13 **Key Points:**

14 • The 2017 Kos $M_w6.6$ main shock and its aftershock sequence revealed the geometric

15 and kinematic properties of a major north dipping normal fault

16 • Rupture process and coseismic slip model in agreement with aftershock distribution

17 define the seismogenic layer and imply nucleation at its lower part

18 • Coulomb stress changes evidence the main shock possible triggering by recent

19 moderate earthquakes, and aftershock activity triggering due to the coseismic slip

20

21

Abstract

22
23 On 20 July 2017 an M_w6.6 earthquake occurred offshore Kos Island, the largest to occur in
24 the affected area in the instrumental era, and in the past 60 years in southeastern Aegean
25 Sea. We estimated the aftershocks relative locations by applying the double difference
26 technique using both differential times from phase picked data and waveform cross
27 correlation. The relocated aftershocks are clustered at least in three distinctive patches,
28 creating a zone getting a total length of about 40 km, elongated in a nearly east–west
29 direction, mainly concentrated at depths 8–15 km, with the main shock hypocenter placed
30 at ~13 km, implying a seismogenic layer of 7 km thickness, indicative for normal faulting
31 earthquakes with M_{max}~6.5. The aftershock fault plane solutions are predominantly
32 suggestive of normal faulting in response to the north south extension of the back arc Aegean
33 area. We further applied the satellite radar interferometry (InSAR) technique to define the
34 coseismic surface displacements. This field of deformation along with the available vectors
35 of displacement measured by Global Navigation Satellite System (GNSS) technique were
36 combined with the seismological data to determine the rupture geometry and process, with
37 the coseismic slip ranging between 0.5 and 2.3 m. The peak moment release occurred in the
38 depth interval of 9–11 km, consistent with the depth distribution of seismicity in the study
39 area. We used the variable slip model to calculate Coulomb stress changes and investigate
40 possible triggering due to stress transfer to the nearby fault segments.

Plain Language Summary

42 The 21 July2017 M_w6.6 Kos, Greece, earthquake ruptured a normal fault in the back arc
43 Aegean area. The area was not visited recently by strong earthquakes, and the main rupture
44 along with the vigorous aftershock sequence, constitute a challenge in investigating source
45 and deformation properties, with implications to regional seismotectonics. We relocated
46 aftershock seismicity and with the highly relocated hypocenters, we defined the main
47 rupture geometry, a 32 km long north-dipping fault, and identified secondary activated fault
48 segments of the local fault network, the activation of which is well-explained by stress
49 transfer due to the main shock coseismic slip. We applied satellite radar interferometry
50 (InSAR) technique to define the coseismic surface displacements. We combined Global
51 Navigation Satellite System (GNSS) with the seismological data to determine the fault

52   geometry and study the rupture process. Our findings document the north dipping fault

53   plane and provide a comprehensive image of the characteristics of the seismic sequence and

54   the associated local fault network.

1 Introduction

56   On 20 July 2017, at 22:31:10 UTC (01:31 local time), a moment magnitude $M_w6.6$ earthquake

57   occurred close to the northeastern coastline of Kos Island and Aegean coast of Turkey (Fig.

58   1, yellow rectangle). Its occurrence seriously affected the city of Kos and several minor towns

59   in Turkey mainland to the northeast of the epicentral area. Southeastern Aegean Sea is one

60   of the most seismically active areas in the Eastern Mediterranean, with a distinctive seismic

61   zone extending from western Turkey, and characterized mainly by normal faulting and

62   diffuse crustal seismicity. Frequent strong (M>6.0) main shocks are known from historical

63   information and instrumental recordings in this extensional zone, displaying clustering

64   behavior (Papadimitriou et al., 2005). The largest event occurred in 1956 with $M_w7.5$

65   (hereafter, we drop the subscript w and refer to the earthquake magnitude as the moment

66   magnitude, unless otherwise noted), associated with a normal fault bounding the southern

67   coastline of the Amorgos Island. Strong events commonly involve shallow normal faulting

68   and occasional have significant strike slip component (Papazachos et al., 1998). Their

69   aftershock sequences settled in characteristic parallel grabens that are formed and bounded

70   by normal faulting both onshore and offshore. The individual slip rates are estimated to be

71   comparatively low ranging between 1-3 mm/yr from geodetic studies (McClusky et al., 2000;

72   Reilinger et al., 2010). Despite the generally slow tectonic loading on the regional fault

73   networks, the strong (M>6.0) earthquake activity is appreciable, associated with the fault

74   segments bounding the flanks of the onshore grabens and the coastlines of the Aegean

75   Islands. The closest main shock of this order of magnitude occurred in 1933 with M=6.6

76   offshore the southern coastline of the Kos Island.

Figure 1. Map of the eastern Mediterranean region along with its major seismotectonic characteristics. The solid red lines represent the active tectonic boundaries, and the arrows represent the direction of the plate relative motion. The yellow square is the study area. NAT, North Aegean Trough; KTFZ, Kefalonia Transform Fault Zone; RTF, Rodos Transform Fault; NAF, North Anatolia Fault; EAF, East Anatolia Fault.
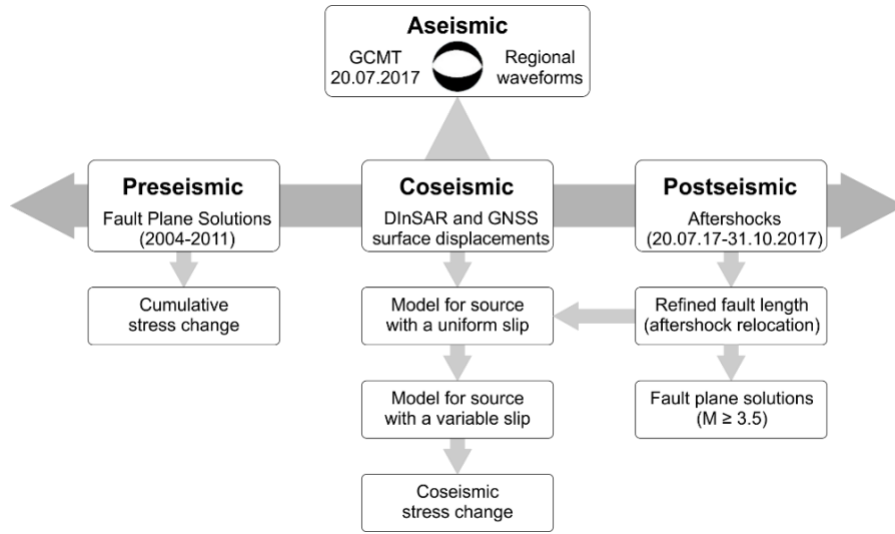

The 2017 Kos main shock is the largest to have occurred in the southeastern Aegean area since 1969 and followed by a rich aftershock sequence, which occupied an area of relative quiescence in the last twenty years. This seismic sequence attracted the attention of several research teams (Table S1) because of the relatively large magnitude of the main shock resulted to the loss of life in both countries, Greece and Turkey, the appreciable aftershock productivity and the accompanying consequences. The global centroid moment tensor (GCMT) solution (https://www.globalcmt.org/CMTcite.html) denotes that the main shock is associated with normal faulting (strike=278°; dip=36°; rake=-82°) with a seismic moment of $M_o=1.16\times10^{26}$ dyn•cm, at a centroid depth of 12 km. Four aftershocks attained magnitudes M>5.0, three of them occurring within 15 km of the main shock epicenter and two of those three within the first 24 hours after the main shock. A moderate tsunami was recorded, with a runup of 1.9 m, which Heidarzadeh et al. (2017) attributed to a fault with

95 length of 25 km, width of 15 km and uniform slip of 0.4 m, independently of the preference

96 for the dip of the fault plane, either to the north or south. A south dipping fault at ~50° was

97 considered by Kiratzi & Koskosidi (2017) and a slip model with bilateral rupture

98 propagation at a rate of 2.8km/s and a maximum value of ~1.6m was proposed, with two

99 shallow slip patches located either side of the hypocenter. Based on the relocated aftershock

100 activity Karakostas et al. (2018) supported a north dipping fault plane. Ocakoğlu et al. (2018)

101 considered the area to be dominated by normal faulting and considerable strike-slip motion

102 according to multichannel seismic profiles.

103 Tiryakioğlu et al. (2018) analyzed pre- and post-earthquake continuous static Global

104 Navigation Satellite System (GNSS) measurements for defining the coseismic slip

105 distribution, by fitting a southward dipping to ~65 km long fault onto which three patches

106 were constrained with maximum slips of 13, 26 and 5 cm, respectively. In Karasözen et al.

107 (2018) the GNSS measurements performed by Tiryakioglu et al. (2018) were jointly analysed

108 with the deformation patterns received from differential interferograms applying the

109 satellite Interferometry with Synthetic Aperture Radar (InSAR) approach in order to model

110 the geometry of the main rupture. The authors propose a different solution for north

111 direction of the dip of ~37°, with the earthquake nucleation at 11 km and a bilateral and

112 upwards rupture propagation. The aftershock locations defined in the same study reached a

113 depth of 15 km and distribution around the western, eastern and downdip edges of a 25-km

114 long rupture plane. Ganas et al. (2019) applied similar approach to modeled the main fault

115 from joint inversion of deformation field (based on delineated interferometric fringes)

116 derived from InSAR data and co-seismic displacement vectors calculated for stations from

117 several regional networks measured by GNSS. The authors assume a homogeneous slip on a

118 rectangular fault. The result of this study showed the better fitting model of the join inversion

119 for a north-dipping normal faulting case mainly with a significant strike-slip component of

120 2.03 m, 14 km length and 12.5 km width of the modelled rupture. Similar study (Konca et al.,

121 2019) that also include campaigned GNSS measurements propose a fault model with ~40o,

122 north-dipping, 20-25 km long, E-W striking, normal fault geometry, with coseismic slip

123 exceeding 2 m.

124   Sboras et al. (2020) used seismological and geological observations to conclude that the main

125   shock and its aftershock sequence evidence the prevailing tectonic setting of the area,

126   consisting of roughly E-W striking normal faults forming inner horsts and grabens. Cordrie

127   et al. (2021) use the fault model proposed by Ganas et al. (2019) to perform tsunami

128   simulations to constrain the source. The authors concluded that the comparison between the

129   maximum wave heights model and the field data favor the north-dipping fault scenario.

130   The presented results of the most notable published studies on the 2017 Kos event revealed

131   a significant uncertainty in the faulting geometry mainly concerning the dipping direction,

132   and type and size of the slip component. In the present paper, we attempt to clarify processes

133   associated with the 2017 Kos sequence using an abundant data set, comprising seismological

134   and geodetic measurements, and implement them in an integrated inversion fault model.

135   Our study is focused on the coseismic processes but also verifies pre- and postseismic phases

136   of the fault activation (Fig. 2). Our aim is to contribute with a more precise identification of

137   the main rupture and the aftershock sequence properties. The accurately located sequences

138   provide the opportunity to investigate the tectonics and earthquake source properties

139   within a seismically active region, which however was not visited by strong (M>6.0)

140   earthquakes in the last few decades when the regional networks were significantly

141   improved. The 2017 Kos sequence is a significant challenge for this scope, with fault

142   modelling of a major regional fault, and contributes shedding more light to its geometry and

143   kinematic properties, along with the investigation of off fault aftershock activity. Faults that

144   are associated with the numerous aftershocks revealed the characteristics of a local fault

145   network with hierarchical features, where the main rupture possesses the first order.

Figure 2. Data and techniques applied in the current research to study the evolution of the rupture and seismic activity related with the 2017 event

The causative fault cannot be unambiguously related with previous known strong (M>6.0) earthquake, since the distinction between the failure of antithetic faults is debatable even for the current main shock, given that in a seismic excitation multiple segments are activated, and the aftershock locations are ambiguously associated to a certain segment among them. The investigation of the 2017 strong seismic activity including the main shock and the refined locations of the subsequent series of aftershocks contributes to the better constraint of the main rupture geometry along with the activated adjacent fault segments, the extension of the seismogenic layer and the seismic sequence evolution. In turn, these findings contribute to the realistic seismic hazard scenario and assessment. Our results reveal that unidentified minor fault segments, either along strike or antithetic to major ones, are adequate to accommodate regional strain capable to culminate in significant seismic activity. Geodetic data obtained by GNSS measurements (Ganas et al., 2019) at ground stations and deformation maps generated by the usage of Differential InSAR (DInSAR) technique applied to two pairs of Sentinel-1 satellite data acquired by the European Space Agency (ESA) are exploited to better identify the fault geometry and calculate a variable

164   coseismic slip distribution model. This allows for a thorough investigation of stress transfer

165   and determination of possibly triggered secondary fault segments of the local fault network.

166   **2 Seismotectonic setting and past seismicity**

167   The affected area, including Kos Island and Bodrum peninsula, is located in the SE Aegean

168   Sea where an extensive mostly E-W-trending fault population produces remarkable

169   seismicity and frequent strong earthquakes with M6-M7, as the result of relatively fast N-S

170   back arc extension. The area of interest belongs to Gokova basin, filled in with the latest

171   Miocene-Pliocene-Quaternary sediments of maximum thickness ~2.5 km (Kurt et al., 1999).

172   The gulf opened by the north-dipping, mainly E-W-trending Datca fault, which is located at

173   the southern part of the gulf, with antithetic faults at the north, and an overall constant

174   extension rate of at least 1.1 mm/yr. The gulf opening started in late Miocene-Pliocene and

175   the continuing extension might be responsible for a second phase of faulting with WNW-ESE

176   oriented subgrabens in the gulf and major E-W normal faulting in the northeast margin (Kurt

177   et al., 1999). Thus, although the main orientation of the gulf is E-W, the more recent WNW-

178   ESE structures are remarkable in the mid-gulf and in its eastern part. Younger active faulting

179   in the central part, with a NE strike, exhibits sinistral strike-slip motion and acts as a transfer

180   fault (Uluğ et al, 2005).

181   Tur et al. (2015) consider the orientations of the three families of faults, with NW-SE, E-W

182   and ENE-WSW strikes, as inconsistent with a simple N-S extensional regime. These authors,

183   based on seismic reflection profiles, multibeam bathymetry and GNSS vectors suggested that

184   the area developed as a lazy-S-shaped graben, due to a counterclockwise rotation of the back

185   arc Aegean, as subduction roll back took place during Pliocene-Quaternary. This is the

186   youngest of a series of back arc basins, which started opening from the west during the

187   Pliocene and progressing eastward during the Quaternary.

188   The SE Aegean area accommodates frequent strong (M>6.0) earthquakes, for which

189   adequate testimonies exist since the 6th century BC (full historical catalog from Papazachos

190   & Papazachou, 2003), given that in the area many significant ancient Greek cities were

191   flourished with developed civilization and scientific observations. The map of Figure 3a

192   depicts the epicenters of the historical (grey stars) and instrumentally recorded (red stars)

193   earthquakes. The highly clustered historical activity may be attributed to the historical

194   descriptions, which are mainly based on the earthquake damage caused to the important at

195   that time cities. Nevertheless, the severity and frequency of the seismic activity is obvious.

196

197   **Figure 3. (a)** Epicenters of all known strong (M>6.0) historical (grey stars) and instrumental

198   (red stars) earthquakes since 6th century BC that occurred in the southeastern Aegean area

199   (yellow rectangle from Fig.1). The size of the symbols is scaled according to the earthquake

200   magnitude. **(b)** Rate of M>6.0 earthquakes during 20th century. The color and the size of each

201   symbol denote different magnitude ranges, as it is shown in the legend.

202   Since the beginning of the instrumental era, when the catalog is found complete for M>6.0

203   earthquakes in the area of Greece, their occurrence rate approximates a value of r˙~0.25.

204 Figure 3b shows the occurrence rate of M>6.0 earthquakes since the beginning of the 20th

205 century, with the activity not equally distributed in time, but with periods of relative

206 quiescence to be alternated with periods of higher activity. It is noteworthy, however, that

207 the activity was intense during the first six decades of the 20th century. A period of

208 remarkable excitation with seven M>6.0 earthquakes in three years, namely 1956-1959, was

209 followed by a period of quiescence after 1970 up to 2005. Even if we will take into account

210 the magnitude estimations uncertainties in the early period of the instrumental catalog, the

211 pattern remains unaltered, and must not be ignored in the estimates of seismic hazard. After

212 1970 the activity becomes significantly weakened, with a few M>6.0 earthquakes and lack of

213 M>6.5 ones. In the close vicinity of the 2017 main shock, the last M>6.0 earthquake occurred

214 in 1968 near the southwester coast of Kos Island.

215 Investigation of earthquake mechanisms for moderate earthquakes (Mw>5.0, during 1986-

216 2005) revealed E-W striking high-angle normal faults with small strike slip components

217 occasionally, and the maximum extension axes oriented from N-S to NW-SE (Yolsal-

218 Çevikbilen et al., 2014). Their finite-fault slip distributions exhibited uniform and circular

219 shaped down-dip rupture propagations close to earthquake foci at depths from 10 to 15 km.

220 The most recent (prior to 2017) activity in the study area involved a series of moderate

221 earthquakes in 2004-2011, some of which occurred within just a few kilometers from the

222 epicenter of the 2017 main shock (Table 1).

223 **Table 1.** Information on the source parameters of moderate earthquakes (4.7<M<5.5) that

224 occurred near the 2017 main shock since 2004. The last column gives the reference of the

225 determined fault plane solution, as 1: Pondrelli et al., 2007, 2: Pondrelli et al., 2011, 3: GCMT

227 In an attempt to investigate the role of the recent moderate magnitude seismicity in the 2017

228 main shock occurrence, we calculated the static Coulomb stress changes caused by the

229 coseismic slip of the eight earthquakes with 4.7<M<5.5 listed in Table 1. Five out of these

230 eight earthquakes occurred in August 2004 at a distance of 15-25 km from the 2017 main

231 shock. We used their fault plane solutions (strike/dip/rake) and moment magnitudes (M_w)

232 for calculating the source parameters. For calculating the coseismic slip (*u*) we applied the

233 scaling laws (Wells & Coppersmith, 1994) for the fault length, and the relation *u=Mo/μA*,

234 where *A* is the rupture area and μ is the shear modulus for crustal faults (3×10^{11} dyn/cm2,

235 Hanks & Kanamori, 1979), while the M_0 is the seismic moment provided by GCMT.

236 The static Coulomb stress change, ΔCFF, in a simplified form to account for pore pressure

237 effects, is given by (King et al., 1994):

238 $$\boldsymbol{\Delta CFF = \Delta \tau + \mu' \Delta \sigma_n}$$ (1)

239 where $\Delta\tau$ is the change in shear stress onto the fault plane, considered positive in the slip

240 direction, $\Delta\sigma_n$ is the normal stress changes, considered positive in unclamping, and μ' is the

241 effective coefficient of friction, taken equal to 0.4 as it has been widely accepted

242 (Papadimitriou, 2002; among others). Figure 4 shows the cumulative stress transferred by

243 these earthquakes for a receiver fault of the main shock, calculated at a depth of 10 km, which

244 is considered as the nucleation depth of the local seismogenic layer. We found that the main

245 shock epicenter is located inside a stress-enhanced area, where the positive stress changes

246 have taken values >0.01 bar. Although tiny, we consider this prior activity as encouraging

247 the 2017 seismic excitation.

248

Figure 4. Stresses imparted by the eight moderate earthquakes that occurred at a distance
of ~20 km from the 2017 main shock epicenter, resolved according to the GCMT fault plane
solution of the 2017 main shock (strike/dip/rake= 278°/36°/-82°) at a depth of 10 km. The
focal mechanisms are plotted as equal area lower hemisphere projections at the epicenter of
each shock. The values of the static Coulomb stress change (ΔCFF) are given in bars
according to the color scale in the right hand side of the figure. The main shock epicenter
from 2017 is denoted by yellow star.

3 Seismicity relocation, fault plane solutions and spatiotemporal evolution

3.1 Relocation of the aftershock seismicity

The data recorded by the regional seismological networks often contain drawbacks related
to the fact that the routine analysis offers fast and large number of locations and magnitudes

260 in almost real time, traditionally used for civil protection purposes (information and rapid

261 response). The location procedure for a seismic sequence in the routine analysis is based on

262 the manually picked and automatically revised marked P- and S-phase arrivals. Particularly

263 the first hours and days, a number of lower magnitude earthquakes is missing as their body

264 wave arrivals are obscured due to the high occurrence rate of the bigger events.

265 For the fault geometry constraint and associated tectonics, we relocated the aftershocks that

266 occurred between July 20 and October 31, 2017. The rate of aftershock occurrence became

267 very low in the following period. We used the arrival-time picks of the waveform data

268 recorded by the Hellenic Unified Seismological Network (HUSN, doi:10.7914/SN/HL), the

269 Kandilli Observatory and Earthquake Research Institute (KOERI, doi:10.7914/SN/KO), as

270 well as arrival-time picks from the Disaster and Emergency Management Authority (AFAD,

271 doi:10.7914/SN/TU) seismological networks. Aftershocks phase picks and waveforms from

272 the three mentioned networks were gathered by the Geophysics Department of the Aristotle

273 University of Thessaloniki (AUTH, doi:10.7914/SN/HT) to constitute our data source. We

274 used the recordings of 17 seismological stations being at distances up to 160 km (Fig. 5) for

275 the aftershock relocation. The closest station (BDRM) to the earthquake sequence is located

276 in a mean distance of 14 km from the aftershock area. The recordings of the regional stations

277 at larger distances were not considered for the aftershock relocation, aiming to avoid

278 interference of large lateral heterogeneities in the crustal model. During the study period

279 more than 1450 events with magnitudes M>1.4 were recorded by the three above mentioned
280 seismological networks.

281

Figure 5. Black hexagons and triangles depict the geographical distribution of the 17
seismological and the 24 GNSS stations, the recordings of which were used for the seismic
sequence location and the calculation of the surface deformation, respectively. The red star
shows the main shock epicenter.

286 For our study purposes, to obtain a highly precise relocated catalog, we manually checked
287 and repicked the P- and S-phase arrivals, when it was considered necessary. For the early
288 aftershocks, we exerted an extra effort to add more data in the initial catalog, since the
289 spatiotemporal behavior of the early aftershocks provide crucial information for the main
290 rupture geometry and properties. There were 13312 P and 8260 S arrivals picked for 1298
291 events, from the stations illustrated in Figure 5. We used these picks to locate the
292 earthquakes along with a proper software and a velocity model, an appropriate velocity ratio

293 and stations corrections, which adjust the lateral homogeneities in the path of wave

294 propagation (e.g. Papadimitriou et al., 2017). The velocity model including 6 layers over a

295 half space is given in Table 2 (Akyol et al., 2006) and was used along with a recalculated v_p/v_s

296 ratio, which was found equal to 1.737 after applying the Wadati method (Wadati & Oki,

297 1933) to a data set of earthquakes with at least 10 S phases. The origin times of all

298 earthquakes reduced to zero and the velocity ratio was calculated using a common plot of t_s-

299 t_p versus t_p (Fig. 6), where t_s and t_p are the arrival times for the S and P wave, respectively.

300 Given that the 1D velocity model accounts only for velocity variability with depth, we

301 calculated corrections for each one of the seismological stations aiming to consider lateral

302 heterogeneities as well. Time corrections range between -0.27 and 0.22 sec, with 12 (71%)

303 of them in the range -0.1 +0.1 sec, evidencing that the 1D velocity model represents

304 adequately the real crust structure. Using the phases from these stations and the

305 corresponding corrections, the velocity model and the HYPOINVERSE computer program

306 (Klein, 2002), aftershock location was achieved, with spatial errors in these calculations of

307 the order of a few kilometers.

308 **Table 2.** 1D velocity model for the seismicity relocation (after Akyol et al. 2006)

| V_p (km/sec)	Depth (km)
4.70	0.0
5.10	1.5
5.80	3.0
6.00	5.0
6.30	15.0
6.40	21.0
7.80	29.0

309

Figure 6. V_P/V_S ratio for the aftershock sequence resulted from the linear fit of t_P-t_S versus

311   t_p

312   After the initial location, a double difference algorithm was applied for the relocation

313   (Waldhauser & Ellsworth, 2000; Waldhauser, 2001), followed by cross correlation of the

314   waveforms in the time domain (Schaff & Beroza, 2004; Schaff & Waldhauser, 2005). The

315   final catalog comprises 1134 events recorded at five or more stations. The lower
316 magnitude is 1.4 and by applying the goodness of fit method (Wiemer & Wyss, 2000) at the

317 95% confidence interval the completeness threshold was found equal to 3.1 (Fig. 7).

318

319 **Figure 7.** Identification of the completeness magnitude of the aftershock sequence: **(a)**

320 cumulative and incremental frequency as a function of the magnitude. **(b)** Goodness of fit

321 approximation. The M3.1 is adopted as the magnitude threshold given that at this point the

322 residual drops below 5%.

323 Location errors derived by the hypoDD software using the LSQR approximation are of the

324 order of a few meters, these values, however, have no physical meaning (Waldhauser, 2001).

325 In order to estimate the achieved accuracy, an error analysis was performed in X, Y and Z

326 directions, by applying a bootstrap resampling method (Efron, 1982). Figure 8 shows the

327 histograms of the errors in each direction. The data are divided in those relocated using both

328 cross correlation and phase picking (red color), and those relocated using only phase picking

329 (blue color). One can clearly observe that cross correlation results significantly improve the

330 relocation accuracy. The mean values of the errors in the X, Y and Z directions are 575 m,

331 373 m, and 452 m, respectively. There is a considerable difference between the two

332 horizontal errors, which is probably due to the spatial distribution of the stations in the N-S

333 direction. The data accuracy as assessed by the aforementioned calculated errors is sufficient

334 to adequately describe the aftershock distribution.

335

336 **Figure 8.** Histograms of the errors calculated by a resampling bootstrap method in the three

337 directions X, Y, and Z., for data relocated by both, cross correlation (cc) and phase picking

338 (red color) and data relocated using only phase picking (blue color).

339   3.2 Moment tensor solutions

340 We computed moment tensors for earthquakes with ML≥3.5 using waveform inversion

341 implemented in the ISOLA package (Sokos & Zahradnik, 2008, 2013), and adopted solutions

342 provided by GCMT and GFZ (Table 3). They concern aftershocks (either on or off fault

343 aftershocks) located close to the main shock epicenter (given in the first row of Table 3) as

344 well as the adjacent seismicity clusters (Fig. 9). We calculated Green's functions for stations

345 located within 150 km from the earthquake epicenter using a 1D velocity model (Akyol et al.,

346 2006, Table 2). The inversion was performed for a deviatoric moment tensor and the

347 waveforms are filtered to frequency range of 0.04-0.08 Hz. To assess the quality of the

348 computed moment tensors, we consider a number of quality factors as described by Sokos &

349 Zahradnik (2013). Briefly, we checked the spatio-temporal variability of the focal

350 mechanism (FMVAR), and obtained a mean value of 14. Then, the surface of the area in the

351 space-time plot occupied by the solutions within a given correlation threshold, normalized

352 by the total area of the investigated space-time region (STVAR), is calculated with a mean

353 value of 0.2. Additionally, we considered on average eight stations for each inversion that

354 resulted in solutions with a mean double couple (DC) of 81%, and mean condition number

355 (CN) of 3. The finally selected fault plane solutions are shown as lower hemisphere equal

356 area projections in Figure 9 and are plotted at the epicenter of each earthquake. The size of

357 each beach ball is proportional to the earthquake magnitude.

358 **Table 3.** Information on the fault plane solutions determined by GCMT (noted by number 1

359 in the last column of the table), determined in this study (2), and by German Research Centre

360 for Geoscience – GFZ (http://geofon.gfz-potsdam.de/eqinfo/list.php) (3)

361

Figure 9. Fault plane solutions of the main shock (the epicenter of which is denoted by the yellow star) and the aftershocks listed in Table 3, shown as equal area lower hemisphere projections. The number on the top of each beach ball corresponds to the number given in the first column of Table 3.
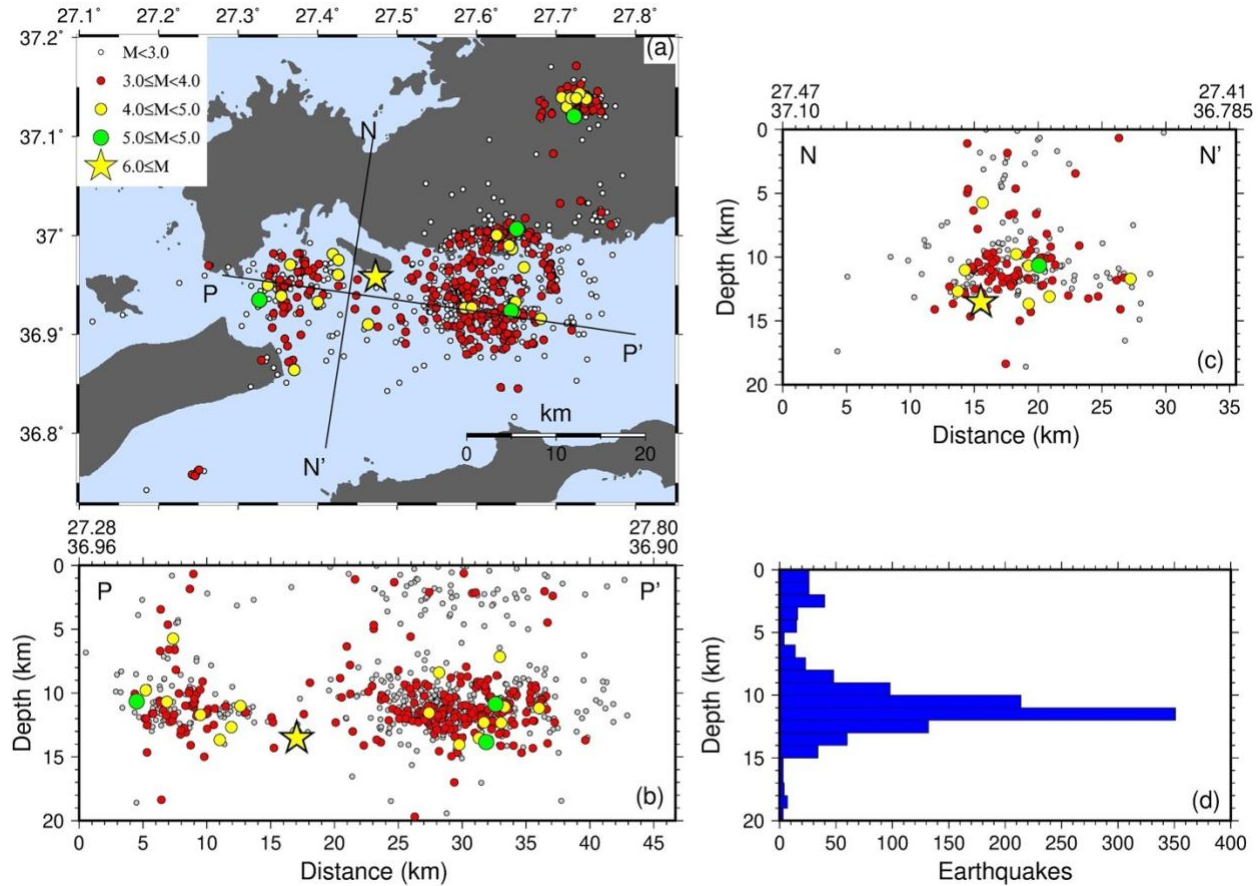

Both Table 3 and Figure 9 evidence the prevalence of the normal faulting, with E-W striking nodal planes in full agreement with the N-S regional extensional stress field. This faulting type characterizes foreshocks onto or very near the main rupture, as well as the off fault aftershocks forming two clusters, to the east and northeast of the main shock. The appearance of a slight strike slip component in some aftershocks of lower magnitude cannot be ruled out and provides the basis for considering complexity of the faulting mechanics, but

372 there is not adequate information (small number of solutions) on which a robust discussion

373 can be built.

374   3.3 Spatiotemporal evolution of the aftershock seismicity

375 The epicenters of the 1134 relocated earthquakes are plotted on the map of Figure 10a. They

376 are distributed in an almost east-west oriented seismic zone with over ~40 km length, which

377 is larger than the expected fault length for an M6.6 main shock, as it is given from well-known

378 scaling laws connecting main shock magnitude and rupture length (Wells & Coppersmith,

379 1994; Papazachos et al., 2004; among others). The almost E-W alignment is generally

380 consistent with the dominant N-S extension. The refined relocation of the aftershocks

381 improves our knowledge on the geometry and kinematic details of the activated structures.

382 The identification of as much as possible smaller magnitude aftershocks enhance the

383 detailed analysis of the spatiotemporal evolution of the sequence. In the strike parallel cross

384 section (Fig. 10b) along the line PP', an area of more than 10 km in length around the main

385 shock epicenter is devoid of aftershocks, implying an asperity, at the edges of which the

386 aftershocks are densely concentrated. In the strike normal vertical cross section along the

387 line NN' (Fig. 10c) a north dipping trend is observed, coherent with the one nodal plane of

388 the GCMT solution. The main shock is located in the deeper part of the north dipping

389 aftershock zone. The histogram, of the aftershocks focal depths (Fig. 10d) shows that the vast

390 majority of the aftershocks are distributed at depths between 7 and 15 km, consistent with
391 the brittle crust thickness of the back arc Aegean area.

392

Figure 10. (a) Map showing the epicentral distribution of the relocated aftershocks. The
yellow star depicts the main shock epicenter. Earthquake epicenters are colored as a
function of magnitude according to the scale. **(b)** Strike parallel cross section of the relocated
aftershocks along the line PP'. **(c)** Strike normal cross section of the relocated aftershocks
along the line NN'. **(d)** Histogram of the focal depths of the relocated aftershocks.

398 A spatiotemporal distribution (Fig. 11) in an almost W-E direction (along the line PP' of Fig.
399 10a), shows that the seismic activity expanded almost immediately in the entire aftershock
400 zone. From this distribution we may observe distinct characteristics, as that in the first day
401 of the sequence seven earthquakes of M>4.0 (the main shock including) occurred in the
402 western part and only four in the eastern part. Instead, the number of the lower magnitude
403 earthquakes is significantly higher in the eastern part. This might be rather attributed to the

404   fact that large fault patches were failed in the larger magnitude aftershocks in the western

405   part than to the obscurement of the waveforms of smaller aftershocks by the larger

406   aftershocks' waveforms. After the first two days, the seismic activity in the western part

407   considerably diminished. Around the main shock epicenter, the aftershock density is clearly

408   less dense, implying stress free area in a fault patch where the maximum coseismic slip took

409   place. This steadily remained free of aftershock epicenters in the entire 100-day span of our

410   data set. It is worth to note that two M>5.0 aftershocks (green circles) that occurred on the

411   same day with the main shock, are located at the two opposite edges of the activated area,

412   implying triggering effects at the fault tips, where the stress concentrations receive the

413   highest positive values.

414

415   **Figure 11.** Spatiotemporal aftershock distribution along an almost west-east direction

416   (along the line PP' shown in the map of Fig. 10a). Symbols are as in Figure 10.

417   In the eastern part of the aftershock zone (Fig. 11) the seismic activity was higher, hosting

418   the largest aftershock (M5.3) of the sequence, that was triggered eighteen days later and was

419   accompanied by its own aftershocks (increased rate of the M>3.0 aftershocks, red circles).

420   The intense activity on the eastern cluster is attributed, as will be shown below, to the

421   positive Coulomb stress changes at this location, due to the main shock slip. To the N-NE of

422   the main activity (Fig. 10a), a second distinctive cluster originated four days after the main

423 shock occurrence with the activity peaked twenty days afterwards. It exhibits a high spatial

424 concentration, with the maximum magnitude earthquake of M=5.0, and several M>4.0

425 events.

426 Figure 11 shows that during the days 17-21 after the main shock occurrence (06-10 August

427 2017) a cluster of earthquakes in the easternmost part of the aftershock zone was formed.

428 The stronger earthquake (M5.3) of this cluster occurred on 8 August 2017. A second

429 distinctive cluster, which was not included in the space time plot because it is out of the main

430 aftershock zone, took place in the period 12-17 August 2017. Aiming to examine the spatial

431 features of these two clusters, all the aftershock epicenters of the period 06-16 August were

432 plotted on the map of Figure 12a. The first cluster is developed along the coasts of Bodrum

433 peninsula, elongated in an almost E-W direction, with a total length equal to 11 km. In

434 addition to the M5.3 earthquake, three more earthquakes with M>4.0 are included in this

435 cluster and several with M>3.0. A cross section normal to the cluster's orientation (Fig. 12b)

436 along the line N1N2 shown on the map of Figure 12a, striking at N170°, shows that the focal

437 depths are distributed in the range of 8-14 km. The earthquakes of this cluster occupy the

438 left part of Figure 12b and show a clear dip to the north in agreement with the one nodal

439 plane of the fault plane solutions (Table 3). A few days later, the second cluster formed at a

440 distance of about 15 km NNE of the main rupture zone (Fig. 12a), with the stronger

441 earthquake in this cluster having a magnitude of M5.0, and six more earthquakes of M>4.0.

442 The epicenters are all tightly concentrated in space, aligned along an east-west orientation,

443 forming a zone with length of about 6 km. A cross section along the line N3N4 in the direction

444 N185° shows a depth distribution (9-13 km) similar with the previous cluster, one

445 convincing indication for the thickness of the brittle layer and the depth of seismicity pick.

446 The hypocenters indicate an activated fault dipping to the north, in agreement with the one

447 of the nodal planes of the three available focal mechanisms of this cluster (Table 3 and Fig.

448 9).

449

Figure 12. (a) Spatial distribution of the seismicity forming two distinct clusters, namely the

eastern and northeastern ones. **(b)** Vertical cross section of the seismicity encompassed in

the eastern cluster along the line N_1N_2 shown in the map of Fig. 12a. **(c)** Vertical cross section

453   of the seismicity encompassed in the northeastern cluster along the line N$_3$N$_4$ shown in the
454   map of Fig. 12a.

455   **4 Geodetic observations of the coseismic surface**

456   The geodetic data used in the current study consist of two types of coseismic observations –

457   deformation maps with areal coverage derived by applying the Differential Interferometry

458   Synthetic Aperture Radar (DInSAR) technique, and pointwise displacements measured by

459   Global Navigation Satellite System (GNSS) and available in the literature.

460   4.1 Surface displacement obtained with Differential Satellite Interferometry
461   (DInSAR)

462   Proven by numerous examples from the last several decades (Massonnet et al, 1993, among

463   others), the application of the technique of satellite interferometry with synthetic aperture

464   radar (InSAR) plays a notable role in defining the field of surface deformations caused by

465   moderate to strong earthquakes. The special range of deformations is also used alone or in a

466   join inversion for modelling of the causative fault. To estimate the surface displacement by

467   Differential InSAR (DInSAR), C-band satellite radar images with wavelength of ~5.55 cm,

468   acquired by the Sentinel-1 mission of the European Space Agency (ESA) have been used. The

469   data are available on the ESA's data hub (Copernicus Sentinel Data, 2021). The used in the

470   current study images are in Interferometric Wide (IW) swath mode, in Single Look Complex

471   (SLC) format with average special resolution of 3x22 m (range x azimuth). We combined two

472   coseismic pairs of images with VV polarization, namely one pair from the ascending track

473   131 from the dates 18/7/2017-24/7/2017, and a second pair of the image from the

474   descending track 36 from dates 18/7/2017-30/7/2017. The ESA's Sentinel Application

475   Platform (SNAP) was used to process the radar interferogram couples. The Shuttle Radar

476   Topography Mission (SRTM; EROS, doi:/10.5066/F7PR7TFT) 1 arc-second (30-m

477   resolution) Digital Elevation Model (DEM) was applied for the topographic phase removal.

478   Multilooking (6 range x 2 Azimuth looks) and a Goldstein filter (Goldstein & Werner, 1998)

479   are applied to the received wrapped interferograms (Fig. 13) aiming to reduce the noise and

480   to support the unwrapping of the radar phases.

481

482   **Figure 13.** Wrapped coseismic Interferograms: (left) between 18 and 24 July 2017

483   calculated from images acquired in Sentinel-1 ascending track № 131, and (right) between

484   18 and 30 July 2017 calculated from images acquired in descending track № 36.

485   Both resulted wrapped interferograms, ascending and descending, show six-seven fringes

486   over the area of the Kos Island associated with the coseismic surface displacement caused

487   by the main rupture, postseismic motions and the stronger aftershocks within the timespan

488   of the interferograms. The usage of C-band Sentinel-1 radar images reveals a corresponding

489   approximate displacement in the line-of-sight (LOS) direction to the slant-range looking

490   satellite at the level of more than 16-19 cm (six-seven times the half wavelength). Strong

491   additional influence on the patterns in Figure 13, most probably due to atmospheric effects

492   (Dogru, 2020), is also clearly visible and must be considered as an additional distortion on

493   the deformation values over the area of interest. The correction for atmospheric delays

494   provided by the Generic Atmospheric Correction Online Service (GACOS, Yu et al., 2017) was

495   implemented by the KITE module of Pyrocko package on a later step. The Minimum Cost

496   Flow (MCF) method (Chen & Zebker, 2000) was applied with the SNAPHU algorithm for

497   phase unwrapping and receiving the total amount of displacements in LOS directions.

498   The unwrapped interferograms were further processed with the KITE software (Isken et al.,

499   2017), so that the unwrapped phase is transformed into surface displacement and

500   subsequently subsampled (Fig. 14). The quadtree subsampling algorithm (Jónsson et al.,

501   2002) is applied with a root mean square (RMS) threshold of 0.1 and a minimum tile size of

502   0.01o. The approach is used in order to obtain a computationally efficient displacement

503   scene where areas with high displacement gradients are sampled with a higher resolution,

504   whereas sample density is lower in areas with low displacement gradient. The variance-

505   covariance matrix of the subsampled data was estimated after selecting a noise window to

506   quantify the noise contribution to the data. Finally, the crustal model of Akyol et al. (2006)

507 (Table 2) was used to estimate static displacements using the PSGRN/PSCMP backend

508 (Wang et al., 2006).

509

510 **Figure 14.** Unwrapped ascending and descending coseismic displacement maps showing the

511 sampling used in the first stage of fault geometry modelling

512   4.2 GNSS data used in the fault modelling procedure

513 The displacement GNSS vectors from all available permanent GNSS network in the area used

514 here are those estimated by Tiryakioglu et al. (2018) and Ganas et al. (2019) (Table 4, Fig.

515 5).

516 **Table 4.** Components of coseimic displacement at GNSS stations (sources are denoted as 1:

519   Tiryakioglu et al. (2018) used data from 20 GNSS stations (15 continuous stations and 5

520   campaign-surveyed stations). The permanent stations were distributed in the borderlands

521   of Greece and Turkey. The GNSS campaign data were acquired during five measurement

522   sessions between 2002 and 2013. To obtain the displacement values, the campaign stations

523   were re-measured three days after the main shock (on 24 July 2017). The coordinates of all

524   GNSS stations were estimated using GAMIT/GLOBK software, based on the rapid GNSS

525   products. Ganas et al. (2019) used the data from the Tiryakioglu et al. (2018) paper, however

526   they additionally determined displacements from other GNSS stations. They determined the

527   GNSS displacement vectors using the Precise Point Positioning (PPP) technique in the

528   GIPSY/OASIS II software (ver. 6.4). To obtain the highest precision of estimation, the authors

529   used final GNSS orbital and clock products.

530   Based on the data from the aforementioned articles, it can be noted that the closest GNSS

531   station (YALI) was located about 7 km from the main shock epicenter, and the farthest

532   station (CESM) was about 178 km away. Considering the measured GNSS displacements, the

533   largest horizontal and vertical deformations occurred for the BODR station (about 10 km far

534   from the main shock epicenter).

535   **5 Joint inversion for fault geometry modelling**

536   One pivotal aspect in examining aftershock activity, surface displacements, and coseismic

537   stress changes is the calculation of a fault model geometry and estimation of the coseismic

538   slip distribution of the main rupture, either uniform or variable. In the current study, the

539   fault modelling was performed in two stages (Fig. 15). Firstly, using regional waveforms,

540   GNSS displacement vectors, and DInSAR surface deformations, a rectangular fault with

541   uniform slip respecting the Okada (1992) definition was proposed. Then, the second step

542   aimed to define the fault geometry with a variable slip distribution using finite join inversion

543   based on the chosen geodetic data and the aftershock distribution. The modelled fault was

544   used to calculate the coseismic stress changes and the surface displacements. All the data

545   preparation and the modelling were handled with the various software tools under the

546   Pyrocko toolbox (Heimann et al., 2017).

547

548   **Figure 15.** Modelling strategy – input data, phases of processing and output products

549   The waveforms recorded by eleven broadband regional stations belonging to the Greek

550   seismographic network (HUSN) and Turkish networks (AFAD and KOERI, see Section 3) in

551   distances ranging between 155 and 465 km have been used in this study (Fig. 16). The

552   stations were chosen aiming to achieve a satisfactory azimuthal coverage. The inversion was

553   performed in the time domain, using the complete waveform, and tapered with a flat

554   frequency response of 0.005-0.02 Hz, falling to zero at 0.003Hz and 0.03Hz, defined as

555    $f_{min}/1.5$ and $f_{max}*1.5$. The crustal model of Akyol et al. (2006) (Table 2) was assumed for the

556 calculation of the Green's functions using the QSEIS backend (Wang, 1999), through the
557 Fomosto tool of the Pyrocko package.

558

559 **Figure 16.** Seismological stations from the Greek (HUSN, blue triangles) and Turkish
560 (KOERI, AFAD, red triangles) national networks, used in the joint inversion for the uniform
561 slip model. The star denotes the main shock epicenter.

562 The optimization for the initial uniform slip source was performed using all available
563 datasets (regional waveforms, displacement field from DInSAR and displacement vectors
564 from GNSS) with the GROND software (Heimann et al. 2018), which performs a Bayesian
565 bootstrap-based probabilistic joint optimization procedure. The models are evaluated based
566 on the L2-norm misfit (e_{norm}) for each target *i* of a given target group (waveform, DInSAR or
567 GNSS)

568
$$|e_{norm}| = \sqrt{\frac{\sum(w_i \cdot |d_{obs,i} - d_{synth,i}|)^2}{\sum(w_i \cdot |d_{obs,i}|)^2}}, \tag{2}$$

569 where d_{obs} and d_{synth} are the observed and synthetic data, respectively, and *w* is the target
570 weight. The global misfit when combining multiple target groups is the RMS of the

32

571 normalized target group misfits. A number of parallel bootstrapping on model misfits is
572 performed to ascertain model uncertainties.

573 Following the Okada (1992) definition of a simplified rectangular source by nine parameters,
574 we assumed a rectangular uniform slip source and performed the optimization for the fault
575 dimensions (length, width), position (depth of upper fault edge, shift in northern and eastern
576 direction of the center of the upper edge from the relocated hypocenter), faulting
577 characteristics (strike, dip, and rake angles) and a uniform slip value. The aftershock spatial
578 distribution (Section 3) implies a north-dipping fault and the moment tensor of GCMT (and
579 other institutions) points to an almost E-W strike. We thus constrained the parameters
580 searching for a north dipping fault, striking at 270±30º.

581 For the first stage of the optimization, models were randomly selected from the possible
582 model solutions for 5000 iterations, and they were evaluated and formed a high-score list.
583 For the next 50000 iterations, a directed sampling of the high-score list was accomplished.
584 This was based on a normal distribution that is determined from the standard deviations of
585 high-score models multiplied by a logarithmically decreasing scaling factor, which in our
586 case started from 1.5 and ended at 0.25. A set of 200 bootstrapping chains (Daout et al., 2020;
587 Foumelis et al., 2021) were carried out for estimating the uncertainties of the parameters.
588 The results and uncertainties for the uniform slip model are presented in Table 5 for the best
589 fitting model (Fig. 17 – dashed green rectangle).

590 **Table 5.** Parameters estimated for the uniform slip model with their standard deviation
591 (std) values. The north and east shift from the relocated epicenter (star in Fig. 17a) are
592 denoted with (+) shift to the east and to the north.

Parameter (unit)	Value ± std
East Shift (km from epicenter)	0.9±1.3
North Shift (km from epicenter)	-8.4±1.0
Length (km)	15.4±2.7
Width (km)	9.3±1.7
Depth (km) (the upper middle point)	3.2±0.5
Strike (°)	286±8

Dip (°)	39±3
Rake (°)	-77±8
Slip (m)	2.1±0.4
M_0 (N·m)	9.92e+18
M_W	6.6

593   The optimization suggests a 15.4 km long slip patch of normal faulting, onto a plane striking

594   WNW-ESE and dipping at 39°, with a slight left lateral component (rake=-77°). The faulting

595   characteristics, position and dimensions, are in agreement to the aftershock distribution

596   (Fig. 10a) as well as with several north-dipping proposed models (Karakostas et al., 2018;

597   Karasözen et al., 2018 – uniform slip model; Ganas et al., 2019; Konca et al., 2019; Cordie et

598   al., 2021, see Table S1). The same is also valid for the seismic moment, estimated as

599   *M0=μ·A·D*, μ being the shear modulus taken equal to 33GPa, A being the area of the fault, and

600   D being the uniform slip, which corresponds to a moment magnitude of Mw6.6

601   (*Mw=2/3·log₁₀ Mo-16.1*), (Hanks and Kanamori, 1979). The standard deviations (Table 5) as

602   well as the model fits for waveform (Fig. S1) and static displacement (Table 4) targets

603   indicate a good quality model to proceed to the variable slip inversion. The parameters

604   correlation plot (Fig. S2) reveals that the position of the fault (east and north shift, depth)

605   appears to be better constrained than the fault dimensions (length and width) which are

606   more scattered. Since this is an intermediate step and the variable slip model was calculated

607   for an extended version of this geometry, we deemed those results acceptable.

608   After defining the fault geometry and orientation, we used the geodetic data (DInSAR and

609   GNSS) to infer the variable slip distribution using the BEAT software (Vasyura-Bathke et al.,

610   2019; 2020). We extended the rectangular model by a factor of 0.8 along strike and 0.6 along

611   dip (Fig. 17a – green rectangle) for including the entire area of aftershock activity. This

612   resulted in 777 (37x21) rectangular patches with dimensions of 1x1 km². For each patch,

613   two slip parameters were optimized, one in the strike parallel and one in the strike normal

614   direction. A smoothing constraint was applied via a Laplacian regularization factor to weight

615   down large differences in slip between bordering patches. The variable slip optimization on

616   the extended area (Fig. 17a – dashed blue rectangle) reveals one main asperity where high

617   slip values are concentrated with a maximum slip value equal to 2.3 m. The slip distribution

618 diminishes faster in the west part of the main asperity, whereas in the eastern part of the

619 main asperity values of 0.5 m can be observed up to the eastern limit of the extended fault

620 area (Fig. 17a, b). The contour of 0.5 m slip (Fig. 17a) forms a rather elliptical shape with the

621 lengths of major and minor axis equal to 32 km and 13 km, respectively. It encompasses a

622 total area of 306 km^2, which is capable to produce an earthquake of M6.6 according to the

623 known empirical relations (Wells and Copersmith, 1994; Papazachos et al., 2004).

624 Considering that this area represents the dislocation plane from where the accumulated

625 elastic strain was released during the main shock, the estimated seismic moment, which

626 results in Mo=1.046·10^{19}Nm and consequently to a moment magnitude M6.6, is in good

627 agreement with that estimated by moment tensors solutions of several institutions. The slip

628 distribution is comparable to that estimated by previous studies (Karasözen et al., 2018;

629 Konca et al., 2019 – north-dipping distribution, Table S1) and is rather different from the slip

630 distribution defined by Tiryakioglou et al. (2018), where multiple slip patches are evident

631 and maximum co-seismic slip appears at very shallow depths (<3 km).

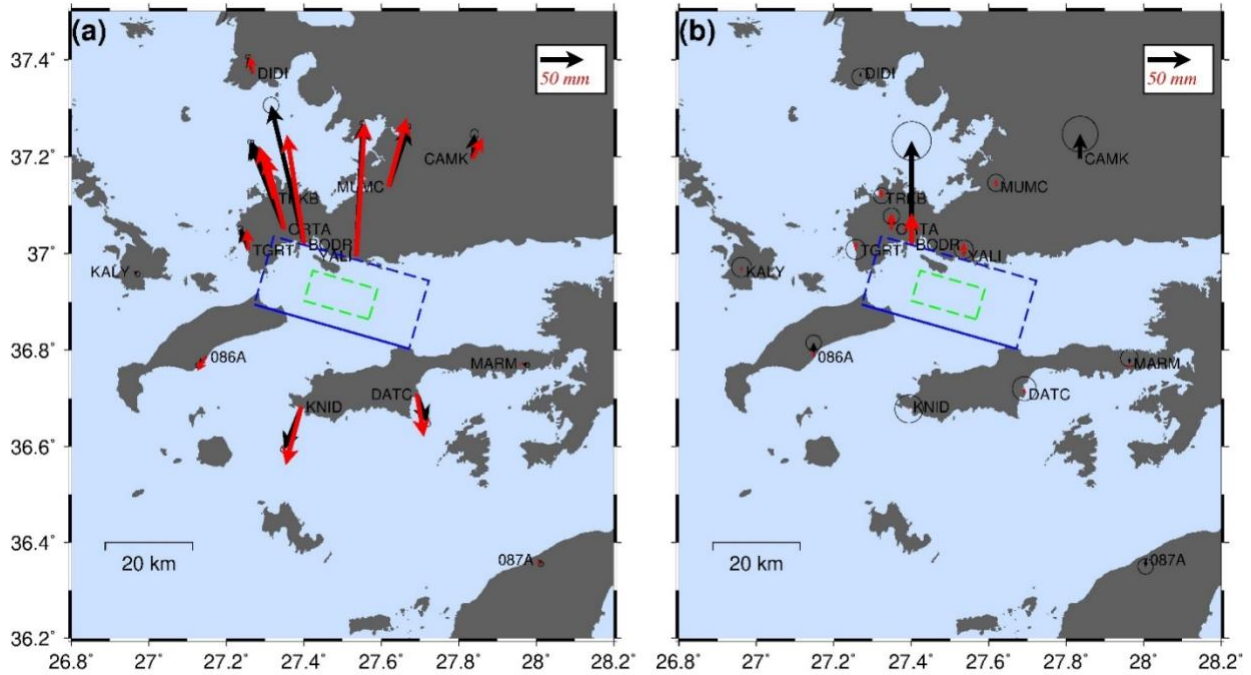

632

Figure 17. (a) Map projection of the variable slip distribution along with the relocated

seismicity (Section 3). Slip values are in meters according to the color scale to the right. Green

635   dashed rectangle designates the fault geometry solution (Table 5) and blue dashed rectangle

636   is the extended area used for the variable slip inversion. Dark isolines show contours for

637   slips over 0.5 m with a 0.5 m step. **(b)** Strike parallel (P1-P1') cross section of the blue dashed

638   rectangle along with the seismicity enclosed by the blue rectangle in (a)

639   For the modelling of the static surface displacements derived from the estimated slip

640   distribution at the locations of the GNSS stations, we only considered the area of cells

641   assigned a slip of 0.5 m or more as they constitute the main rupture area. The calculated

642   model displacements at these positions are generally in agreement with the observed

643   horizontal components (Fig. 18a, Table 4), while this is not the case for the observed vertical

644   components where some of the stations are not adequately modelled (Fig. 18b – stations

645   BODR, CAMK KNID, 086A). Discarding the higher uncertainties in GNSS vertical components

646   (Table 4) as a possible result of additional subsidence due to soft sediments and their

647 compaction due to the vibration during the main shock, we consider that our model
648 adequately represents the static displacement field.

650 **Figure 18.** Displacement vectors – measured (black arrows) and modelled (red arrows), at
651 the closest GNSS stations: **(a)** horizontal displacements, **(b)** vertical displacements. Blue and
652 green dashed boxes are the same as in Figure 17.

653 **6 Stress changes due to the main shock coseismic slip and possible triggering**

654 Extensive research work has evidenced that strong earthquake occurrence either
655 encourages or inhibits subsequent seismicity, depending upon its position and faulting
656 properties relative to these of the main shock. The static stress changes provide the tool and
657 are frequently used to explain the spatial aftershock distribution and its association with the
658 stress field properties (King et al., 1994; Karakostas et al., 2003; Papadimitriou et al., 2017;
659 among others). This is particularly the case in aftershock sequences, where the coseismic
660 slip of the main shock triggers the occurrence of aftershocks, both onto and off the main fault.
661 The stress transfer due to the main shock occurrence perturbs the local fault network. Thus,
662 the aftershock activity is the result of stress residuals onto the main rupture (areas that did
663 not slip during the main rupture) or stress increase beyond the fault edges due to stress
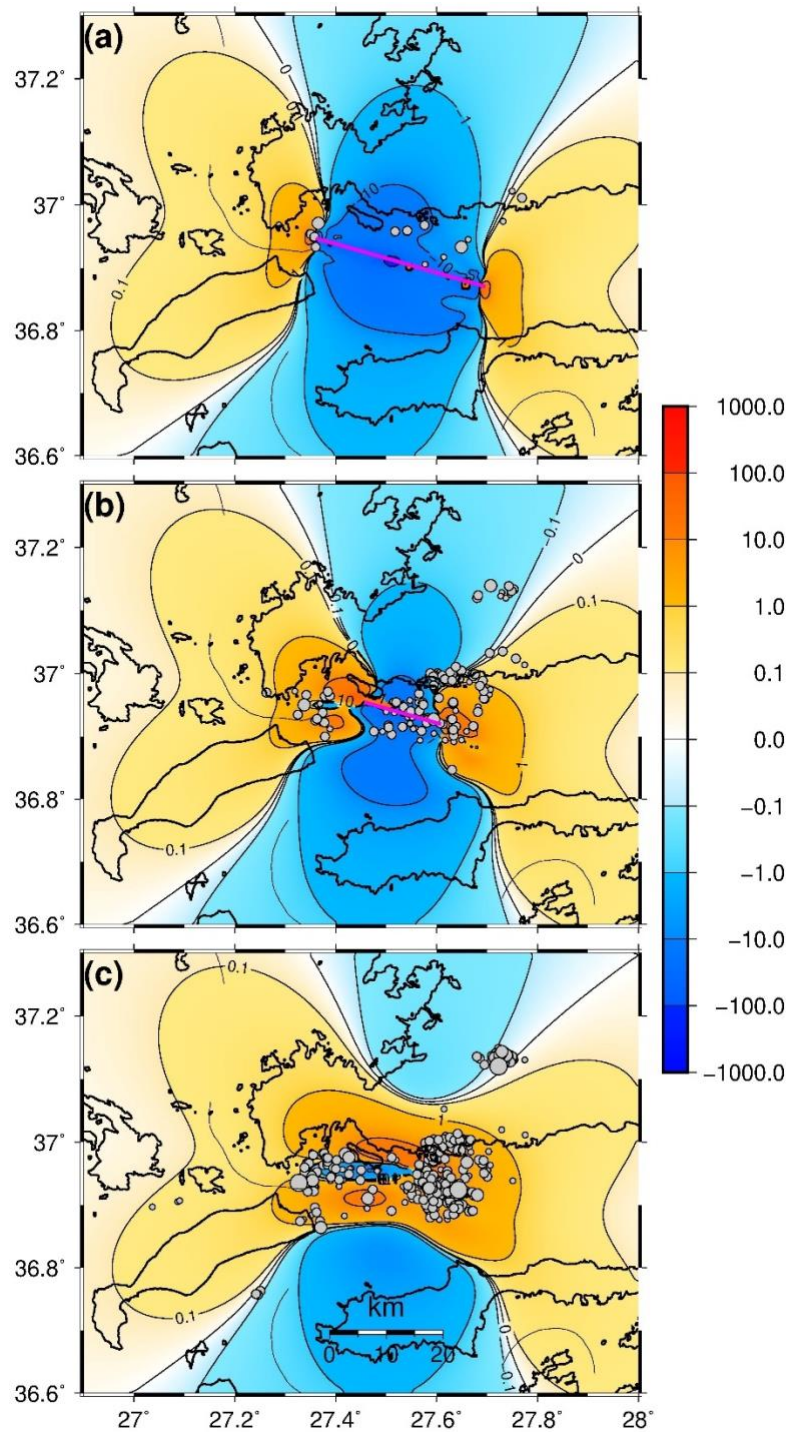

664   transfer. This also complies with the assumption that the main shock static stress changes in

665   a given location favor the focal mechanisms aligned with the static stress change as well as

666   the spatial distribution of seismicity in locations where the static stress change aligns with

667   the background stress (Hardebeck, 2014).

668   Based on our detailed slip distribution model the Coulomb stress changes were estimated at

669   three different depths. This has been done because the map view representation of the stress

670   distribution pattern is considerably different at different depths, when the causative fault is

671   not vertical or close to that geometry, but dips at a lower dip angle. Given the 39° dip angle

672   of the main rupture, the multiple calculations of the stress pattern at different depths seems

673   indispensable for its comparison with the aftershock locations.

674   For the coseismic stress changes calculation we followed the same approach as with the

675   modelling of the slip at the position of the GNSS stations. More specifically, we considered

676   cells with slip values of 0.5 m or more and treated each cell as a separate rectangular source

677   with an area of 1x1 km^2, assuming a rigidity of 33GPa and a Poisson ratio of 0.25. Coulomb

678   stress changes were calculated on three horizontal planes located in three different depths,

679   namely 6 km, 9 km and 12 km, respectively (Fig. 19). In each case, the earthquakes with focal

680   depths ±1.5 km above or beneath the calculation depth were plotted. Figure 19a shows the

681   distribution of Coulomb stress changes calculated at the depth of 6 km. The magenta line is

682   the inferred trace of the fault plane at that depth. The number of aftershocks is very limited

683   in this depth range, with almost half of them beyond both fault edges, where the positive

684 stress changes have their highest values. Few aftershocks are located inside stress shadow

685 areas.

686

687 **Figure 19.** Coulomb stress changes caused from the variable coseismic slip model, calculated

688 on three horizontal planes at depths of 6 km **(a)**, 9 km **(b)** and 12 km **(c)**, and given in bars

40

689 according to the color scale shown in the right hand side of the figure. Epicenters of the

690 earthquakes are gray circles plotted in a crustal slice of ±1.5 km around that depth. Magenta

691 lines denote the inferred fault trace in each depth for (a) and (b)

692 Figure 18b shows the distribution of Coulomb stress changes calculated at the depth of 9 km.

693 The aftershock activity located in the depth range between 7.5 and 10.5 km is more intense

694 than in the shallower depth range. Possible triggering is evidenced for a cluster located at

695 the western fault tip, and the same can be stated for the largest percentage of the aftershock

696 activity to the east of the eastern fault tip. Figure 18c shows the distribution of Coulomb

697 stress changes at the depth of 12 km, below the lower part of the seismogenic fault. Almost

698 all the seismic activity here collocates with stress-enhanced areas.

7 Discussion

699

700 The 2017 Kos aftershock sequence shares many similarities with previous sequences in the

701 Aegean area, where multiple faults participated in the seismic excitation, with the secondary

702 structures being triggered by the main rupture slip. The fault plane solutions and aftershock

703 spatial distribution disclosed that the main shock nucleated at a structure that was favorably

704 oriented with respect to the regional stress field and consequently failure of preexisting fault

705 with optimal orientation. The latter is in turn part of the extensional complex network of

706 active faults in the southeastern part of back arc Aegean area, where the intense stretching

707 deformation attains the rate of 7 mm/yr (Nocquet, 2012). Strong (M>6.0) historical

708 earthquakes are relatively rare in the study area, with a remarkable quiescence in the second

709 half of the 20th century. Although moderate seismicity is not remarkable as well, in the period

710 2004-2011 eight earthquakes of M>5.0, took place near the main shock. The cumulative

711 Coulomb stress changes caused from their coseismic slip, created a stress-enhanced area at

712 the position of the 2017 main rupture.

713 The main shock triggered a vigorous aftershock sequence, which revealed secondary

714 structures of the local fault network. Several hundreds of aftershocks followed, from which

715 1134 were relocated in this study, occurring in the next 103 days, mostly between 7 and 15

716 km, thus implying a crustal seismogenic layer with 8 km thickness and an unreformed upper

717 crustal layer. The main shock produced clusters of off fault aftershocks, mainly occurred

718   beyond the eastern fault tip as well as one cluster of aftershocks occurred to the north, which
719   raised concerns about possible triggering. This off fault activation was detected and
720   investigated as involving stress transfer and triggering of closely spaced subparallel faults,
721   which however is puzzling, as rupture on one fault segment may discourage on nearby
722   potential slip interfaces. It is of interest to discuss that the coseismic slip amplitude varies
723   with depth. It has been shown that the amount of slip in the middle of the seismogenic layer
724   is systematically larger than the slip at larger or shallower depths, and negligible at the
725   surface. This slip distribution agrees with the shear model for faults cutting through the
726   velocity-strengthening layer in the top few kilometers of the crust (Scholz, 2019), where the
727   coseismic slip is inhibited and most of slip occurs aseismically.

728   The proposed north dipping geometry, firstly suggested by Karakostas et al. (2018),
729   supports the north dipping uniform slip fault proposed by Ganas et al. (2019) while the
730   variable slip rupture shares common features with the north-dipping rupture models of
731   Karasözen et al. (2018) and Konca et al. (2019), in terms of the extend of the rupture area,
732   maximum slip depths and model geometry. The north dipping fault is further supported by
733   tsunami simulations in both tide-gauge signals and water height distribution (Cordrie et al.,
734   2021). The accurately located earthquakes along with the joint inversion for fault geometry
735   led us to dismiss a south dipping fault plane. As it has been found, the maximum slip took
736   place in the depth interval between 5 and 8 km, which perfectly agree with the pick of the
737   depth distribution of the aftershocks. This in turn agrees with models that predict that the
738   most favorable conditions for the earthquake nucleation are met at the mid depth of the
739   seismogenic zone. Taking into account that the seismogenic layers in the Aegean area is in
740   depths of 3-15 km, the results of our study suggest that the depth interval where instability
741   dominates is at this part of the seismogenic layer. These findings are in full agreement with
742   relevant results from recent seismic sequences in the Aegean area (e.g. Karakostas et al.,
743   2021; Ganas et al., 2021). The positive Coulomb stress changes that were calculated with our

744 detailed slip model for the main shock are in satisfactory agreement between aftershock
745 locations and stress changes comply with the stress triggering concept (e.g. King et al., 1994).

746 **8 Conclusions**

747 The results of aftershock analysis from the 2017 Kos main shock revealed that the
748 combination of data from the seismological networks from both, Greece and Turkey, along
749 with the relocation techniques and the analysis of the deformation field from DInSAR and
750 the available GNSS displacement vectors contributed to achieve a more complete picture of
751 the fault geometry and kinematics, and also to study the spatiotemporal evolution of the
752 sequence. The improved double-difference depths in the cross sections clearly show a group
753 of aftershocks consistent with the one of the nodal planes in the GCMT solution (and several
754 more solutions that were determined in this study and adopted from other agencies),
755 namely, the north-dipping one. The activated area exhibited a total lateral extent of about
756 ~32 km. The aftershock focal depths range between 7-15 km, showing a peak concentration
757 at 10-11 km. Focal mechanisms of aftershocks with moderate magnitudes also indicate a
758 fault geometry consistent with the relocated seismicity and the focal mechanism of the main
759 shock, and are consistent with the extensional regional stress pattern. The aftershock
760 locations were not completely aligned with the strike of the main rupture, with abundant off
761 fault seismicity.

762 A rupture model was built in a two-stage procedure, initially by joint inversion of
763 seismological and geodetic data to infer fault geometry and then by inversion of geodetic
764 data to derive a variable slip model. The proposed model is that of an asperity break with
765 maximum slip values in depths between 5 and 8 km with significant slip values spreading to
766 the eastern end of the fault, where the aftershock activity was more energetic. The largest
767 portion of the coseismic slip occurred in one main patch down dip of the main rupture
768 offshore, without extending to the shallow part and not reaching the surface. Our preferred
769 model with the largest concentration of slip near the coastline and downdip under a
770 submarine environment is in good agreement with the timing and magnitude of the observed
771 tsunami and geological investigation for the observed displacement. It concerns a rather

772   simple rupture geometry where the maximum slip is concentrated onto a main patch of the

773   rupture plane and the maximum slip occurred in the mid depth of the seismogenic layer.

774   Although there was an absence of strong earthquakes near the main shock area, several

775   moderate (M4.7-5.5) earthquakes occurred from 2004-2011 in distances ranging between

776   15-30 km from the 2017 main shock epicenter. The calculation of the static stress field

777   revealed that the 2017 main shock area lies in a stress-enhanced area increasing the

778   likelihood of slip propagation in the area. The variable fault slip model, which was

779   consequently used for calculating the Coulomb static stress changes induced by the main

780   shock slip, contributed in deciphering that the spatial distribution of the aftershocks might

781   be encouraged by stress transfer from the main rupture.

797   **Open Research**

798   The ΔCFS were computed with a program of J. Deng (Deng and Sykes, 1997), based on the

799   DIS3D code of S. Dunbar (Erikson, 1986) and the expressions of G. Converse. The plots we

800 performed with the Generic Mapping Tools software (Wessel et al. 2013). For stations

801 belonging to the HA, HL and HT networks data were collected from the NOA Node of EIDA

802 (European Integrated Data Services – http://www.orfeus-eu.org/data/eida/) and for those

803 belonging to the KO network from the KOERI node of EIDA (http://eida.koeri.boun.edu.tr/)

804 and for those belonging to the AFAD network from the online database of AFAD

805 (https://deprem.afad.gov.tr/). The Sentinel-1 data are freely available after account log-in

806 at the Copernicus Sentinel Data, (2021). The Digital Elevation Model (DEM) used in the

807 Sentinel-1 data processing is the freely available SRTM (EROS, doi:/10.5066/F7PR7TFT).

808 The software used for the processing of the Sentinel-1 data is Sentinel Application Platform

809 (SNAP,). The correction for atmospheric delays applied to the Sentinel-1 data is Generic

810 Atmospheric Correction Online Service (GACOS, Yu et al., 2017). The GNSS data are retrived

811 from the scientific publications Ganas et al. (2019) and Tiryakioglu et al. (2018). The data

812 integration and source modelling (section 4 and 5) are perfomed using various software

813 tools under the Pyrocko toolbox (Heimann et al., 2017).
