019). Unlike polar-orbiter retrievals providing only snapshots, high
141 temporal resolution geostationary data can capture the oscillation of the wake. We use ABI local
142 cloud-motion vectors over an 8-hr daytime period, combined with two early morning ASCAT
143 surface wind snapshots, to characterize the evolution of the vortex street wind field including the
144 downstream advection and decay of vorticity. To our knowledge, this is the first demonstration of
145 the spaceborne measurement of atmospheric vortex shedding.

146   The paper is organized as follows. Section 2 describes the satellite winds, atmospheric
147 reanalysis fields, other auxiliary data used as well as the calculation of basic flow parameters.
148 Section 3 gives an overview of the meteorological situation at Guadalupe Island on 9 May 2018,
149 determines vortex street geometry, and illustrates GOES-16 and ASCAT retrievals of the vortex
150 street wind field. Section 4 contains a quantitative analysis of the wake's temporal evolution.
151 Finally, section 5 summarizes our results and provides an outlook on the further potential of high
152 spatial and temporal resolution satellite winds for the characterization of unsteady geophysical
153 flows.
154

2 Materials and Methods

2.1 Wind Datasets

2.1.1 GOES-16 Local Cloud-Motion Vectors

Our primary data, the GOES-16 local cloud-motion vectors (or "local winds") were calculated using a simplified version of the operational GOES-R Derived Motion Winds (DMW) algorithm (Bresky et al., 2012; Daniels et al., 2010). The simplified version involved use of only the feature tracking portion of the GOES-R DMW algorithm. The local motion winds were not assigned heights as is the case in the operational version, limited quality control was performed on the output, and the tracking was done using image pairs instead of image triplets, in order to increase the spatial coverage and temporal frequency of the retrievals. Winds were extracted from multiple 0.5-km resolution ABI band 2 (0.64 μm visible red band) image pairs separated by a 5-minute time interval, starting at 14:32 UTC and ending at 22:37 UTC. Retrievals were generated every 5 minutes over a 602×602-pixel domain encompassing Guadalupe and its wake down to 26°N latitude. A 5×5-pixel (~2.5×2.5 km^2) sub-scene was centered on each pixel in this domain and then tracked forward in time by minimizing the sum-of-squared-difference (SSD) similarity measure between the target image sub-scene and the search image sub-scene. Because our research application is more noise-tolerant than numerical weather prediction (NWP) data assimilation systems, the only quality constraint placed on the raw local motion vectors was that each matching sub-scene had to meet a correlation threshold of 0.8 with the initial target sub-scene.

2.1.2 MODIS–GOES-16 3D Cloud-Motion Vectors

We also used data from a novel MODIS–GOES joint wind retrieval algorithm (Carr et al., 2019), which provides horizontal wind vectors with geometric height assignments derived from the stereo tracking of cloud patterns in a triplet of consecutive GOES-16 CONUS scenes and a single MODIS granule. The *Terra* and *Aqua* overpasses yielded two snapshots of the wind field at 18:12 UTC and 21:22 UTC. The algorithm is based on red band imagery (ABI band 2, MODIS band 1) as it offers the finest spatial resolution in both systems, 0.5 km and 0.25 km at the respective subsatellite points. Feature templates are taken from the central repetition of the GOES-16 triplet and matched to the other two repetitions 5 minutes before and after, providing the primary source of velocity information. The GOES-16 feature template is then matched to the MODIS granule which is observed from a different perspective, providing the stereoscopic height information. The apparent shift in the pattern from each match, modeled pixel times, and satellite ephemerides feed the retrieval model to enable the simultaneous solution for a wind vector and its geometric height. These joint MODIS–GOES-16 retrievals, hereafter referred to as "3D winds", are derived using 8×8 km^2 templates sampled every 2 km. As such, they have a slightly coarser resolution than the GOES-16 "local winds" described previously. At the same time, the larger template and use of GOES-16 image triplets rather than image pairs lead to visually less noisy, smoother retrievals.

2.1.3 ASCAT Ocean Surface Wind Vectors

194
195 The Advanced Scatterometer (ASCAT) is a C-band scatterometer carried by the MetOp
196 satellites. Here we used data from ASCAT-A and ASCAT-B, which at the time of our case study
197 were flying half an orbit apart in the same polar orbit with a separation time of ~50 min. ASCAT
198 is a VV (vertical transmit and vertical receive) polarized C-band radar with six fan beam antennas,
199 three at each side of the satellite. Two beams look forward at 45° azimuth with respect to the
200 satellite moving direction, two look cross-track at 90° azimuth, and two backward at 135° azimuth.
201 The radar cross section of the ocean surface is thus measured from three directions in two swaths
202 of about 550 km width (Figa-Saldaña et al., 2002). The ASCAT Wind Data Processor (AWDP) is
203 the standard software for deriving near real-time ocean surface wind vectors from the radar
204 measurements on 25-km and 12.5-km operational grids (KNMI, 2013). In this study, full resolution
205 radar cross sections from the European Organization for the Exploitation of Meteorological
206 Satellites (EUMETSAT) were processed with AWDP using a finer grid spacing of 6.25 km.
207 Although the retrievals have a true spatial resolution of ~17 km, the resulting wind field is
208 oversampled to prevent information loss (Nyquist sampling) and hence the 6.25 km product shows
209 considerably more detail than the coarser resolution operational products (Vogelzang et al., 2017).

210 We further note that ASCAT measures stress-equivalent winds at 10 m height, derived
211 assuming a near-neutral wind profile in the surface layer (de Kloe et al., 2017). These 10-m winds
212 differ from cloud-motion winds due to the height difference and ocean drag. For example, for a
213 typical aerodynamic roughness of 0.1 mm, near-surface friction velocity of 0.2 m s^{-1}, and 10-m
214 wind of 6 m s^{-1}, the corresponding wind at 1 km height is ~40% faster. This height scaling directly
215 applies to vorticity as well, assuming a constant diameter vortex, and therefore ASCAT wind
216 speeds and vorticity are substantially lower than cloud-motion wind speeds and vorticity.
217

2.1.4 Processing of the Wind Datasets

218
219 All three wind products were regridded onto the same Universal Transverse Mercator
220 (UTM) grid covering our study domain with a spacing of 6.3 km to match the spacing of the
221 coarsest ASCAT data. To reduce noise, each UTM gridbox was assigned the median of the wind
222 vectors it contained. The presence of occasional outliers affected mostly the highest resolution
223 GOES-16 local motion vectors, but for consistency the median filter was applied to the other wind
224 datasets as well. The vertical (spanwise) component of relative vorticity ζ was then calculated
225 from the horizontal wind components using standard finite difference methods (see e.g. Belmonte
226 & Stoffelen, 2019). As additional noise reduction, the regridded and median-filtered data fields
227 were also smoothed with a 3×3-gridbox averaging window.

228 The original north-south (N-S) and east-west (E-W) wind components were converted to
229 the more fitting streamwise V and transverse U wind components by rotating the coordinate system
230 hourly to align its x-axis with the upstream wind taken from ERA5 (C3S, 2017). This conversion
231 was only approximate, because the upstream wind direction and thus the direction of vortex
232 shedding changed during the day, resulting in a curved vortex street centerline. As a result, the
233 upstream wind direction at any given time was representative of the streamwise (vortex advection)
234 direction only in the near wake but could deviate from it in the far wake.
235
236

237 **2.2 ASTER Global Digital Elevation Model**

238   The topography of Guadalupe Island is characterized by the Advanced Spaceborne
239 Thermal Emission and Reflection Radiometer (ASTER) Global Digital Elevation Model Version
240 2 (GDEM V2) derived from stereo image pairs (NASA/METI/AIST/Japan Spacesystems &
241 U.S./Japan ASTER Science Team, 2009). The ASTER GDEM is distributed in 1°×1° tiles with
242 elevation data posted on a 1 arc-second (~30 m at the equator) grid and has an overall accuracy of
243 ~17 m (Meyer et al., 2011). Combining the GDEM with ERA5 wind and temperature profiles
244 allowed us to calculate the crosswind island diameter at inversion base level, which is the length
245 scale that determines vortex spacing. As shown in Figure 2, Guadalupe's shape is not an
246 approximately axisymmetric cone typical of volcanic peaks (e.g. Jan Mayen and Gran Canaria),
247 but rather resembles an elongated inclined flat plate. The effects of such a shape on the flow are
248 twofold. First, it makes the crosswind island diameter vary considerably with wind direction.
249 Second, it naturally defines a leading edge and trailing edge relative to the upstream wind. In
250 Figure 2 we plotted the "mass density" ellipse fitted to Guadalupe, which clearly indicates that
251 under the prevailing northwesterly winds the northern and southern shores act as the leading and
252 trailing edge, respectively. The angle of attack α, defined as the angle between the upstream wind
253 vector and the major axis of the fitted ellipse, varied between 9° and 32° in our case. As we discuss
254 in section 4, vortex shedding behind an inclined flat plate at low angle of attack is distinct from
255 that behind a circular cylinder.
256

257 **2.3 MODIS and VIIRS Imagery**

258   Vortex street geometry (vortex spacing and aspect ratio) was determined from Moderate
259 Resolution Imaging Spectroradiometer (MODIS) and Visible Infrared Imaging Radiometer Suite
260 (VIIRS) 0.64 μm red band images. The advantages of polar-orbiter imagery over geostationary
261 imagery are better resolution and minimized image distortion due to the curvature of the Earth.
262 The MODIS *Terra*, VIIRS *Suomi National Polar-Orbiting Partnership* (*Suomi NPP*), and MODIS
263 *Aqua* observed the vortex street at 18:12 UTC, 20:17 UTC, and 21:22 UTC, respectively. The
264 images used were obtained from the NASA Worldview application in an equirectangular map
265 projection with a pixel resolution of 0.25 km.
266

267 **2.4 Basic Flow Parameters**

268 **2.4.1 Reynolds Number**

269   In a nonrotating unstratified fluid, the nature of the wake only depends on the Reynolds
270 number, which is the dimensionless ratio of inertial force to viscous force. The Reynolds number
271 is defined as

272 $$Re = UD/\nu, \tag{1}$$

273 where U is the upstream velocity, D is the obstacle (cylinder) diameter, and ν is the kinematic
274 viscosity of the fluid (generally water in laboratory experiments). For atmospheric vortex streets
275 U is of O(1-10) m s^{-1} and $D = D_{inv}$, the crosswind island diameter at inversion base, is of O(1-10)

276 km. Using the kinematic viscosity of air ν_{air}, which is of $O(10^{-5})$ m^2 s^{-1}, would yield an exceedingly
277 large *Re* of $O(10^8\text{-}10^{10})$ implying extremely turbulent conditions.

278   However, the cloud patterns of atmospheric vortex streets resemble the more laminar
279 patterns observed in laboratory flows with *Re* < ~300 (see the photographs in Samimy et al., 2003
280 and Van Dyke, 1982). In order to achieve a semblance of similarity between natural and laboratory
281 conditions, one must invoke the use of the eddy viscosity in the determination of *Re* for
282 atmospheric vortex streets. The eddy viscosity ν_E is at least five orders of magnitude larger than
283 ν_{air}, however, its appropriate value for atmospheric flows is still debated—a topic not pursued any
284 further in this paper. Suffice it to say, the eddy viscosity approach behaves relatively poorly for
285 large-eddy coherent structures and it allows, at most, only qualitative comparisons between
286 geophysical and laboratory phenomena as pointed out by Boyer and Davies (2000).
287

288   ### 2.4.2 Froude Number

289   The Froude number is the dimensionless ratio of flow inertia to an external field. Although
290 originally introduced in naval architecture to formulate the resistance experienced by partially
291 submerged vessels moving through water, the parameter was also found relevant in the description
292 of stratified atmospheric flows—in which case it is the ratio of inertial force to buoyancy force.
293 There are various formulas for the Froude number (Heinze et al., 2012; Leo et al., 2016) and here
294 we use the one based on the dividing streamline concept of Snyder et al. (1985). The dividing
295 streamline at height h_c separates the air parcels that go over from those that go around the obstacle.
296 The flow above h_c is three-dimensional near the obstacle with a significant vertical component.
297 Below h_c, however, flow splitting leads to quasi two-dimensional streamlines in horizontal planes.

298   For the atmosphere where wind speed and stratification generally vary with height *z*,
299 Snyder et al. (1985) derived an implicit expression which can be solved for h_c by iteration:

300 $$\frac{1}{2}U^2(h_c) = \int_{h_c}^{h_m} N^2(z)(h_m - z)\, dz. \tag{2}$$

301 Here $U(z)$ is the ERA5 upstream wind speed profile, $h_m = 1,298$ m is the peak height of Guadalupe,
302 and

303 $$N(z) = \left(\frac{g}{\theta}\frac{\partial\theta}{\partial z}\right)^{1/2} \tag{3}$$

304 is the Brunt–Väisälä frequency, with $g = 9.81$ m s^{-2} being the gravitational acceleration and $\theta(z)$
305 being the ERA5 upstream potential temperature profile. Equation (2) assumes that all horizontal
306 kinetic energy is converted into potential energy and thus provides the lowest possible dividing
307 streamline, which in reality might be found at a somewhat higher level.

308   Etling (1989) showed that the dividing streamline height obtained above for vertically
309 varying atmospheric wind speed and stratification profiles can be converted to a Froude number
310 that facilitates comparison with laboratory flows under constant upstream velocity and constant
311 stratification:

312 $$Fr = 1 - h_c/h_m. \tag{4}$$

313   Laboratory experiments with three-dimensional obstacles in stably stratified flows found spanwise
314   vortex shedding only for $Fr < 0.4$ (Boyer et al., 1987; Brighton, 1978; Hunt & Snyder, 1980), a
315   condition also met by the four atmospheric vortex street cases with available radiosonde profiles
316   that were analyzed by Etling (1989). This restriction on the static stability of the flow requires that
317   $h_c > 0.6h_m$, that is the quasi two-dimensional split-flow regime must cover at least 60% of the
318   vertical extent of the island (~779 m for Guadalupe).
319

2.4.3 Rossby Number

321   In the study of rotating fluids, one more dimensionless dynamical parameter has to be
322   introduced, which usually is the Rossby number. The Rossby number is the ratio of inertial force
323   to Coriolis force, defined as

$$Ro = U/fD = U/2D\Omega \sin \phi, \tag{5}$$

325   where U is the upstream velocity, $D = D_{inv}$ is the crosswind island diameter at inversion base, and
326   $f = 2\Omega \sin \phi$ is the Coriolis parameter, with $\Omega = 7.29 \times 10^{-5}$ s^{-1} being the rate of Earth's rotation
327   and $\phi = 29.03°$ being Guadalupe's latitude.

328   Thus, for the general case of a stratified rotating fluid a basic set of independent
329   dimensionless control parameters consists of Re, Fr, and Ro. Alternatively, the Ekman number Ek,
330   the ratio of viscous force to Coriolis force, can be used instead of the Reynolds number, in which
331   case $Re = Ro/Ek$ is not an independent parameter any longer.
332

2.4.4 Strouhal Number

334   Although not a control parameter, the Strouhal number is an essential dimensionless
335   quantity in the description of oscillating flows. It can be considered a normalized shedding
336   frequency, defined as

$$St = D/TU, \tag{6}$$

338   where U is the upstream velocity, $D = D_{inv}$ is the crosswind island diameter at inversion base, and
339   T is the shedding period between two consecutive like-rotating vortices. The importance of St
340   stems from the fact that a similarity relationship was observed between St and Re by several
341   laboratory studies, allowing the identification and categorization of distinct flow regimes. Roshko
342   (1954) found for a circular cylinder that St increases steadily with Re from 0.120 to 0.205 for $50 <$
343   $Re < 300$ and then St asymptotes to the value of 0.210 for $300 < Re < 10^4$. The behavior of St and
344   the definition of flow regimes for even higher Re are reviewed in Williamson (1996).

345   The Strouhal number for an inclined flat plate, which is a better first-order model of
346   Guadalupe than a cylinder or a cone, has also been studied albeit less extensively (see Rostami et
347   al., 2019 and references therein). The St based on the projected plate width shows a complicated
348   behavior with Reynolds number and angle of attack. Some investigators found a near constant
349   value of $St \approx 0.148$ (Fage and Johansen, 1927; $30° < \alpha < 90°$) or $St \approx 0.17$ (Yang et al., 2012; $20°$
350   $< \alpha < 30°$, $Re = 1,000$). Others observed St decreasing with α from 0.18 to 0.14 (Lam & Leung,
351   2005; $20° < \alpha < 30°$, $Re = 5,300$). In contrast, the latest study found St increasing sharply from

352   0.02 at $\alpha = 5°$ to 0.17 at $\alpha = 50°$ and then remaining constant at higher angles (Rostami et al.,
353   2019; $Re = 10^4–10^5$). What emerges robustly from all these studies, however, is that the St values
354   for an inclined flat plate correspond to the $Re < 200$ regime of a circular cylinder and stay below
355   the asymptotic value of 0.21.
356

3 Kármán Vortex Street in the lee of Guadalupe on 9 May 2018

357

    3.1 Meteorological Conditions

358

359   Satellite imagery showed a well-developed Kármán vortex street in the cloudy wake of
360   Guadalupe on 9 May 2018. Supplementary animation S1 compiled from GOES-16 band 7 (3.9
361   μm) and band 2 (0.64 μm) images revealed coherent vortex shedding during the entire day.
362   Although the nighttime shortwave (band 7) infrared brightness temperatures have coarser
363   resolution (2 km) and less contrast than daytime visible reflectances, they still clearly capture the
364   formation and downstream advection of vortex pairs. In fact, vortex shedding was observed
365   throughout 7–9 May and also on 11 May with a vortex-free weak wake pattern in between on 10
366   May indicating relatively uniform atmospheric conditions favorable to vortex formation over
367   several days. The animated images demonstrate the excellent geolocation of ABI data, but also
368   hint at the sporadic presence of very thin high-level clouds that could hamper the tracking of low-
369   level clouds and thus introduce noise in the wind retrievals.

370   The hourly ERA5 potential temperature and wind speed profiles upstream of Guadalupe
371   are plotted in Figure 3. The diurnal variation of the most relevant meteorological and flow
372   parameters is also tabulated in Table 1. The marine boundary layer had a well-mixed subcloud
373   layer capped by a strong temperature inversion with a weaker stably stratified layer above and thus
374   exhibited the typical conditions for atmospheric vortex streets. The inversion base was near 350 m
375   in the morning and near 570 m in the afternoon and evening. Wind speed varied between 7 and 12
376   m s^{-1} with the lowest values occurring in the early hours and showed only a slight increase with
377   height below the mountain peak. The dividing streamline height fluctuated somewhat but was
378   mostly above the 779 m threshold for Guadalupe. Consequently, the Froude number was close to
379   or distinctly below the critical value of 0.4, especially after 12 UTC. Given the uncertainties in
380   ERA5 profiles and considering that h_c calculated from equation (2) was likely a slight
381   underestimate, the Froude number did indicate atmospheric conditions conducive to coherent
382   vortex shedding all day long.

383   The upstream wind direction and thus, the direction of vortex shedding, increased from
384   311° at 04–05 UTC to 334° at 15–17 UTC and then decreased to 322° at 22 UTC. The relatively
385   large (23° and 12°) directional swings of these northwesterly winds are apparent in the satellite
386   image loop too. For example, vortex shedding in the near wake as well as the advection of earlier-
387   shed vortices in the far wake shifted noticeably to the east after 17 UTC, as the more westerly
388   background flow introduced an increased zonal wind component. The westerly turn of background
389   winds also resulted in two consecutive anticyclonic vortices being pushed close together and

390 thereby weakening each other (vortices V2 and V4 in later figures). Such interaction between two
391 successive like-rotating vortices in the same row would not happen under steady uniform flow.

392   The crosswind island diameter varied systematically with inversion base height and wind
393 direction (see Table 1). Inversion base height had the slightly larger effect, although the changing
394 wind direction also caused significant variations in D_{inv} due to Guadalupe's non-axisymmetric
395 shape. The combined effect of these two parameters produced a factor of two variation in D_{inv}
396 during the day (10–22 km). The crosswind island diameter was also mostly responsible for the
397 variations in Ro. The Rossby number was consistently well above 1 and varied between 5 and 15,
398 with the lower values occurring early in the morning.
399

400   **3.2 Vortex Street Geometry**

401   Vortex spacing and vortex street aspect ratio were determined from 0.25-km pixel
402 resolution MODIS *Terra*, VIIRS *Suomi NPP*, and MODIS *Aqua* images spanning a ~3-hr period
403 between 18:12 and 21:22 UTC. The images are plotted in Figure 4 with the centers of the ten
404 vortices identifiable in the earliest MODIS *Terra* image labelled V1–V10 in increasing
405 downstream order. Due to the temporal change in wind direction, wind speed, and crosswind island
406 diameter, all of which had an effect on vortex spacing, shedding frequency, and advection velocity,
407 the vortex street had a rather irregular geometry. Notably, the background flow became more
408 westerly between 17 and 22 UTC, introducing an easterly shift in vortex shedding and advection.
409 This was most apparent for the near-wake vortices V1–V6, while the far-wake vortices V7–V10
410 shed much earlier between 06 and 10 UTC under more northerly winds were less affected.

411   The distortion of vortex street geometry was largest near vortex pair V3–V4. The line
412 connecting the centers of a cyclonic–anticyclonic vortex pair (V1–V2, V5–V6, etc.) typically had
413 a WNW–ESE orientation. The orientation of the V3–V4 pair, in contrast, gradually rotated from
414 WSW–ENE in the MODIS *Terra* image to SW–NE in the MODIS *Aqua* image—at 16:12 UTC,
415 however, V3–V4 still had the usual WNW–ESE orientation. As the background winds turned, the
416 anticyclonic V4 vortex was pushed east and got caught up in the southeasterly flow of the lower
417 part of the succeeding anticyclonic V2 vortex, which dragged it northwestward relative to its
418 cyclonic companion the V3 vortex (see also supplementary animation S1). In fact, the much larger
419 and stronger V2 severely weakened and eventually absorbed V4 such that by 22:07 UTC V4 was
420 not identifiable as a separate local peak in the vorticity field.

421   In order to avoid the most severe distortions, geometric parameters were only calculated
422 for the three southernmost vortex triplets t1 = (V6, V7, V8), t2 = (V7, V8, V9), and t3 = (V8, V9,
423 V10). The vortex street centerline, obtained by fitting a third-order polynomial to the intervortex
424 midpoints of vortices V5–V10, had an upper segment with considerable curvature and eastward
425 shift caused by the faster easterly advection of the V5–V6 pair. The centerline segment
426 corresponding to vortices V7–V10, on the other hand, was consistently linear and showed a much
427 smaller eastward shift.

428   As given in Table 2, the aspect ratio H/L of vortex triplets t1 and t2 increased sharply in
429 time, because the transverse spacing H increased and the streamwise spacing L decreased. The t1
430 and t2 aspect ratios varied between 0.50 and 0.80 and were far outside the 95% confidence interval
431 of 0.36–0.47 obtained by Young and Zawislak (2006) for regular atmospheric vortex streets. The

432 aspect ratio of t3, which was the triplet least affected by changes in the background flow, however
433 showed good temporal consistency and agreed well with the results of Young and Zawislak (2006).
434

435 **3.3 Vortex Street Wind Field**

436 **3.3.1 ASCAT Surface Winds**

437 The vortex street and the corresponding ocean surface winds at the ASCAT-A overpass
438 time are shown in Figure 5. Lower resolution, reduced contrast, and presence of high-level clouds
439 made it more difficult to discern low-level cloud structures in GOES-16 band 7 nighttime images
440 compared to daytime band 2 images. Nevertheless, the characteristic "mushroom" patterns formed
441 by counterrotating vortex dipoles were still recognizable, especially in the depth map rendition of
442 the brightness temperatures. The vortex street had a curved centerline because the vortices furthest
443 downstream were shed under more northerly winds on 8 May.

444 The surface winds showed flow splitting coupled with deceleration on the windward side
445 of the island and acceleration zones on the eastern and western flanks, characterized by higher
446 shear and "cornering" winds 2-3 m s^{-1} faster than the background flow. In the lee of the island, a
447 meandering wake of reduced wind speeds and fluctuating wind directions was clearly visible down
448 to 27.5°N. The maximum speed reduction was ~3 m s^{-1} that was accompanied by a ~45° maximum
449 turn in wind direction, both of which gradually diminished downstream. In the vorticity field, eight
450 local peaks could be unambiguously associated with the four vortex pairs seen in the band 7 image.
451 Peak vorticity generally decreased with increasing distance from the island.

452 As discussed in the next section, the wake effect—speed reduction, oscillations in wind
453 direction, magnitude of vorticity—was stronger and observable considerably further downstream
454 in GOES-16 daytime cloud-motion winds. The coarser resolution of ASCAT retrievals and ocean
455 drag were definitely major reasons for a less pronounced wake and smaller vorticity values. It
456 should be noted, however, that the Froude number was larger at 04–05 UTC ($Fr = 0.42$–0.43) than
457 after 14 UTC ($Fr < 0.4$), indicating slightly less favorable conditions for vortex formation in the
458 early hours of the day. In addition, the upstream wind was the most westerly (311°) and
459 consequently the angle of attack was the highest (32°) at the ASCAT observation times, which
460 might have also contributed to a weaker and less southwardly extended wake. Results for the
461 ASCAT-B overpass (not shown) were similar but with the wake shifted further to the east.

462 We note that Kilpatrick et al. (2019) reported systematic climatological wind errors near
463 coastal mountains in certain scatterometer wind products. The AWDP-processed winds used here
464 have a 180° wind direction ambiguity, but this is generally resolved by the AWDP 2D variational
465 ambiguity removal procedure, which uses empirically-derived spatial structure functions
466 (Vogelzang and Stoffelen, 2012, 2018). In our experience, island lee vortices are captured well by
467 the KNMI ASCAT products, which yield physically consistent wind structures.
468

469 **3.3.2 GOES-16 Local Winds**

470 Hourly snapshots of GOES-16 local wind vectors between the MODIS *Terra* and MODIS
471 *Aqua* overpasses are plotted in Figure 6, while the variation of local winds over the entire 8-hr
472 period between 14:37 and 22:32 UTC is given every 5 minutes in supplementary animation S2.

473 The local winds were somewhat noisy and had coverage gaps before 16:00 UTC, probably caused
474 by the presence of thin high-level clouds. Later on, however, there were only occasional speed or
475 direction outliers in the retrievals. The wake signature extended all the way down to 26°N. Flow
476 splitting and deceleration on Guadalupe's windward side and lobes of acceleration on its flanks
477 were also apparent at cloud level. The maximum speed reduction in the wind shadow was
478 ~5 m s^{-1}. Note that the background flow south of Guadalupe was spatially nonuniform as winds
479 were stronger west of the wake than east of the wake—and they also became more westerly after
480 17 UTC (see Table 1). These spatial and temporal variations in background wind speed and
481 direction introduced a westerly crossflow through the vortex street.

482 Wind direction within the wake changed by up to 90° at the western rim of cyclonic and
483 eastern rim of anticyclonic vortices, often in association with a zone of acceleration similar to the
484 one on the flanks of the island. The locations of the largest swings in the wind coincided with local
485 minima or maxima in vorticity and the magnitude of the swings generally decreased with
486 downstream distance. Counterclockwise turns in wind direction (decreases in angle) were larger
487 than clockwise turns in wind direction (increases in angle) due to the westerly crossflow. The wind
488 oscillations lead to alternating bands of positive ("westerly") and negative ("easterly") transverse
489 (cross-street) jets, the former again being more prominent than the latter. A westerly jet runs
490 between the bottom of a cyclonic vortex and the top of the preceding anticyclonic vortex, while an
491 easterly jet runs between the bottom of an anticyclonic vortex and the top of the preceding cyclonic
492 vortex. Because of the added westerly crossflow, "easterly" jets had only a weak easterly absolute
493 wind component and typically showed a more northerly orientation. The transverse jets advected
494 downstream with the vortices. For example, the westerly jet located at ~28°N (between 117°W
495 and 118°W) in the MODIS *Terra* image advected down to ~27.6°N (and also further to east) by
496 the time of the MODIS *Aqua* overpass, following the movement of vortex pair V5–V6 shown in
497 Figure 4.

498 Snapshots of the corresponding streamwise wind component are plotted in Figure 7 with
499 its 8-hr temporal evolution given in supplementary animation S3. The streamwise component
500 showed clearly the wind shadow of Guadalupe with speed reductions up to 5 m s^{-1} in the wake. It
501 had local minima at the locations of the five westerly jets. However, the local minima
502 corresponding to what would have been easterly jets under uniform mean flow conditions were
503 missing, because the westerly crossflow gave these opposing jets a more northerly orientation and
504 thus an increased streamwise wind component.

505 The oscillating nature of the wake could perhaps be best seen in the transverse wind
506 component plotted in Figure 8 and supplementary animation S4. The transverse wind field
507 exhibited alternating bands of positive and negative values at the locations of the opposing cross-
508 street jets, with the streamwise distance between bands of the same sign regulated by the vortex
509 shedding frequency. Note that the midpoint of the diverging color palette in Figure 8 was shifted
510 from 0 to +1.5 m s^{-1} to account for the westerly crossflow and aid visualization. The regular pattern
511 of the ten alternating bands was somewhat broken by the interaction of the V2 and V4 vortices
512 caused by a change in the shedding direction, as described in section 3.1. This resulted in the
513 corresponding positive and negative bands being distorted into a more circular shape and ending
514 up at approximately the same axial location rather than following each other along the streamwise
515 axis. Also note that several of the bands showed the transverse wind being the strongest near the
516 end points of a cross-street jet and weaker in between, which is the classic pattern in laboratory

517 flows. The formation and downstream advection of the transverse wind bands was nicely captured
518 in the supplementary animation.

519   Snapshots of the vertical component of relative vorticity are plotted in Figure 9, while its
520 8-hr temporal evolution is given in supplementary animation S5. The magnitude of vorticity
521 calculated from cloud-motion winds was a factor of ~2 larger than that calculated from ASCAT
522 surface winds (cf. Figure 5d). This difference was due mostly to the higher spatial resolution of
523 GOES-16 retrievals and ocean drag affecting ASCAT retrievals, although the effect of temporal
524 changes in the atmospheric state—e.g. slightly more favorable conditions for vortex formation
525 after 14 UTC as indicated by the Froude number—could not be ruled out. The plots show the V2
526 vortex gradually absorbing the V4 vortex, the latter of which almost completely disappeared by
527 22:02 UTC both in the vorticity maps and visible satellite images. Most importantly, the vorticity
528 calculations revealed an asymmetric downstream vortex decay with cyclonic trailing-edge vortices
529 being stronger than anticyclonic leading-edge vortices at the same axial location. This asymmetry
530 between the counterrotating vortices, which could also be seen in ASCAT retrievals, is further
531 discussed and quantified in section 4.3.
532

3.3.3 GOES-16 3D Winds

534   The GOES-16 3D winds and the derived vorticity are plotted in Figure 10 for the MODIS
535 *Terra* overpass. Results for the MODIS *Aqua* overpass (not shown) were of similar quality. As
536 described in section 2.1.2, the 3D winds are representative of a somewhat larger area (8×8 km^2 vs.
537 2.5×2.5 km^2) and longer averaging time (10 min vs. 5 min) than the local winds, which explains
538 most of the differences between the two products. Because of the larger image template and
539 Guadalupe's location close to the edge of the CONUS sector, the coverage of 3D winds did not
540 extend as far west as that of local winds. The 3D wind retrievals were smoother and exhibited less
541 pronounced minima and maxima. For example, the magnitude of local minima in the streamwise
542 component and the magnitude of local maxima in the transverse component, that is the intensity
543 of the westerly jets, as well as the strength of the individual vortices were all slightly reduced
544 compared to the higher resolution local winds. Nevertheless, the comparison statistics tabulated in
545 Table 3 indicated a good overall agreement between the datasets within 5%. The 3D winds had a
546 slight fast bias due to the less marked wind shadow and showed marginally smaller differences for
547 the E-W component than the N-S component. Although the two wind products were derived from
548 the same imagery and hence were not fully independent, their consistency still enhanced our
549 confidence in both.

550   The salient feature of the joint wind retrieval is the stereoscopic height assignment, which
551 is potentially more accurate than traditional infrared brightness temperature-based height
552 assignment techniques. Examining the retrievals for cloud-free feature templates over land
553 provides a useful self-consistency validation, since the algorithm is expected to return near-zero
554 winds and heights close to the terrain elevation. This is a technique pioneered with MISR (Horváth,
555 2013; Lonitz & Horváth, 2011; Moroney et al., 2002). The *Aqua* granule provided ample ground-

556 point retrievals, which showed a median height retrieval error of 28.3 m and a standard deviation
557 of 66.9 m.

558   The stereo cloud-top heights (CTHs) showed a cloud layer between 600 and 900 m
559 encountering the island peak and revealed that vortex formation left the vertical structure of the
560 cloud layer largely undisturbed. The median stereo CTH was nearly the same at the two MODIS
561 overpass times, 742 m and 726 m respectively. Brightness temperature-based CTHs from the
562 collection 6 MOD06 and MYD06 operational MODIS products were biased slightly high: 900–
563 1000 m upstream and 900–1200 m downstream. The stereo CTHs were more consistent with a 570
564 m inversion base height (see section 3.1) and a typical marine stratocumulus thickness of 200–300
565 m (Stevens et al., 2007).
566

4 Wake Flow Dynamics

4.1 Observed Vortex Shedding Mechanisms

569   Visual analysis of the high spatial and temporal resolution animations of GOES-16 band 2
570 imagery (S1) and derived vorticity (S5) enabled us to draw a basic sketch of vortex shedding
571 behind Guadalupe. The animations revealed different vortex formation mechanisms at the trailing
572 edge and the leading edge. Flow separation at the trailing edge is unaffected by Guadalupe's
573 elongated shape and thus the counterclockwise-rotating vortices simply roll up and shed directly
574 from the trailing edge. At the leading edge, however, the island itself acts as a long after-body
575 object for flow separation. The clockwise-rotating vortices generated at the leading edge first
576 extend along the streamwise direction and develop into a large recirculation region on the eastern
577 flank of Guadalupe that remains attached to the island for some time. The growth and eventual
578 detachment of this clockwise recirculation region as a fully-fledged leading-edge vortex is
579 controlled largely by the development of the next counterclockwise-rotating trailing-edge vortex.
580 As a result, leading-edge vortices shed into the wake at an axial location near the trailing edge too.
581 This implies that at the same streamwise location, leading-edge vortices have undergone a longer
582 birth and more diffusion than trailing-edge vortices, which might explain the smaller anticyclonic
583 vorticities downstream (more on this in section 4.3). These vortex formation processes observed
584 behind Guadalupe are in excellent qualitative agreement with the asymmetric vortex shedding
585 found behind an inclined flat plate both in large-eddy simulations (LES, Breuer & Jovičić, 2001)
586 and wind tunnel experiments (Lam & Leung, 2005), further confirming the flat plate as a better
587 model for Guadalupe than the circular cylinder or cone.
588

4.2 Temporal Variation of Wind Components

590   The temporal variation of wind speed and the various wind components during the 8-hr
591 daytime period is plotted every 5 minutes in Figure 11 for one downstream location outside and
592 one inside the wake. The background flow was sampled near the western edge and central latitude
593 of our domain (27.685°N, 118.166°W), while the wake was sampled at the western end point of
594 the first transverse jet closest to the island (28.596°N, 118.047°W), where wind oscillations were
595 the largest.

596   Wind speed showed a ~2 m s^{-1} variation during this time period, generally increasing after
597 16:32 UTC. The wind speed deficit between the selected main flow and wake locations was also

598   ~2 m s^{-1}. Because the wake was sampled near the edge of rather than the middle of the wind
599   shadow, the speed reduction was smaller than the maximum value of ~5 m s^{-1} found earlier. The
600   westerly crossflow was indicated clearly by the increasing E-W component of the main flow after
601   16:32 UTC (Figure 11a), which was due both to the strengthening and the westerly turn of the
602   background winds. The corresponding N-S component also increased slightly with increasing
603   wind speed. Aligning the coordinate system hourly with the ERA5 upstream wind vector
604   accounted for the turning wind direction to first order and resulted in a transverse component with
605   much reduced fluctuations around zero (Figure 11b). Coordinate system rotation alone could not
606   completely eliminate the crossflow and thus the transverse component still exhibited a small
607   variation, switching from slight negative to slight positive values at 16:32 UTC. Apart from these
608   relatively small, smooth, and slow variations, however, the wind field did not exhibit any
609   observable oscillations outside the wake.

610   In contrast, winds within the wake experienced quasiperiodic oscillations of significant
611   magnitude. Given the driving northwesterly winds, the E-W and N-S components both showed
612   oscillations, the magnitude of which was slightly larger for the former than the latter (Figure 11c).
613   The oscillations were the clearest and had the largest amplitude in the transverse component, while
614   the streamwise component showed the smallest temporal variations with no obvious periodicity.
615   Rotating the coordinate system mostly accounted for the westerly crossflow in the first half of our
616   study period and hence the transverse component showed positive and negative fluctuations of
617   comparable magnitude (±4–5 m s^{-1}). After 20:00 UTC, however, there was a distinct shift towards
618   positive values in the transverse wind as a result of the uncorrected crossflow.

619   The 8-hr time period encompassed two full vortex shedding cycles and some. By visual
620   analysis of the GOES-16 image loops, we estimated the shedding period between two consecutive
621   like-rotating vortices varying between 2 and 4 hr during the entire day. With the diurnal variations
622   in upstream velocity and crosswind island diameter, this yielded a Strouhal number between 0.09
623   and 0.18 with the higher values occurring early in the morning. This *St* range was considerably
624   below the 0.21 asymptotic value for a circular cylinder.

625   As revealed by the oscillations in the transverse wind component (Figure 11d) and also
626   confirmed by the GOES-16 animations, the shedding period gradually increased from 2.2 hr to 3.7
627   hr between 15 and 22 UTC, corresponding to a decrease in *St* from ~0.12 to ~0.09. During the
628   same time period the crosswind island diameter increased and the upstream wind speed slightly
629   decreased, leading to an overall increase in *Re*. For a circular cylinder, *St* increases steadily with
630   *Re* in the regime below the asymptotic value. The observed decrease in *St* with *Re* is therefore
631   inconsistent with the classic similarity relationship for a circular cylinder. On the other hand, the
632   angle of attack also increased between 15 and 22 UTC, and *St* decreasing with α qualitatively
633   agrees with Lam & Leung (2005)'s findings for an inclined flat plate. However, a note of caution
634   is in order here, because there is no consensus yet on the *St*–α relationship among experimental
635   studies and its dependence on *Re* is also largely unexplored, as discussed in section 2.4.4. In our
636   case *Re* and α varied simultaneously, which prevents disentangling their independent effects.

637   It is instructional at this point to examine the time-averaged wind and vorticity fields,
638   plotted in Figure 12. The wind vectors show flow splitting with deceleration on the windward
639   northern shores, a prominent leading-edge lobe of acceleration on the eastern flank, and a
640   reattachment region just south of the island at 118°W. Downstream the reattachment region, the
641   wind vectors indicate a NW–SE orientation with approximate parallel streamlines as the velocity

642 oscillations averaged out to a large degree. The shape of the reduced-wind-speed zone, however,
643 still revealed the meandering of the wake over time. Towards the south of the island, the time-
644 averaged winds suggested a counterclockwise recirculation zone associated with the trailing edge.

645   For comparison, the time-averaged velocity field behind a circular cylinder with periodic
646 Kármán vortex shedding shows two symmetrically placed counterrotating standing vortices
647 attached to the cylinder and streamlines parallel to the main flow past the reattachment point
648 (Goharzadeh & Molki, 2015). The time-averaged flow behind an inclined flat plate is similar, but
649 the clockwise recirculation region at the leading edge is considerably larger than the anticlockwise
650 recirculation region at the trailing edge (Breuer & Jovičić, 2001; Yang et al., 2012). Interestingly,
651 this flow pattern with two steady counterrotating recirculation regions is characteristic of the
652 laminar steady regime ($5 < Re < 50$) that occurs between "creeping flow" ($Re < 5$) and laminar
653 periodic vortex shedding ($50 < Re < 190$). The lack of the clockwise recirculation zone in our time-
654 averaged wind field might have been caused by the uncorrected westerly crossflow or retrieval
655 uncertainties in the largely cloud-free area immediately east of the island.

656   The vorticity map corresponding to the time-averaged wind vectors (Figure 12b) outlined
657 the positive and negative vorticity generation regions on the western and eastern flanks of the
658 island. The tendency towards stronger cyclonic than anticyclonic vortices *downstream* Guadalupe
659 was apparent here too, as the tongue of elevated positive vorticities extended further south than
660 the corresponding negative contour line of the same magnitude. The vorticity generation areas
661 *near* the island, however, showed the opposite asymmetry in strength. The peak vorticity of the
662 anticyclonic region associated with the leading edge was -5.73×10^{-4} s^{-1}, while that of the cyclonic
663 region associated with the trailing edge was 4.67×10^{-4} s^{-1}. Higher peak vorticity production near
664 the leading edge than the trailing edge but stronger cyclonic than anticyclonic vortices further
665 downstream agrees again with the experimental results of Lam & Leung (2005) for an inclined flat
666 plate.
667

4.3 Asymmetric Vortex Decay

669   The vorticity maps in Figure 9 have already indicated visually that (i) the strength of
670 individual vortices decreased with downstream distance and (ii) the decrease was faster for
671 anticyclonic (negative) vorticity than for cyclonic (positive) vorticity. In this section, we quantify
672 the asymmetric vorticity decay and discuss its potential causes. The downstream (axial) distance
673 was measured from Guadalupe's center and was normalized by the crosswind island diameter at
674 inversion base height: $x^* = x/D_{inv}$. We used vorticity calculated from GOES-16 local winds for the
675 time period 15:32–20:32 UTC, which excluded the noisiest earlier retrievals as well as later
676 retrievals most affected by the crossflow (see Figure 11).

677   Peak vorticity as a function of x^* is plotted in Figure 13, separately for the vorticity
678 production regions on the flanks of the island (plus signs) and for individual vortices advecting
679 downstream (filled circles). A statistical summary of the results is also given in Table 4. Echoing
680 the findings for the time-averaged winds, the mean peak vorticity was higher in the anticyclonic
681 vorticity production region than in the cyclonic vorticity production region: -6.19×10^{-4} s^{-1} vs
682 5.61×10^{-4} s^{-1}. The asymmetry, however, was the opposite for vortices shed into the wake. The
683 average peak vorticity of anticyclonic vortices was not only smaller than that of cyclonic vortices,

684   -3.67×10^{-4} s^{-1} vs 4.74×10^{-4} s^{-1}, but the streamwise linear decay rate of anticyclonic vorticity was
685   also twice as high as that of cyclonic vorticity: 0.19×10^{-4} s^{-1} / D_{inv} vs -0.09×10^{-4} s^{-1} / D_{inv}.

686   At $x^* = 10\text{–}11$ there was an anomalous drop in both negative vorticity (to -2.5×10^{-4} s^{-1}) and
687   positive vorticity (to 3.5×10^{-4} s^{-1}), which corresponded to the V3–V4 vortex pair located at the
688   geometrically most distorted portion of the vortex street (see Figure 4 and section 3.2). As
689   discussed previously, the larger anticyclonic V2 vortex started to absorb and weaken the smaller
690   anticyclonic V4 vortex due to the westerly turn of the background winds. The westerly crossflow
691   also pushed the cyclonic V3 vortex close to the V4 vortex (in fact the V3–V4 pair had the smallest
692   transverse separation of all vortex pairs), resulting in the overlap of the adjacent eddy cores and
693   partial cancellation of vorticity of opposite signs. Excluding the V3–V4 pair from the analysis,
694   however, did not change our finding of a markedly asymmetric downstream vorticity decay.

695   Note that ASCAT-A/B ocean surface winds showed the same cyclonic-anticyclonic
696   asymmetry in vortex strength and downstream decay rate, although in a much smaller sample. The
697   magnitude of vorticities and the difference between them were considerably smaller than those for
698   GOES-16 cloud-motion winds, due to the coarser resolution of the scatterometer data and ocean
699   drag effects. In contrast, decay rates per D_{inv} were higher because the crosswind island diameter
700   was a factor of 2 larger at the ASCAT overpass times than during the GOES-16 observations.
701   Decay rates per 100 km, however, were fairly comparable between the instruments (see Table 4).

702   Another measure of vortex street intensity is the peak transverse wind in cross-street jets,
703   which is plotted as a function of x^* in Figure 13b. Similar to peak vorticity, positive jets were on
704   average stronger than negative jets, although this discrepancy was due partly or perhaps mostly to
705   the uncorrected westerly crossflow—an ~ 1 m s^{-1} crossflow could easily eliminate the observed
706   asymmetry. Here we note that while a spatially uniform crossflow biases the transverse wind
707   component, it does not bias the vorticity. Regardless, the intensity of transverse jets clearly
708   decreased as the wind oscillations dampened downstream, suggesting a nonlinear decay with the
709   decline being steeper in the near wake and then tapering off in the far wake.

710   In the classic Lamb-Oseen vortex model, peak vorticity decreases inversely with time,
711   which translates to a hyperbolic spatial decay along the streamwise axis for a roughly constant
712   vortex advection speed. Such a vortex model was used successfully to describe the viscous decay
713   of 2D vortices shed by a circular cylinder as observed in both laboratory experiments and direct
714   numerical simulations (Ponta, 2010). In our retrievals, the peak transverse wind could be fitted
715   reasonably well with a hyperbola, but the peak vorticity followed a linear decay. The different
716   decay functions might have been the result of using *raw* transverse winds but *smoothed* vorticities
717   in the analysis. Deviations from the 2D Lamb-Oseen vortex model in a significantly 3D wake or
718   variations with Re could also lead to more linear decay laws (Hamid et al., 2015).

719   To recap, the general decay of vortices can be explained by the viscous diffusion of
720   vorticity. In a manner analogous to the diffusion of heat, vorticity spreads into the flow as vortices
721   advect in the wake. The size of eddies also increases downstream due to diffusion, a tendency that
722   can be seen in Figure 4 too, leading to the gradual overlapping of viscous cores and cancellation
723   of vorticity of opposite signs. To account for the asymmetry in the cyclonic and anticyclonic decay
724   rates, however, requires considering the effects of Earth's rotation or obstacle shape on the flow.

725   For a circular cylinder, asymmetric vortex decay could only be achieved in both laboratory
726   experiments and numerical simulations by the inclusion of moderate background rotation. In a
727   rotating environment the Rossby number is an additional control parameter. When $Ro \ll 1$

728 (geostrophic regime), the strong background rotation tends to two-dimensionalize the flow and
729 thus stabilize columnar vortices against perturbations. Taylor–Proudman theory suggests that in
730 this regime cyclones and anticyclones behave very similarly (Carnevale et al., 1997). In the
731 opposite limit, when $Ro \gg 1$, the flow does not feel the rotation and again there is no fundamental
732 difference between cyclones and anticyclones. It is in the intermediate regime with $Ro \geq 1$ where
733 selective 3D destabilization of anticyclonic vortices can occur through various modes of
734 instability.

735   Boyer & Davies (1982) and Boyer & Kmetz (1983) conducted laboratory investigations of
736 homogeneous flow past a circular cylinder in a rotating water channel. Although they noted clear
737 differences in the flow structure between *f*-plane (constant Coriolis parameter) and *β*-plane
738 (latitudinally varying Coriolis parameter) as well as between westward and eastward flows, the
739 formation of an asymmetric wake with cyclonic eddies dominating anticyclonic ones was common
740 in all experiments. Carnevale et al. (1997) studied the stability of three-dimensionally perturbed
741 individual vortex tubes in a rotating flow using numerical simulations. They found that for a large
742 but finite Rossby number ($Ro = 5$), even small perturbations lead to the complete breakdown of
743 the anticyclonic vortex through centrifugal instability, while the cyclones remain stable.

744   Another set of laboratory studies by Afanasyev & Peltier (1998) and Afanasyev (2002)
745 investigated the evolution of an anticyclonic columnar vortex subjected to either centrifugal or
746 elliptical instability. When the vortex is quasi-circular centrifugal instability dominates, which
747 introduces primary perturbations around the edge of the vortex in the form of toroidal rib vortices
748 with mushroom-like cross section. When the vortex is exposed to a strain field and has a more
749 elliptical shape, elliptical instability is dominant. In this case the core of the anticyclone bends in
750 a sinusoidal manner in the plane corresponding to the direction of maximal strain. The competition
751 between centrifugal (edge mode) and elliptical (core mode) instabilities is governed by the
752 magnitude of ellipticity and the Rossby number. Maximum destabilization was found at $Ro = 4$ or
753 10 for the centrifugal mode and at $Ro = 3$–6 for the elliptical mode.

754   The experimental work perhaps most pertinent to our case is that of Stegner et al. (2005),
755 which investigated the stability of entire Kármán vortex streets, rather than that of single vortex
756 tubes, in a rotating deep-water layer. They concluded that the breaking of symmetry is primarily
757 caused by core-centered sinusoidal perturbations due to elliptical instability. Cyclonic–
758 anticyclonic asymmetry was observed for $Ro \geq 1.2$ where the vertical wavelength of the
759 perturbations increased with Ro. They also found that vorticity decay in coherent vortices comes
760 not only from classic viscous dissipation but also from the direct energy cascade toward small
761 scales induced by the 3D instability. For small Reynolds numbers ($Re \sim 150$), no asymmetry
762 between peak cyclonic and anticyclonic vorticity was detected as standard viscous dissipation
763 dominated. For larger Reynolds numbers ($Re \sim 400$–500), however, viscous dissipation was
764 weaker and selective destabilization of anticyclones was more efficient, resulting in an asymmetric
765 decay. Asymmetric Kármán vortex streets were also observed in a shallow-water configuration
766 more similar to atmospheric flows, where the vertical to horizontal aspect ratio is $\ll 1$.

767   The range of Rossby numbers investigated by the above studies combined is 1–16, which
768 covers our case where Ro varied between 5 and 15. Some of these studies even used satellite photos
769 of Guadalupe vortex streets to build a qualitative bridge between laboratory or numerical model
770 results on rotational effects and geophysical flows. The cyclonic-anticyclonic asymmetry is
771 frequently detectable in the visual appearance of vortices in Guadalupe's wake. Anticyclonic

772 eddies tend to have smaller clear eyes and less well-preserved spiral cloud patterns than cyclonic
773 eddies at the same downstream location, which is apparent in Figure 4 too (e.g. compare the
774 vortices in pairs V1–V2 and V7–V8). The primacy of elliptical instability in causing the wake
775 asymmetry would also imply more elliptically elongated shapes for anticyclones and more circular
776 shapes for cyclones. Because shape perception by a human observer is highly subjective, we defer
777 judgment on this issue until an objective analysis of vortex shapes is conducted in a larger sample.

778   A factor that has been overlooked consistently in explaining the asymmetric island wake
779 is Guadalupe's non-axisymmetric shape resembling an inclined flat plate. Both laboratory
780 experiments (Lam & Leung, 2005) and numerical simulations (Breuer & Jovičić, 2001; Lam &
781 Wei, 2010; Yang et al., 2012) confirmed that an inclined flat plate at angles of attack encountered
782 in our case (9°–32°) produces inherently asymmetric vortex shedding even without background
783 rotation, although the exact cause of asymmetry is not fully understood yet. Lam and Leung (2005)
784 pointed out that leading edge (anticyclonic) vortices undergo a longer birth before detachment and
785 hence are more diffused with a smaller peak vorticity than trailing edge (cyclonic) vortices at the
786 same axial location. The numerical simulations additionally revealed the significant three-
787 dimensionality of the flow—in fact the laboratory-observed vortex dynamics could not be
788 reproduced in 2D simulations. Braids of streamwise vorticity can form around the primary
789 spanwise Kármán rollers and at certain angles of attack even oblique shedding and vortex
790 dislocations can occur. Such wake instabilities are likely to play a part in the selective
791 destabilization of anticyclonic eddies.

792   Background rotation and shape effects are present simultaneously in the case of Guadalupe
793 vortex streets and their relative contributions cannot be determined from satellite measurements
794 alone. The excellent qualitative agreement between the vortex formation topologies observed in
795 the laboratory and in satellite imagery, however, strongly suggests that Guadalupe's inclined flat
796 plate shape is an important factor in the development of the asymmetric wake.
797

798 5 Summary and Outlook

799   We investigated the evolution and dynamics of an atmospheric Kármán vortex street
800 observed by GOES-16 in the lee of Guadalupe Island on 9 May 2018. Exploiting the state-of-the-
801 art imaging capabilities of the ABI instrument and the nested tracking algorithm designed
802 specifically for the GOES-R series, we derived cloud-motion winds in the island's wake on a 2.5-
803 km scale every 5 minutes over an 8-hr daytime period. A novel MODIS–GOES joint wind product
804 provided accurate stereo cloud-top heights and semi-independent wind validation data. ASCAT
805 retrievals processed on a fine 6.25-km grid contributed two additional early morning snapshots of
806 ocean surface winds. These high spatial and temporal resolution research-quality winds enabled
807 the quantitative analysis of atmospheric vortex shedding and vortex decay, for the first time from
808 spaceborne observations.

809   The vortex street developed under atmospheric stratification conducive to coherent vortex
810 shedding. The marine boundary layer had a well-mixed subcloud layer capped by a strong
811 temperature inversion with a weaker stably stratified layer above. The Froude number related to
812 the dividing streamline was typically below the critical value of 0.4, corroborating previous
813 findings. Confirming the quality of the satellite retrievals, the derived wind field around Guadalupe
814 exhibited characteristics expected from laboratory flows past bluff bodies: flow splitting with
815 deceleration on the windward side, lobes of acceleration on the flanks, and an oscillating wake

816   with transverse jets at quasi-regular intervals set by a vortex shedding period of 2–4 hr. A westerly
817   turn in the background winds during the day introduced slight deviations in the observed flow
818   patterns compared to idealized laboratory results obtained under uniform freestream conditions.
819   The westerly crossflow also distorted the vortex street geometry, leading to a curved centerline
820   and uncharacteristically large aspect ratios at most locations. The aspect ratio in the least-affected
821   far wake, however, showed good temporal consistency, varying between 0.42 and 0.46 and falling
822   within the 95% confidence interval of 0.36–0.47 found for regular atmospheric vortex streets by
823   Young and Zawislak (2006).

824   Most importantly, both GOES-16 and ASCAT winds revealed an asymmetric island wake
825   with cyclonic eddies having larger peak vorticities than anticyclonic ones at the same downstream
826   location. Vorticity generally decreased with time, that is with downstream distance, due to viscous
827   diffusion but the rate of decrease was a factor of two higher for anticyclones. For a circular cylinder
828   such asymmetric vortex shedding can only occur under the influence of moderate background
829   rotation. When the Rossby number is larger than unity, as was the case for the studied vortex street,
830   anticyclonic vortices can be selectively destabilized by either centrifugal or elliptical instability,
831   depending on the initial shape of the vortices and the rate of rotation. However, non-axisymmetric
832   obstacles can also produce inherently asymmetric wakes even without the presence of background
833   rotation. An inclined flat plate at low angle of attack, which is a good first-order model for
834   Guadalupe under the prevailing northwesterly winds, sheds weaker leading edge (anticyclonic)
835   eddies than trailing edge (cyclonic) eddies, as found by both laboratory experiments and numerical
836   simulations.

837   Rotational and shape effects act simultaneously on the flow past Guadalupe and their
838   relative contributions can only be determined by future modeling studies, where these two factors
839   can be controlled independently. Nevertheless, the different leading edge and trailing edge vortex
840   formation topologies observed in GOES-16 imagery show excellent qualitative agreement with
841   laboratory results, suggesting that Guadalupe's non-axisymmetric shape does have a substantial
842   influence on the wake. The asymmetric vorticity decay in itself implies a three-dimensional wake
843   structure, because the instabilities that selectively destroy anticyclones produce 3D perturbations
844   either around the edge (centrifugal instability) or in the core (elliptical instability) of the clockwise-
845   rotating vertical vortex tubes.

846   Cloud-motion winds derived from ABI imagery hold great potential for the further study
847   of unsteady geophysical flows. As demonstrated in this work, the retrievals provided by GOES-
848   16 located at 75°W already show good performance, but GOES-17 now positioned at 135°W offers
849   significantly better views of Guadalupe and thus less noisy wind estimates. Reduced measurement
850   noise will improve the calculation of local differential flow properties such as vorticity, since they
851   require a numerical estimation of derivatives. The high temporal resolution of ABI observations
852   also enables the application of analysis techniques that are well-known in dynamical systems
853   theory, but which have largely been overlooked in applied meteorology.

854   A first possible approach is to locate material lines, that is sets of particles with exceptional
855   properties, along which the normal separation is maximized over time. These extremal lines are
856   known as hyperbolic Lagrangian coherent structures (LCS; Haller, 2015), which can be
857   approximated through the finite-time Lyapunov exponent (FTLE; Shadden et al., 2005). The FTLE
858   estimates the maximal expansion rate of a virtual sphere in a dynamical system, which is extremal
859   along material boundaries. Depending on whether the expansion is measured in forward-time or
860   backward-time, this gives rise to repellors or attractors in the flow. Such material boundaries are

861 of great significance in Lagrangian transport analysis, since they divide the domain into
862 compartments of coherent flow behavior that order the flow. For instance, they separate vortices
863 from each other.

864 An alternative avenue is to process local flow properties from a Lagrangian perspective.
865 Instantaneous properties can be averaged along particle trajectories if they can be assumed to be
866 passively advected with the fluid. This so-called Lagrangian smoothing enforces temporal
867 coherence (Shi et al., 2009). In addition, when averaging the deviation of vorticity from its local
868 neighborhood along trajectories, the resulting Lagrangian-averaged vorticity deviation has a
869 desirable property: similar to the aforementioned LCS, it is invariant to rotations and translations
870 of the frame of reference (Haller et al., 2016). Due to the relativity between observer and the
871 observed feature, this formally guarantees that translating and rotating flow structures can be
872 faithfully extracted (Günther & Theisel, 2018). Analyzing a vector field from the perspective of a
873 local observer that moves with the vortices will enable the application of sophisticated steady-state
874 vortex separation and extraction techniques (Rojo & Günther, 2019). Initial experience with these
875 advanced analysis methods applied to the current Guadalupe vortex street is encouraging and will
876 be presented in a future paper.

1134
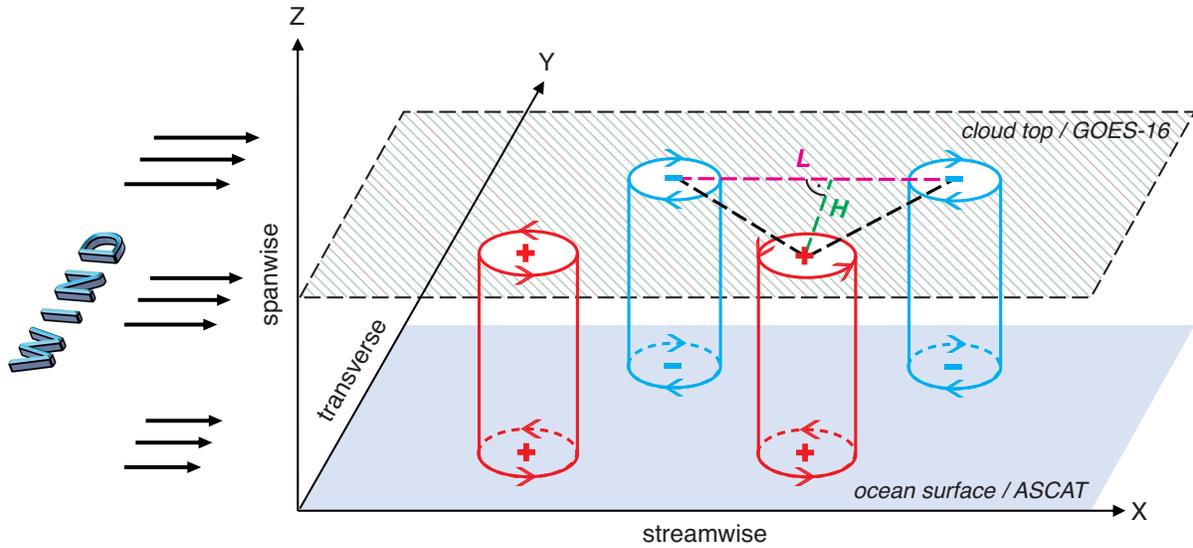

Figure 1. Schematic geometry of an atmospheric vortex street and definition of coordinate axes – the generating mountain is not depicted. The Kármán vortices span the marine boundary layer between the cloud top level and the ocean surface. The vortex street aspect ratio is defined as the transverse distance between the two rows of counterrotating vortices H, divided by the streamwise spacing of like-rotating vortices L. The aspect ratio can be calculated for each triplet of consecutive vortices. The flow at cloud top and the surface is respectively characterized by GOES-16 cloud-motion vectors and ASCAT ocean surface wind vectors. Below a critical Reynolds number of ~190, laboratory flows past a circular cylinder exhibit purely periodic and 2D vortex shedding, as sketched here. Above the critical Reynolds number, however, laboratory vortex shedding transitions into a 3D regime as increasingly intricate streamwise and transverse vorticity structures develop in addition to the primary vertical (spanwise) Kármán vortices.
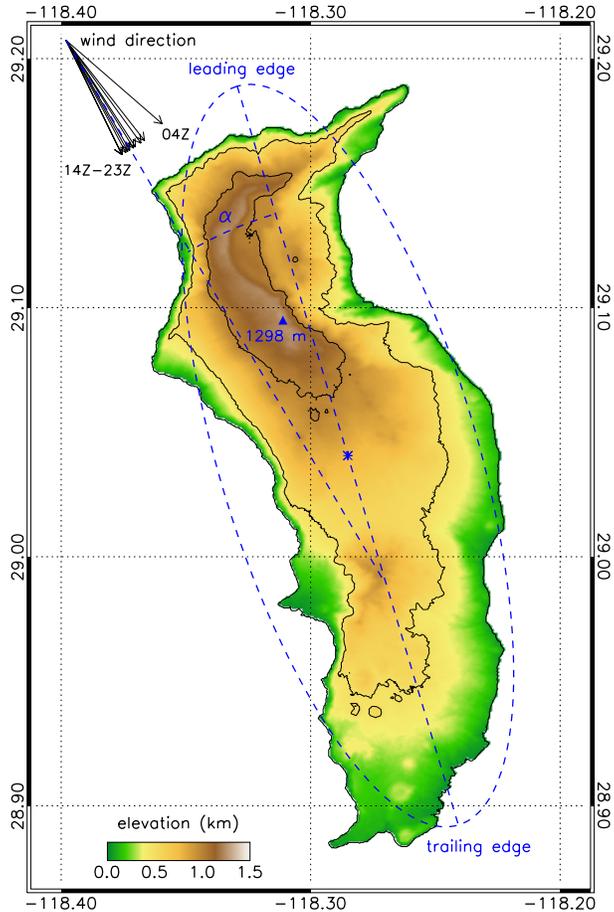

Figure 2. Topography of Guadalupe Island from the ASTER Global Digital Elevation Model (GDEM) Version 2. The black contour lines are drawn at sea level, 0.5 km and 1.0 km and the highest point, Mount Augusta, is marked by the blue triangle. The GDEM was used in conjunction with hourly ERA5 temperature and wind profiles to determine the crosswind island diameter at inversion base height. Black arrows show the ERA5 upstream wind direction at the ASCAT-A/B (04Z-05Z) and GOES-16 (14Z-23Z) retrieval times. The blue dashed outline is the "mass density" ellipse fitted to the island with its major axis oriented at 343.4° and center indicated by the blue asterisk. The angle between the upstream wind vector and the major axis of the ellipse is the angle of attack α. The prevailing northwesterly winds set the northern and southern shores of Guadalupe as the leading and trailing edge.
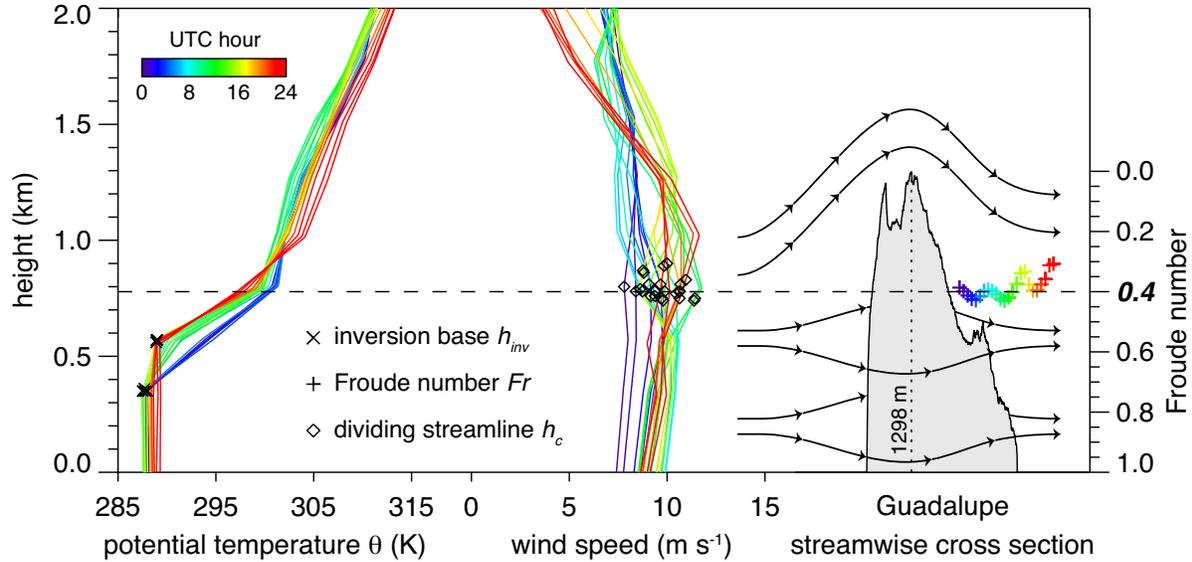

Figure 3. ERA5 vertical profiles of potential temperature θ and wind speed upstream of Guadalupe on 9 May 2018, with UTC hour from 0Z to 23Z being color coded. The height of the inversion base h_{inv} and that of the dividing streamline h_c are respectively marked by crosses and diamonds. Fluid parcels above h_c can flow over the mountain peak, while parcels below h_c tend to pass laterally around the island (flow splitting). The Froude number related to the dividing streamline Fr is plotted with plus signs. For atmospheric vortex street formation Fr is typically below the critical value of 0.4, the corresponding critical dividing streamline height of which is indicated by the dashed line. The cross section of Guadalupe is vertically exaggerated.
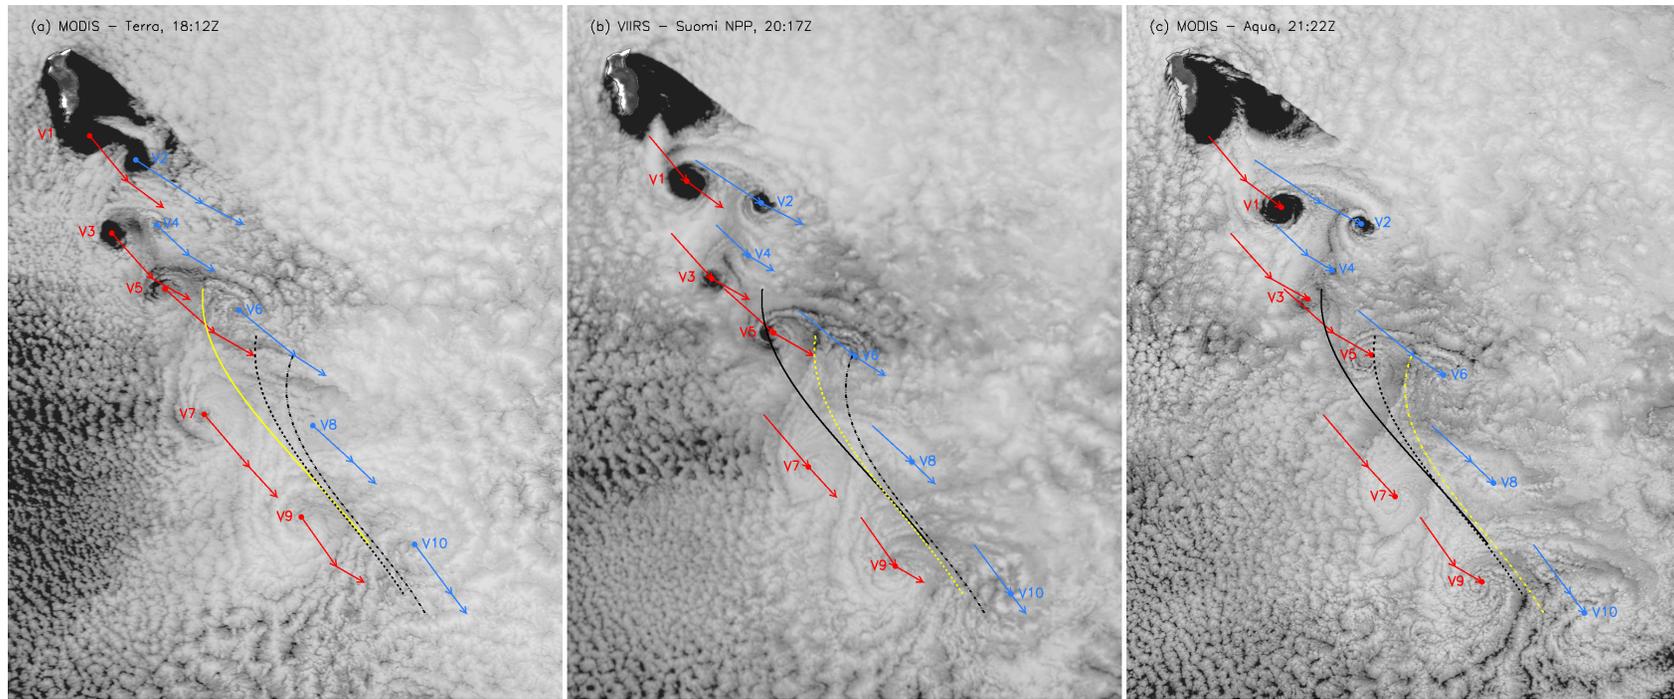

Figure 4. The Kármán vortex street in Guadalupe's wake on 9 May 2018 observed by (a) MODIS *Terra* at 18:12Z, (b) VIIRS *Suomi NPP* at 20:17Z, and (c) MODIS *Aqua* at 21:22Z. Red and blue dots mark the cyclonic and anticyclonic vortex centers in a given image, while the arrows indicate the movement of the vortex centers over the three images. The solid, dashed, and dash-dot-dot lines show the 3rd order polynomial centerline fitted to the locations of vortices V5–V10 respectively at the MODIS *Terra*, VIIRS *Suomi NPP*, and MODIS *Aqua* observation times. The centerline corresponding to a particular image is plotted in yellow.
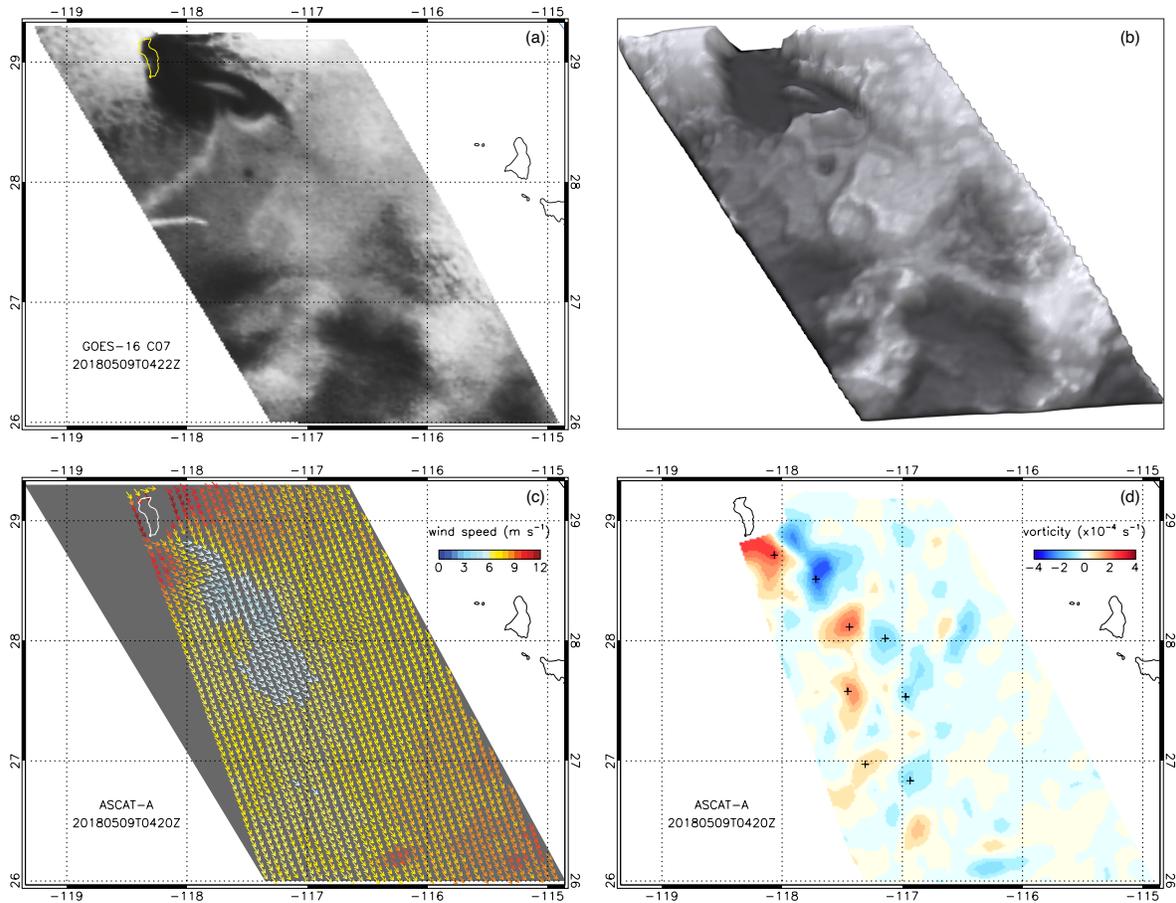

Figure 5. (a) Histogram-equalized grayscale image of GOES-16 channel 7 (3.9 μm) brightness temperatures of the 9 May 2018 Guadalupe vortex street at the ASCAT-A overpass time of 04:20Z, with darker shades representing hotter surfaces. (b) 3D depth map rendition of panel (a) that better accentuates the vortex pair "mushroom" patterns hinted at in the 2D image. The cold and bright high-level cloud streaks near 28°N, 118°W were digitally removed to emphasize the low-level cloud structures. (c) ASCAT-A 6.3 km ocean surface wind vectors colored according to wind speed and (d) the corresponding vorticity field, which was smoothed with a 3×3-gridbox averaging window. The black plus signs in panel (d) mark the locations of vorticity minima and maxima.
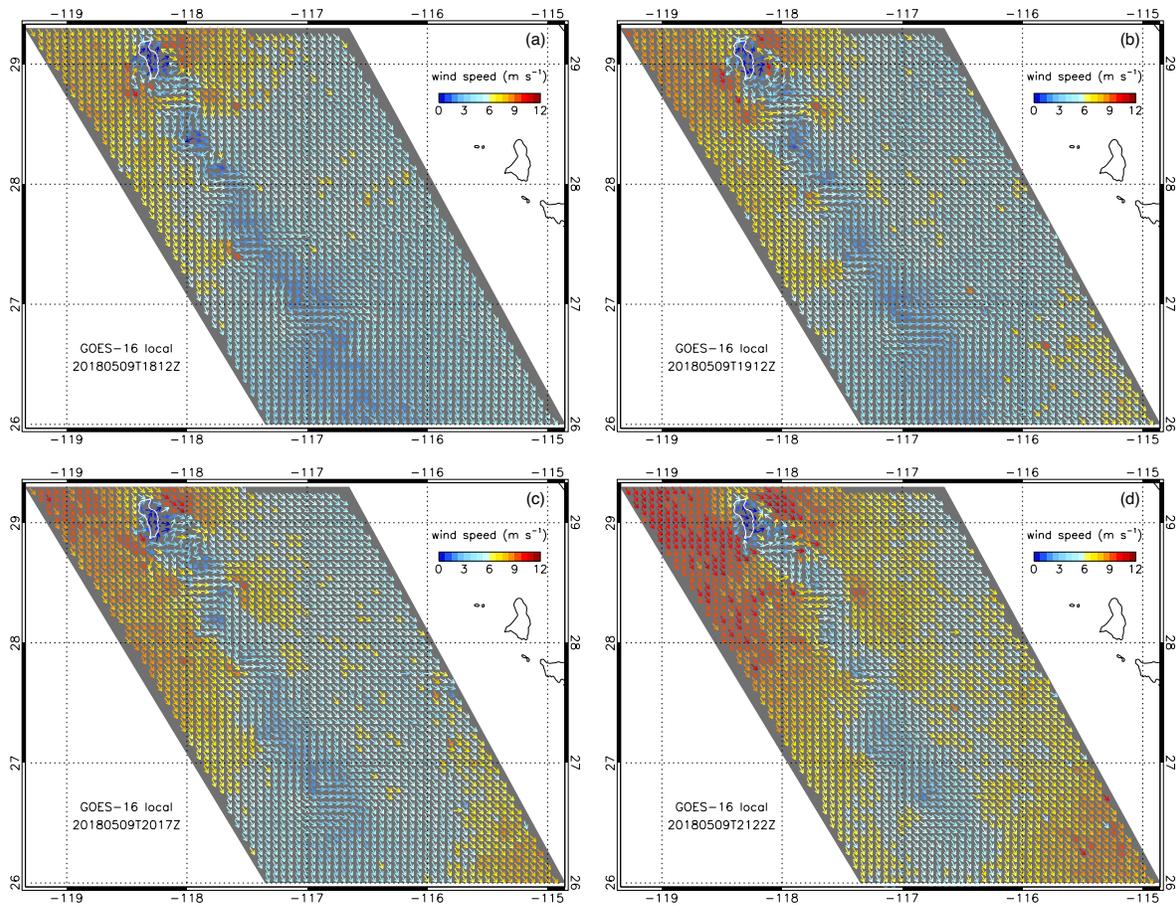

Figure 6. Median-filtered GOES-16 local wind vectors resampled without smoothing on a 6.3-km UTM grid and colored according to wind speed on 9 May 2018 at (a) 18:12Z, (b) 19:12Z, (c) 20:17Z, and (d) 21:22Z. The covered time period is ~3 hr and panels (a), (c), and (d) correspond to the MODIS *Terra*, VIIRS *Suomi NPP*, and MODIS *Aqua* overpass times respectively. The X and Y coordinate axes are aligned with the N-S and E-W directions.
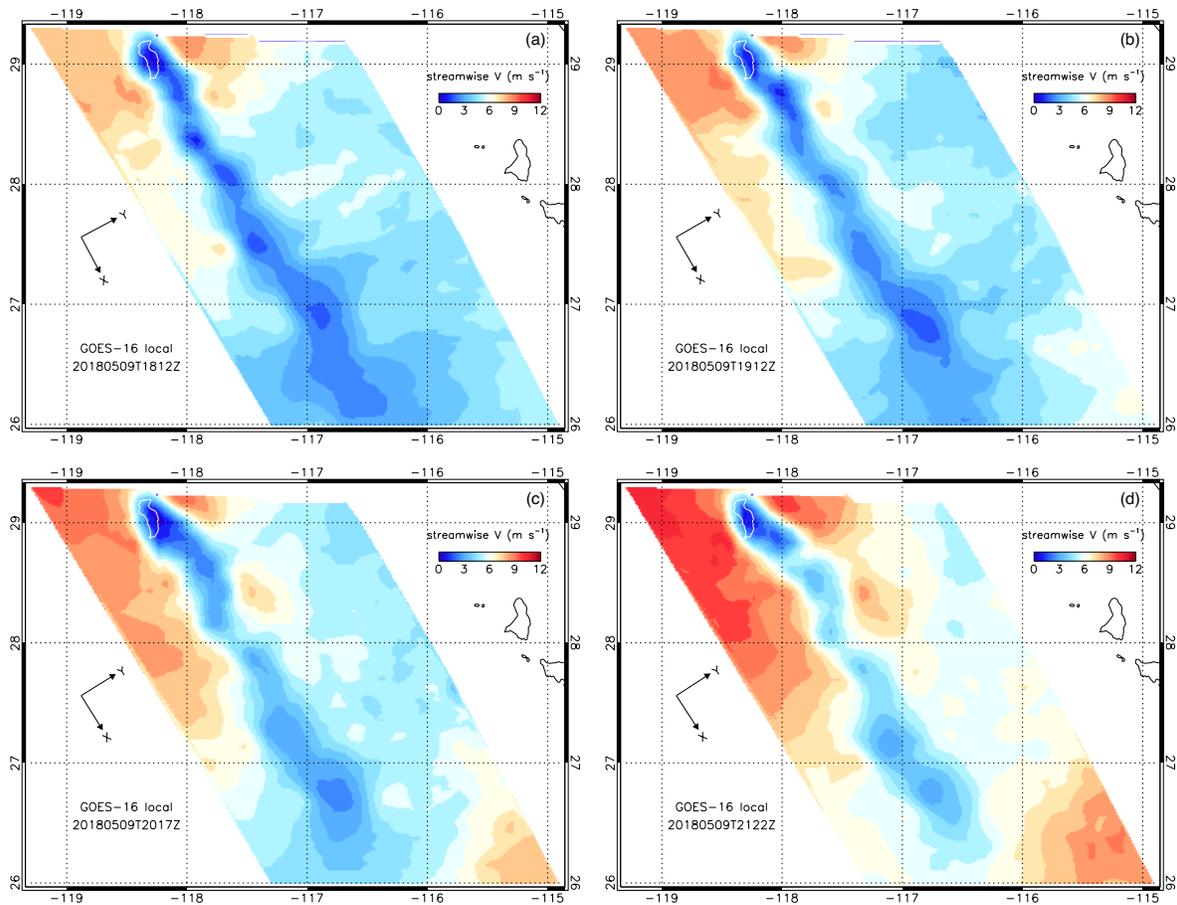

Figure 7. Same as Figure 6, but for the streamwise wind component V smoothed with a 3×3-gridbox averaging window. The X and Y coordinate axes were rotated from the N-S, E-W directions to the streamwise, transverse directions using the ERA5 upstream wind direction.
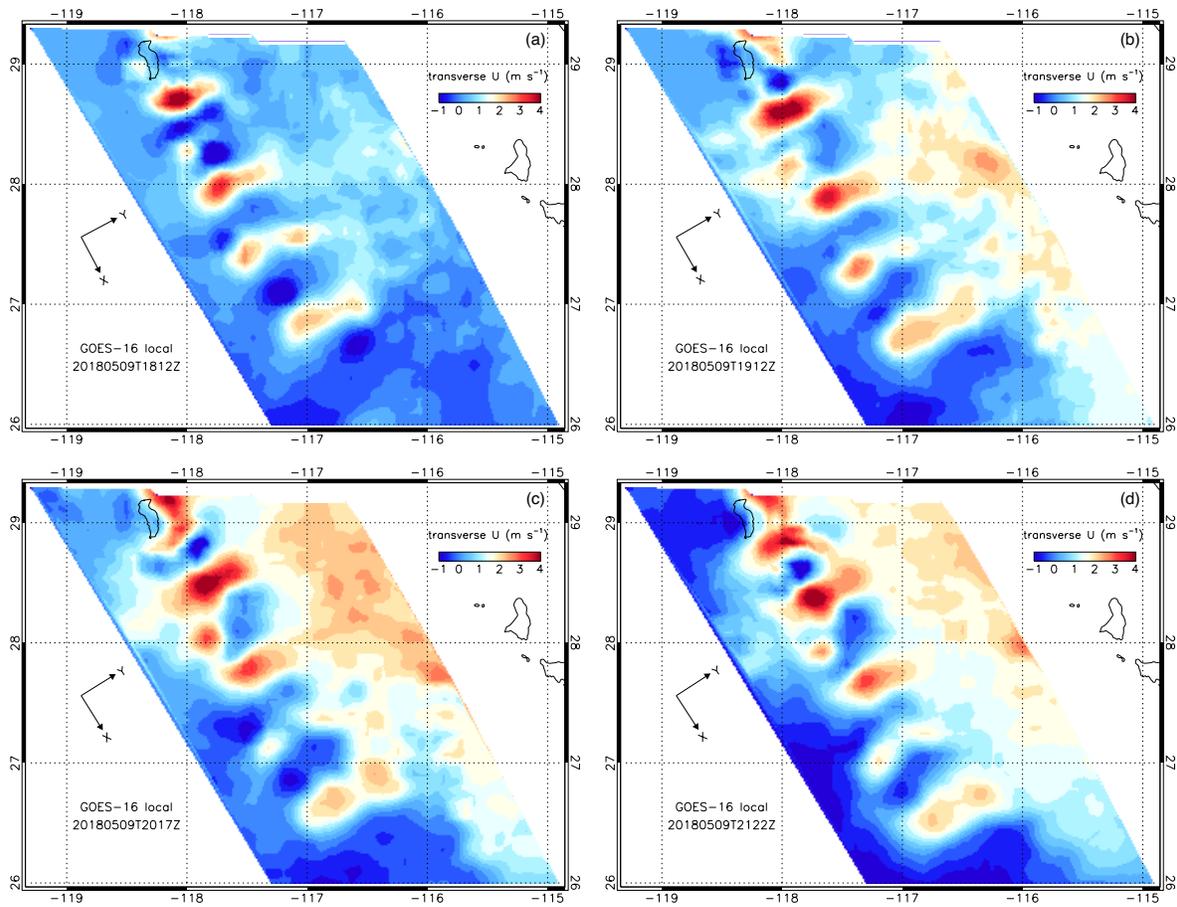

Figure 8. Same as Figure 6, but for the transverse wind component U smoothed with a 3×3-gridbox averaging window. The X and Y coordinate axes were rotated from the N-S, E-W directions to the streamwise, transverse directions using the ERA5 upstream wind direction.
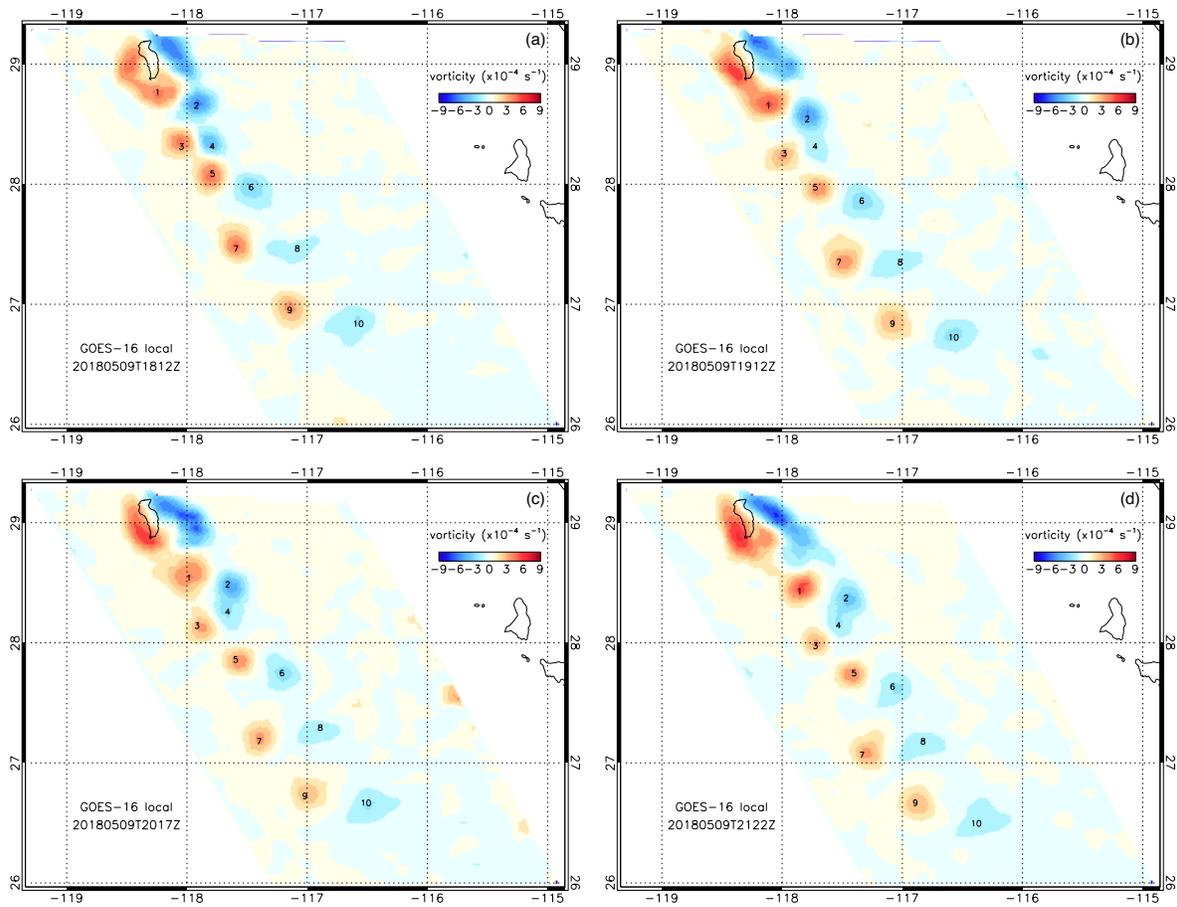

Figure 9. Same as Figure 6, but for the relative vorticity ζ smoothed with a 3×3-gridbox averaging window. The numbers mark the locations of vorticity minima or maxima of the ten vortices identified in Figure 4.
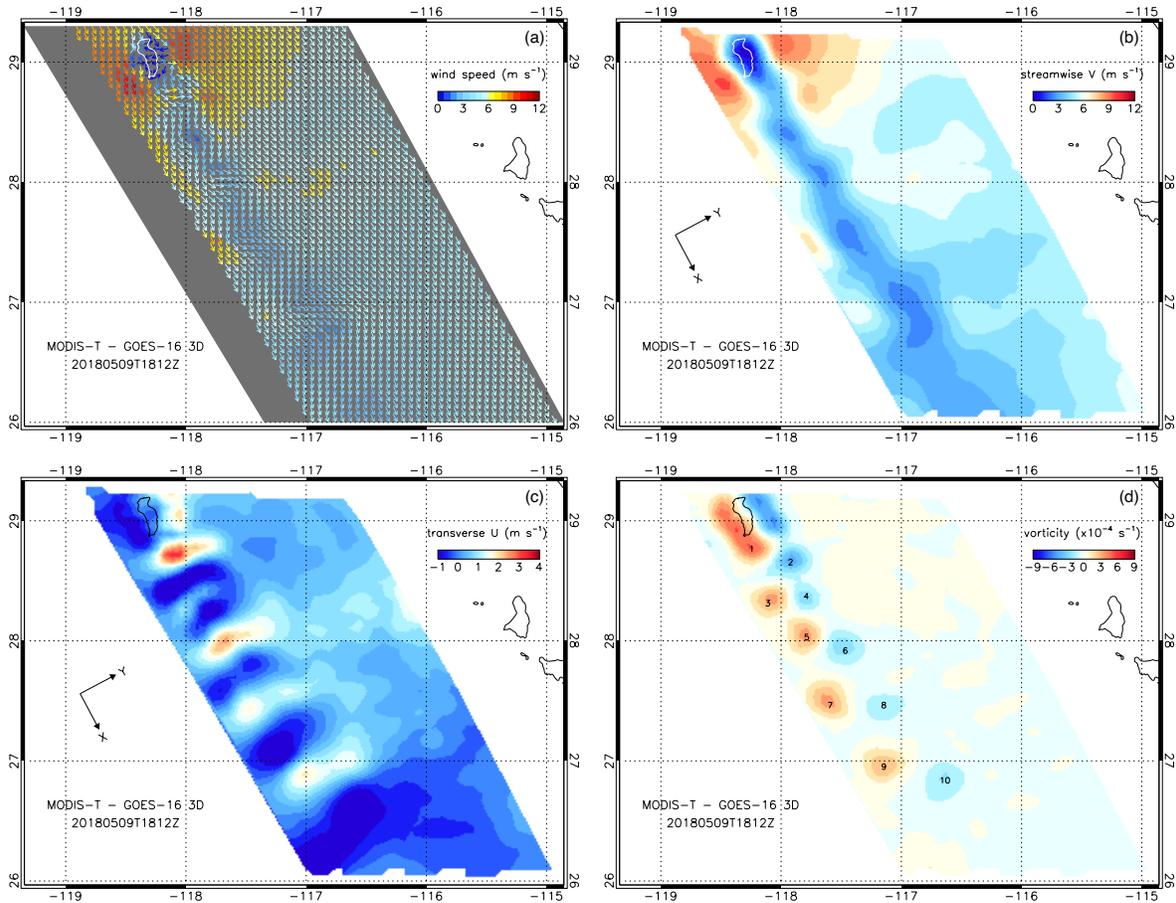

Figure 10. Median-filtered MODIS *Terra*–GOES-16 3D winds resampled on a 6.3-km UTM grid on 9 May 2018 at 1812Z: (a) wind vectors colored according to wind speed, (b) the streamwise wind component V, (c) the transverse wind component U, and (d) the relative vorticity. No smoothing was applied to the wind vectors in panel (a), but the data in panels (b,c, and d) were smoothed with a 3×3-gridbox averaging window. The numbers in panel (d) mark the locations of vorticity minima or maxima of the ten vortices identified in Figure 4. See Figures 6a, 7a, 8a, and 9a for comparison with the corresponding GOES-16 local winds.
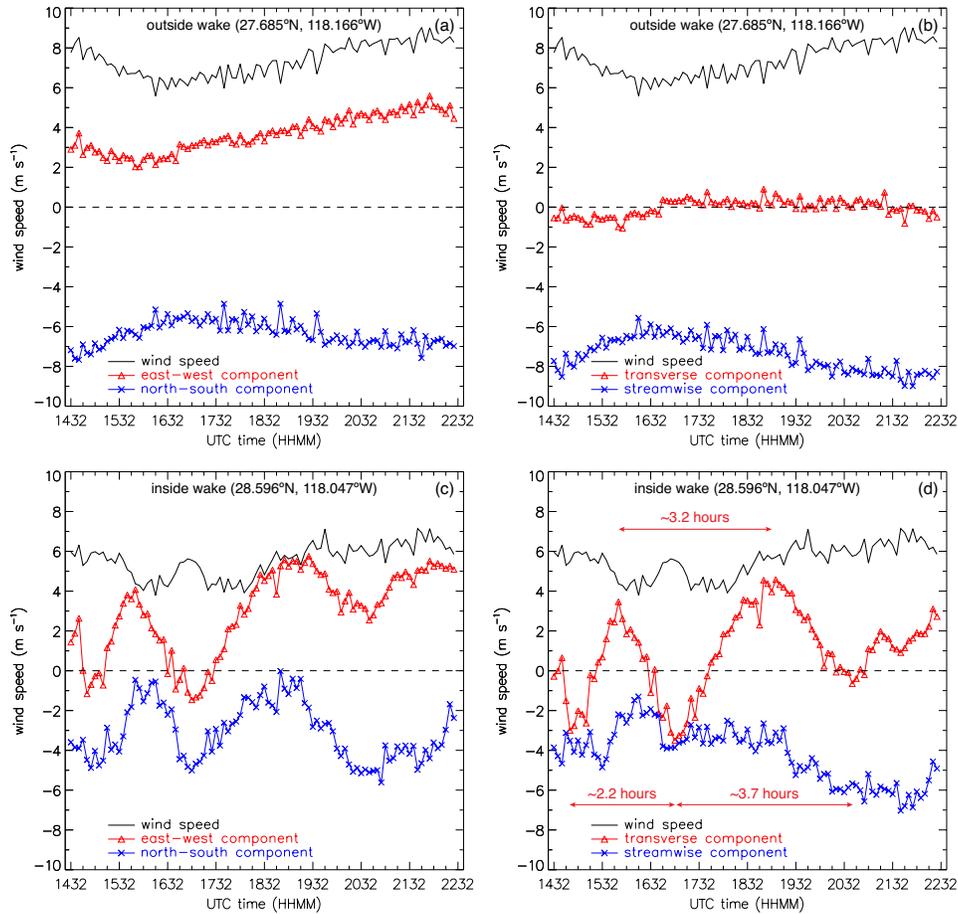

Figure 11. Temporal variation of GOES-16 local wind over an 8-hr period at 5-minute resolution and averaged for a 3×3-gridbox region (a and b) outside and (c and d) inside Guadalupe's wake. Panels (a and c) plot the N-S, E-W components, while panels (b and d) plot the streamwise, transverse components. In panel (d), the time intervals between the minima and maxima of the oscillating transverse wind are also indicated, which correspond to the shedding period T between two consecutive like-rotating vortices.
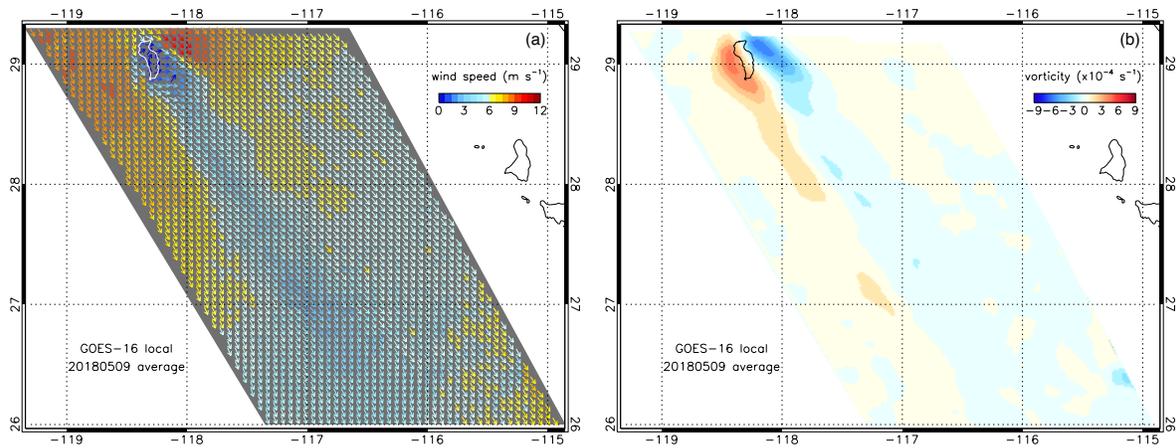

Figure 12. Time average of GOES-16 local winds over the 8-hr period between 14:37 and 22:32 UTC: (a) wind vectors and (b) relative vorticity. No smoothing was applied to the wind vectors, but the vorticity was smoothed with a 3×3-gridbox averaging window.
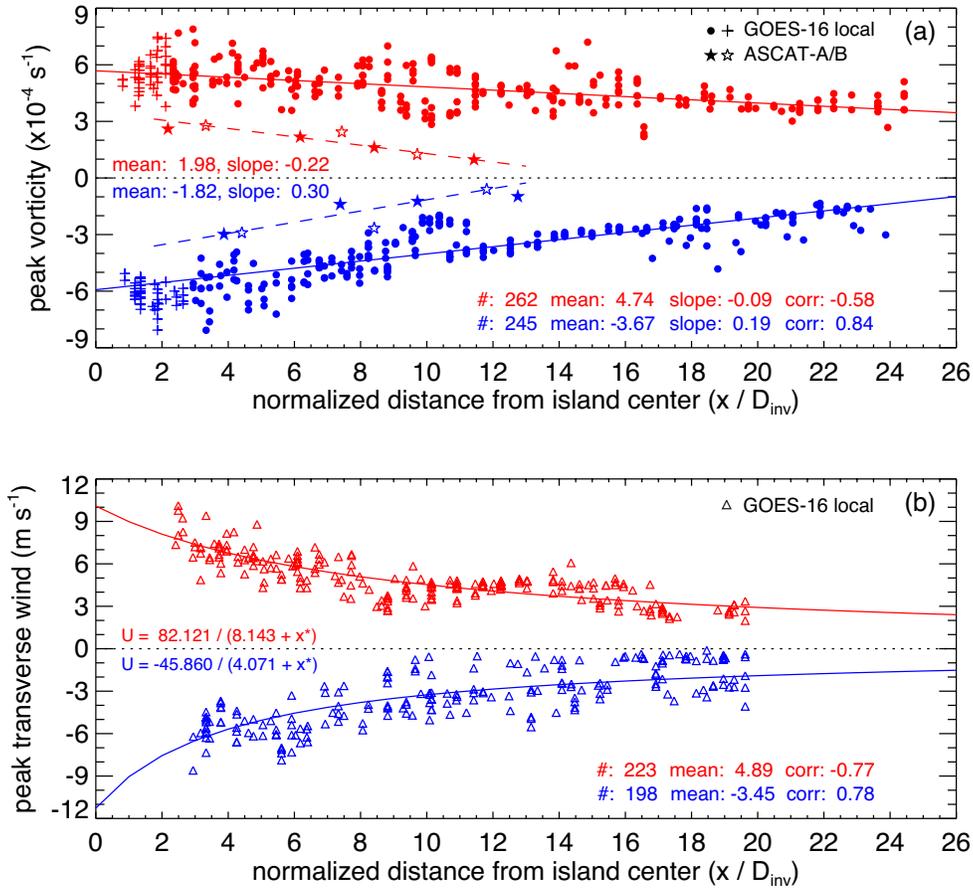

Figure 13. Decrease of (a) peak vorticity and (b) peak transverse wind in Guadalupe's wake as a function of normalized downstream distance $x^* = x/D_{inv}$ for cyclonic (red) and anticyclonic (blue) vortices. The GOES-16 local winds span the 5-hr period between 15:32 and 20:32 UTC, while the ASCAT-A/B surface winds correspond to the overpass times of 04:20 UTC and 05:20 UTC. The noisier vorticity data were smoothed with a 3×3-gridbox averaging window as before, but the transverse winds here are the raw unsmoothed values. In panel (a), the plus signs represent vorticity minima and maxima on the eastern and western flank of Guadalupe, while the filled circles represent the peak vorticity of individual downstream-advecting vortices tracked over time. The solid and dashed lines are linear fits to the downstream vorticity data. In panel (b), the solid curves are hyperbolic fits of the form $A / (B + x^*)$ to GOES-16 peak transverse winds. Note the statistical asymmetry between cyclonic and anticyclonic vortices, with the latter decaying faster than the former.

Table 1. Hourly meteorological conditions in the boundary layer upstream of Guadalupe on 9 May 2018. Inversion base height h_{inv} and the corresponding wind speed and wind direction are from ERA5. The angle of attack α is relative to the major axis of Guadalupe's "mass density" ellipse oriented at 343°. The height of the dividing streamline h_c is calculated from equation (2), while the crosswind island diameter at inversion base height D_{inv} is determined from the ASTER GDEM. The Froude number *Fr* and the Rossby number *Ro* are computed from equations (4) and (5).

UTC hour	Wind speed (m s⁻¹)	Wind direction / α (degree)	h_{inv} (m)	h_c (m)	D_{inv} (km)	Fr	Ro
00	7.76	318° / 25°	354	796	19.85	0.387	5.51
01	8.17	316° / 27°	351	780	20.64	0.399	5.58

[a] ASCAT-A wind retrievals
[b] ASCAT-B wind retrievals
[c] GOES-16 wind retrievals

Table 2. Vortex street geometry as defined in Figure 1 and calculated from the 0.25-km pixel resolution MODIS *Terra*, VIIRS *Suomi NPP*, and MODIS *Aqua* images shown in Figure 4. Results are given for the three southernmost vortex triplets t1 = (V6, V7, V8), t2 = (V7, V8, V9), and t3 = (V8, V9, V10). Bold italic numbers highlight geometric parameters for vortex triplet t3, which was least affected by the change in wind direction and wind speed and thus yielded the temporally most consistent aspect ratios. For comparison, Young and Zawislak (2006) obtained a mean aspect ratio of 0.42 with a 95% confidence interval of 0.36–0.47 for regular atmospheric vortex streets.

	H (km)			L (km)			H/L		
	t1	t2	t3	t1	t2	t3	t1	t2	t3
MODIS T	46.18	38.46	***36.84***	74.00	76.22	***84.39***	0.62	0.50	***0.44***
VIIRS	50.51	43.89	***40.97***	64.89	71.21	***89.10***	0.78	0.62	***0.46***
MODIS A	51.36	42.43	***35.75***	64.20	65.77	***85.59***	0.80	0.65	***0.42***

Table 3. Statistical comparison between MODIS–GOES-16 3D winds and GOES-16 local winds over the Guadalupe domain at the *Terra* and *Aqua* overpass times on 9 May 2018. The two separate wind products were median-filtered and resampled without smoothing on a common 6.3-km UTM grid, resulting in 3866 data pairs.

	Absolute / Relative Bias ($m\ s^{-1}$ / %)	RMSD ($m\ s^{-1}$)	Correlation
Wind speed	0.12 / 2.20	0.72	0.92
E-W component	0.05 / 1.50	0.82	0.86
N-S component	-0.21 / 4.90	0.92	0.85

Table 4. Statistical summary of downstream vorticity ζ plotted in Figure 13a. Here $x^{*} = x/D_{inv}$ is the normalized downstream distance.

	Mean ($\times 10^{-4}\ s^{-1}$)	Median ($\times 10^{-4}\ s^{-1}$)	Correlation (ζ, x^{*})	Slope ($\times 10^{-4}\ s^{-1}$ / D_{inv})	Slope ($\times 10^{-4}\ s^{-1}$ / 100 km)	Count
GOES-16 +	4.74	4.65	-0.58	-0.086	-0.806	262
GOES-16 -	-3.67	-3.47	0.84	0.190	1.792	245
ASCAT +	1.98	2.17	-0.93	-0.222	-0.993	7
ASCAT -	-1.82	-1.39	0.93	0.298	1.331	7
