

# **Just How Vulnerable are American States to Wildfires? A Livelihood Vulnerability Assessment**

Janine A. Baijnath-Rodino, Mukesh Kumar, Margarita Rivera, Khoa Dang Tran, and Tirtha Banerjee  
*Department of Civil and Environmental Engineering, University of California, Irvine*

## **Abstract**

Wildland fires are becoming more destructive and costly in the United States, posing increased environmental, social, and economic threats to fire-prone regions. Quantifying current wildfire risk by considering a wide range of multi-scale, and multi-disciplinary variables such as socio-economic and biophysical indicators for resiliency and mitigation measures, deems inherently challenging. To systematically examine wildfire threats amongst humans and their physical and social environment on multiple scales, a livelihood vulnerability index (LVI) analysis can be employed. Therefore, we produce a framework needed to compute the LVI for the top 14 American States that are most exposed to wildfires, based on the 2019 Wildfire Risk report of the acreage size burnt in 2018 and 2019: Arizona, California, Florida, Idaho, Montana, Nevada, New Mexico, Oklahoma, Oregon, Utah, Washington, and Wyoming. The LVI is computed for each State by first considering the State's exposure, sensitivity, and adaptive capacity to wildfire events (known as the three contributing factors). These contributing factors are determined by a set of indicator variables (vulnerability metrics) that are categorized into corresponding major component groups. The framework structure is then justified by performing a principal component analysis (PCA) to ensure that each selected indicator variable corresponds to the correct contributing factor. The LVI for each State is then calculated based on a set of algorithms relating to our framework. LVI values rank between 0 (low LVI) to 1 (high LVI). Our results indicate that Arizona and New Mexico experience the greatest livelihood vulnerability, with an LVI of 0.57 and 0.55, respectively. In contrast, California, Florida, and Texas experience the least livelihood vulnerability to wildfires (0.44, 0.35, 0.33 respectively). LVI is strongly weighted on its contributing factors and is exemplified by the fact that even though California has one of the highest exposures and sensitivity to wildfires, it has very high adaptive capacity measures in place to withstand its livelihood vulnerability. Thus, States with relatively high wildfire exposure can exhibit relatively lower livelihood vulnerability because of adaptive capacity measures in place. On the other hand, States can exhibit a high LVI (such as Arizona) despite having a low exposure, due to lower adaptive capacities in place. The results from this study are critical to wildfire managers, government, policymakers, and research scientists for identifying and providing better resiliency and adaptation measures to support the American States that are most vulnerable to wildfires.

1 **1. Introduction**

2

3 Wildfires play a crucial component in ecosystem dynamics by balancing fuel types and creating  
4 appropriate vegetation for maintaining healthy forested regimes. For instance, some plant species  
5 and communities have evolved thick bark or fleshy leaves that shield them from heat, while others  
6 require flames to melt their waxy coating for seed propagation (Pyne, 2019). Despite the integral  
7 ecological role of wildfires, uncontrolled burns can cause widespread environmental, economic,  
8 social and sustainable development impacts (Roman et al., 2012; WHO, 2014; Ghorbanzadeh et  
9 al., 2019). Such wildfire impacts include losses to human lives; incurring financial losses from  
10 buildings and homes; widespread social, health and economic costs through evacuations, smoke  
11 exposure, and loss of tourism revenue (Richardson et al., 2012; Moritz et al., 2014; Kramer et al.,  
12 2018). The Insurance Information Institute, gives an example of financial loss due to wildfires  
13 include the 2019 wildfires in California and Alaska that created a loss of 4.5 billion dollars in  
14 damages, largely resulting from the California Kincade and Saddle Ridge wildfires. In order to  
15 minimize ignition and spread during this time, California’s electrical utility provider issued rolling  
16 blackouts to homes and businesses during high wind and extreme dry conditions, however, this  
17 inevitably cost the State billions of dollars in losses (NCEI, 2020). It is therefore evident that  
18 wildfires have a direct impact on the livelihood of many residents in fire-prone communities within  
19 the United States, making them vulnerable to wildland fire exposure within a changing climate  
20 and landcover regime (Westerling et al., 2006).

21

22 Likewise, changes in social and climate conditions can also significantly affect fire regimes,  
23 producing greater potential damage than those previously thought (Roman et al., 2012). Social

24 factors, such as the expansion of the wildland-urban interface (WUI) (where human settlements,  
25 buildings, and wildland vegetation meet) have influenced the dramatic increase in wildfire  
26 suppression costs, as well as the number of homes lost to wildfires in the United States (US) over  
27 the past 30 years (Association for Fire Ecology, 2015; Abatzoglou and Williams, 2016; Kramer  
28 et al., 2018). The 2019 wildfire risk report shows that the US experienced the sixth-highest acres  
29 burned in 2018 since the mid-1900s. According to the National Interagency Fire Center (NIFC)  
30 report, California has topped the list in the US with over 1.8 million acres burned in 2018. Climate  
31 factors, such as extreme weather conditions can also influence the escape of wildfire during  
32 suppression practices, leading to unplanned destructive fire behavior (Calkin et al., 2005; Kramer  
33 et al., 2018), thereby, worsening environmental and socio-economic impacts.

34

35 There have been many wildfire risk-assessment studies that use a wide range of fire risk indices  
36 (Bajjnath-Rodino et al. *in review*). However, many wildland fire risk indices focus on specific  
37 components of wildfires (behavior, danger, threat) and use different metrics and frameworks in  
38 their derivations. For example, a fire risk index may only consider biophysical components such  
39 as weather conditions, topography, fuel, fire size, rate of spread, suppression difficulty, fire  
40 occurrence, or burn severity. Studies such as that by Alexandre et al. (2016), have evaluated fire  
41 risk on structures, taking into account variables pertaining to topography, spatial arrangement, and  
42 vegetation, but they did not account for meteorological factors (atmosphere and weather patterns),  
43 building materials, and fire suppression efforts within different fire regions. However, it is  
44 acknowledged that combining multi-scale socio-economic and biophysical variables into a risk  
45 and vulnerability assessment framework can be challenging. While various studies have attempted  
46 to bridge the gaps among the social, natural, and physical sciences and contributed to new

47 methodologies that confront this challenge (Polsky et al., 2007; Hahn et al., 2008), not much of  
48 this approach has been applied to specifically assess wildfire vulnerability in wildland fire prone  
49 regions of the US. Therefore, there is a need to systematically integrate multi-scale,  
50 multidisciplinary variables into a framework to evaluate wildfire vulnerability in highly exposed  
51 wildland fire regimes, a method often lacking in other risk assessment studies. Thus, the integration  
52 across scales and disciplines to produce a wildfire vulnerability assessment can be conducted by  
53 creating a framework to assess the livelihood vulnerability of highly exposed regions to wildfires.  
54 A livelihood vulnerability framework incorporates not only wildfire exposure in a particular region  
55 (such as biophysical factors) but also quantifies the sensitivity of a region to wildfire exposure,  
56 and its ability to withstand these biophysical exposures (known as adaptive capacity). Thus,  
57 producing a livelihood vulnerability framework is an appropriate method for assessing the  
58 vulnerability of communities to wildfire exposure by not only taking into account biophysical  
59 factors, but by also quantifying socio-economic influences.

60

61 A common thread in the literature is the attempt to quantify multidimensional parameters  
62 (biophysical, social, and economic) using diverse indicator variables as proxies that can be  
63 integrated and combined to produce a vulnerability assessment such as Chambers and Conway,  
64 (1992) , who investigated a sustainability livelihood approach (Hahn et al., 2008). The field of  
65 climate vulnerability assessment, as a whole, has evolved to address the need to quantify the ability  
66 of communities to adapt to changing environmental conditions (Hahn et al., 2008) (such as changes  
67 in wildfire exposure). Thus, a vulnerability assessment is appropriate for describing a diverse set  
68 of methods that are used to systematically integrate and examine interactions between humans and  
69 their physical and social environment (Hahn et al., 2008).

70

71 The definition of the term *vulnerability* varies among disciplines (Adu et al., 2017). However,  
72 there is similar consensus in the definition of vulnerability to climate change by the IPCC and  
73 Food and Agriculture Organization (FAO). These studies define vulnerability as the extent or  
74 degree to which a system (geophysical, biological, or societal) is at risk and incapable of thriving  
75 under negative effects of an exposure (such as climate change) (FAO, 2006; IPCC, 2007; Adu et  
76 al., 2017). Assessing the *livelihood vulnerability* of a system, thus, specifically addresses how a  
77 system's basic necessities of living, such as shelter, work conditions, health and environment are  
78 vulnerable or affected by an exposure, such as wildfires. Studies, such as that by Hahn et al. (2008)  
79 combined previous climate vulnerability methods to construct a livelihood vulnerability index  
80 (LVI) to estimate the differential impacts of climate change on several African communities. Their  
81 method follows heavily on the working definition of vulnerability as a function of three  
82 contributing factors (exposure, sensitivity and adaptive capacity) as defined by the  
83 Intergovernmental Panel on Climate Change (IPCC) (IPCC, 2001). **Exposure represents the**  
84 **magnitude and duration of the climate-related exposure** (in our case wildfires); **sensitivity**  
85 **describes the degree to which a system is affected by the exposure**; and **adaptive capacity**  
86 **describes the system's ability to withstand or recover from the exposure** (Ebi et al., 2006;  
87 Hahn et al., 2008).

88

89 The LVI uses multiple indicators that are aggregated into the IPCC's three contributing factors to  
90 produce a vulnerability framework. Studies have applied the LVI method, such as Albizua et al.  
91 (2019) to assess farmers' livelihood vulnerability to global changes in irrigation agricultural  
92 practices in Spain. They show that an increase in the adoption of irrigation practices have increased

93 the short-term adaptive capacity while displacing small-scale farming. Suryanto et al. (2019) have  
94 also used the LVI approach to assess the livelihood vulnerability of flood risks to farmers for  
95 different regions in Indonesia. Results indicate that regions with similar physical characteristics  
96 and agricultural dependencies show similar vulnerability levels. It is acknowledged that there are  
97 numerous interpretations on how best to apply exposure, sensitivity, and adaptive capacity  
98 concepts to quantify vulnerability (Sullivan, 2002; O'Brien et al., 2004; Vincent, 2004; Ebi et al.,  
99 2006; Thornton et al., 2006; Polsky et al., 2007), with key differences among studies that include  
100 methods used for scaling, gathering, grouping, and aggregating indicator variables (Hahn et al.,  
101 2008).

102

103 We adopt an LVI approach, similar to Hahn et al. (2008), to evaluate recent wildfire impacts in  
104 the US. This is conducted by developing a framework that combines a set of indicator variables  
105 (at multiple spatiotemporal scales) into their respective contributing factors to determine the  
106 critical biophysical and anthropogenic components influencing livelihood vulnerability of selected  
107 wildfire prone States. The information gained from this assessment will provide a clearer  
108 understanding as to which States are most vulnerable to wildfires despite their level of wildland  
109 fire exposure. This information will be critical to researchers, government organizations, and  
110 policymakers in identifying, allotting, and providing better resiliency and adaptation measures,  
111 such as aiding in financial, environmental, and social support to the States that are most vulnerable  
112 to wildfires.

113

114

115

116

117

## 118 **2. Data and Methodology**

119

120 Assessing the LVI to wildfires across selected American States are conducted in two folds. First,  
121 we develop a framework comprising a set of biophysical, social, and economic factors that is used  
122 to assess each region's livelihood vulnerability. A Principal Component (PCA) analysis is applied  
123 to the set of indicator variables under each contributing factor to determine the validity of our  
124 framework. Second, once confident with our framework, we calculate the LVI and its contributing  
125 factors for each State.

126

127 The terminologies and definitions corresponding to our framework are summarized in Table 1,  
128 which describes the overarching contributing factors comprising of exposure, sensitivity, and  
129 adaptive capacity (color coded red, blue and green, respectively). These contributing factors are  
130 divided into major components (first level of divisions within each contributing factor). These  
131 major components are further divided into sub-components (second level of divisions within each  
132 major component) and subsequent indicator variables (measurable units of data for each sub-  
133 component) (figure 1). In our study, the exposure factor pertains to wildfire. Thus, the major  
134 components are wildfire occurrence, topography, weather, and extreme weather events. Sensitivity  
135 describes the degree to which each State is affected by wildfires. Its major components include  
136 demographic, ignition causes, and selected environmental indices that describe specific factors  
137 pertaining to wildfires, such as drought and air quality. Finally, adaptive capacity describes the  
138 ability of each State to withstand or recover from wildfires. The major components of adaptive  
139 capacity include natural capital, physical capital, human capital, social network, and financial

140 capital. Our framework (Table 2) includes the justification for selecting each indicator variable as  
141 it pertains to wildfires.

142

143 The LVI analysis is conducted for 14 fire prone American States. The States selected are Arizona,  
144 California, Florida, Idaho, Montana, Nevada, New Mexico, Oklahoma, Oregon, Utah,  
145 Washington, and Wyoming because they experienced the highest risk of wildfires in 2018, as  
146 determined from by the maximum acres burnt in 2018 and 2019 and as documented in the NIFC  
147 2019 Wildfire Risk Report (Table A1 in the appendix). In 2018, over 8.7 million acres of US land  
148 burned because of wildfire, marking the sixth-highest total since historical records began in the  
149 mid-1900s. The 14 States analyzed in this study had the largest acreage burnt in 2018 across the  
150 United States (Figure 2). Though Alaska was included as a top State listed in the 2019 Wildfire  
151 Risk Report, it was excluded from our study due to the lack of missing comprehensive data and, if  
152 included, would have impeded our comparison analysis among the other States.

153

154 Our analysis is conducted to determine the current LVI and not future LVI projections. Therefore,  
155 most of the data gathered for our assessment was acquired within the past decade (2010-2019). The  
156 exception is given to certain indicator variables that represent a long-term climatological average  
157 (1950 to 2019). In addition, the elevation data for each State was acquired from 1980, with the  
158 understanding that the elevation of each State is not time sensitive and would not have changed  
159 drastically if the measurements were acquired in 2019. The year in which the data was acquired  
160 for each indicator variable in our framework is indicated in Table 2.

161

162 Furthermore, most of the data acquired are entered directly into the framework as raw values,  
163 meaning that they did not require additional computations before the LVI was calculated.  
164 However, some indicator variables under exposure, sensitivity, and adaptive capacity required  
165 further processing to be amenable and included in the analysis. Indicator variables under the  
166 exposure that required initial computations included annual average wind speed, humidity, annual  
167 precipitation, number of days with greater than 0.1 inches or more of precipitation, and annual  
168 temperature. The National Center for Environmental Information (NCEI) provides annual  
169 averages of each indicator for various weather observation stations located in each State. The  
170 values for every weather observation station within each State were spatially averaged over the  
171 State and temporally averaged over a 30-year period (annual 1950-2019) before being used in our  
172 LVI calculations.

173  
174 The indicator variables requiring initial computation under sensitivity included the Palmer  
175 Modified Drought Index (PMDI) and the number of smokers. The National Oceanic and  
176 Atmospheric Administration (NOAA) collects monthly PMDI values from weather observing  
177 stations throughout the US every year. The 2019 annual average was calculated for each station  
178 and then averaged amongst all the stations within a State. We calculate the number of smokers  
179 using data from the United Health Foundation, which provided the percentages of smokers for  
180 every State. To accurately convey the proportions between the States, the State's population for  
181 that year was multiplied by its respective percentage of smokers. Finally, for adaptive capacity,  
182 only the indicator variable pertaining to the total area of lakes had to be computed. The original  
183 data only provided the area for each individual lake, thus, we had to aggregate the area for all lakes  
184 to produce the cumulative lake area in each State.

185

186 The motivation for including the selected indicator variables in our framework was based on  
187 current risk assessment information suggested by the open literature, such as potential health risks  
188 due to wildfires (Gannon et al., 2020). Other examples include indicator variables pertaining to  
189 fuel, weather, and topography (included in our framework) that are important drivers of wildfire  
190 danger and behaviour, as referenced heavily in the literature (Keeley and Syphard, 2019; Banerjee,  
191 2020). Environmental indices such as the PMDI and air quality were also included. While we  
192 acknowledge that there are many fire indices that could be integrated (Baijnath-Rodino et al. (*in*  
193 *review*), we selected PMDI because of its available spatial and temporal data for our study and  
194 because PMDI is a useful indicator in describing an essential environmental factor (drought)  
195 required for the potential onset, ignition, and behaviour of a wildfire (Wotton, 2006). Adding more  
196 fire indices and sub-indices would add redundancy to our framework. We further acknowledge the  
197 nuances that arise from subjectively allocating each indicator variable to a specific contributing  
198 factor in our framework and for that reason we subsequently applied a PCA to our indicator  
199 variables in order to gain confidence of our indicator categorizations within our framework.

200

201 PCA is a variable-reduction technique that takes a large set of variables and organizes them into a  
202 smaller set of principal components. For the purposes of this study, PCA was used to verify our  
203 framework by ensuring the indicator variables were loading into the respective major components  
204 that they were assigned. When conducting a PCA, four assumptions are made about the dataset:  
205 (1) the variables are measured at the continuous level; (2) there is a linear relationship between the  
206 variables; (3) there is adequate sample size; and (4) the dataset contains no outliers (Lund and  
207 Lund, 2018). In addition, two tests are conducted to determine whether the results of the PCA will

208 be beneficial when validating our framework: the Kaiser-Meyer-Olkin (KMO) Sampling  
209 Adequacy Test (Williams et al., 2010) and Bartlett's Test of Sphericity (Tobias and Carlson, 1969).  
210 The KMO test measures the proportion of variance among the indicator variables that may be  
211 caused by underlying factors. KMO is an average of the measure of sample adequacy (MSA) for  
212 each indicator variable within their respective major component. MSA values range from 0 to 1  
213 and represent the extent of a given indicator belonging to a group (Kaiser, 1970). Smaller KMO  
214 values indicate fewer correlations between a given variable and the other indicators. Therefore, if  
215 the KMO value is less than 0.5, the results from a PCA will not be useful because the indicators  
216 do not share high correlations with each other. Bartlett's test of sphericity is conducted to determine  
217 whether the correlation matrix of the indicators is an identity matrix. The null hypothesis is that  
218 the indicators are orthogonal or not correlated. The values for this test range from 0 to 1, with 0  
219 representing a rejection of the null hypothesis. If the indicator variables are not correlated, they are  
220 thereby unsuitable for factor analysis. In addition, a significance value that is less than 0.05  
221 indicates that PCA will provide helpful information. Table A2 in the appendix provides the KMO  
222 test scores for each major component by using the indicator data gathered from the 14 States.

223

224 Once the indicator variables we selected had passed these tests, a PCA was conducted. The  
225 normalized data input for PCA were the standardized index values for each indicator (standardized  
226 index calculation methods to follow). The normalized data encompasses all the indicator values  
227 for each State and for a given year (Table 2). The PCA gives insightful data such as a correlation  
228 matrix, communalities, and total variance explained. However, the output that helped reorganize  
229 and strengthen our framework was the component matrix. The component matrix displays the  
230 Pearson correlations between the indicator variables and principal components. The component

231 matrix was used to verify whether the indicator variables loaded into their respective major  
232 components. This indicates that they are measuring the same underlying construct and are,  
233 therefore, correctly grouped accordingly in our framework.

234

235 Subsequently, we calculate the LVI and the corresponding contributing factor values for each of  
236 the analyzed States. Our methods for computing the LVI follows a similar approach to Hahn et al.  
237 (2018) and Suryanto et al. (2019). Before the computation, we need to interpret whether the  
238 magnitude of each indicator value, under each contributing factor, is influencing the contributing  
239 factor positively or negatively. If affecting the contributing value negatively, then the inverse value  
240 is taken. For example, most indicator variables under exposure suggest that a higher value  
241 corresponds to a higher wildland fire exposure. However, States with higher values of humidity  
242 and precipitation suggests that these indicator variables will yield a lower wildland fire exposure.  
243 Table 2 shows the reason for including each indicator variable in our framework, with the inverse  
244 values highlighted.

245

246 To compute LVI, we first compute the Standardized Index (*SI*) for each indicator variable, where  
247 *I*, is the original indicator variable for each individual State, *I<sub>max</sub>* and *I<sub>min</sub>* represent the State  
248 with the maximum and minimum value, respectively, corresponding to that particular indicator,  
249 equation 1.

250

$$251 \quad SI = \frac{I - I_{max}}{I_{max} - I_{min}} \quad (1)$$

252

253 Second, the Major Component (*MC*) value for each State is computed by averaging the standard  
254 indices, over the number (*n*) of all indicators used in each major component, equation 2.

255

$$256 \quad MC = \frac{\sum_{i=1}^n SI}{n} \quad (2)$$

257

258 Third, each Contributing Factor(*CF*) is computed by taking a weighted average of each computed  
259 major component. This is done by multiplying each major component by its number of indicators  
260 (*Wi*), equation 3.

261

$$262 \quad CF = \frac{\sum [MC \cdot Wi]}{\sum Wi} \quad (3)$$

263 Finally, the LVI for each State is computed by combining the contributing factors of  
264 exposure(*E*), adaptive capacity(*AC*), and sensitivity(*S*), equation 4.

265

$$266 \quad LVI = (E - AC) \cdot S \quad (4)$$

267

268 The LVI and the values for each contributing factor are computed, based on our framework (Table  
269 2). Once the LVI is computed for each State, a constant value of 0.5 is added to each LVI to simply  
270 aid in visualizing and interpreting the rank of LVI (Albizua et al.2019). The results are presented  
271 and discussed in the results section.

272

273

274

275

276 **3. Results**

277 *Principal Component Analysis (PCA)*

278 A PCA was conducted for each major component to test the indicators categorized within them.  
279 Table A2 in the appendix shows the results after running the KMO and Bartlett test. All of the  
280 values from the KMO test are at least 0.5, which is the minimum required value to conduct a PCA  
281 as described in Williams et al. (2012). The only major component that is not at least 0.5 is that of  
282 weather, which has a value of 0.488. Previous research such as Wuensch (2012) suggests a KMO  
283 value of at least 0.6 in order to proceed with PCA. However, due to the small sample size and  
284 indicators tested per PCA (adaptive capacity, 13; exposure, 11; sensitivity, 9) it is difficult to  
285 achieve a KMO value of at least 0.6. Also, in this study, PCA was not utilized for its typical  
286 purpose of reducing variables, but rather, performed to verify whether the indicators within each  
287 major component loaded onto one principal component.

288

289 Table A2 in the appendix also contains the results for the Bartlett test. Some of the major  
290 components achieved a desirable value of less than 0.05. However, some had values greater than  
291 0.05. This is not an issue for two reasons. First, the major components that had a value greater than  
292 0.05 had only two indicators to test. Only having two variables to create a correlation matrix would  
293 make it very difficult to achieve a value below 0.05. Second, the purpose of conducting a Bartlett  
294 test is to assess whether the correlation matrix diverges significantly from an identity matrix for  
295 data reduction (Zach, 2019). Since the goal of the PCA is not variable reduction, the correlation  
296 matrix only needed to be proven as not an identity matrix, that is, a value closer to 0 than 1.

297

298 After computing the PCA, we analyzed the generated component matrices. To validate the  
299 framework, the indicators had to have a strong loading into their respective major components. A  
300 strong loading is considered to be any value above 0.5 and suggests that the indicators are  
301 measuring the same underlying construct. Despite the fact that a PCA was conducted for each  
302 major component, the results are compiled into three tables (Tables A3-A5 in the appendix), one  
303 for each contributing factor. Overall, most of the indicators demonstrated a strong loading into  
304 their respective major components. However, there were some indicators that had weak loadings,  
305 under a value of 0.5, for example, annual average wind speed and annual average temperature in  
306 exposure. These indicators had a factor loading of 0.166 and 0.39, respectively for the major  
307 component of weather. These low values indicate an inverse relationship between the other  
308 indicators under weather (Yong and Pearce, 2013). When a State is characterized by higher wind  
309 speed and temperature, they are more likely to be exposed to wildfires. The other indicators under  
310 weather involve humidity and precipitation. If a State is characterized by higher humidity and  
311 precipitation, then they are less likely to be exposed to wildfires. The same logic can be applied to  
312 the following indicators: acres of forests, number of timber/woodworkers, and annual PMDI.  
313 These indicators all have negative loadings for their respective major components. These inverse  
314 relationships were reflected in the calculation of the LVI. With PCA verifying the construction of  
315 the framework, the validity of the LVI results is strengthened.

316

### 317 ***LVI***

318 We compute the LVI for each of the 14 American States analyzed (figure 3). Most of the States  
319 we analyzed exhibit similar LVI values. However, Arizona and New Mexico experience the  
320 greatest livelihood vulnerability, with an LVI of 0.57 and 0.55, respectively. In contrast,

321 California, Florida, and Texas experience the least livelihood vulnerability to wildfires (0.44, 0.35,  
322 0.33, respectively) (figure 4). To understand these LVI results, we delve into analyzing each  
323 contributing factor.

324

### 325 *Exposure*

326 First, we examine each State's susceptibility to wildfire by examining the exposure contributing  
327 factor. The exposure results indicate that California, Nevada, and Arizona exhibit the highest  
328 exposure to wildfires (0.63, 0.52, and 0.49, respectively) while Oklahoma, Florida, and Montana  
329 have the least exposure (0.25, 0.21, and 0.19, respectively) (left panel in figure 5). To understand  
330 the exposure results, we assess the four major components of exposure (*wildfire*, *topography*,  
331 *weather*, and *weather extreme events*) for each State (right panel in figure 5). *Wildfire* (blue) is  
332 predominant for the State of California, Texas, and Arizona. This is because these States  
333 experience the greatest number of wildfires and the greatest acres burnt due to wildfires in 2019.  
334 Nevada and Arizona also experience relatively greater values of *weather* (yellow), which indicates  
335 favorable weather conditions for the development of wildfires, such as relatively higher winds  
336 speeds and lower humidity. In addition, *weather extreme events* (green) represent extreme wildfire  
337 and extreme heat events and are most prevalent in California and Nevada.

338

339 The major component, *topography*, represents mean height and highest elevation for each State.  
340 This variable is important because higher elevations in complex terrain can be conducive to the  
341 propagation of wildfire behavior, add uncertainties to the prediction of the wildfire rate of spread  
342 (Storey et al., 2020), and make fire suppression efforts more challenging. Thus, States with higher  
343 topographic values could potentially be more at risk, or dangerously affected by wildfires. Nevada

344 also ranks high in *topography*. While *topography* is also relatively high for other States, such as  
345 Wyoming and Utah, other major components, such as *wildfires*, *weather*, and *weather extremes*  
346 are negligible, thereby, reducing the overall exposure of wildfires in these States. Furthermore,  
347 Florida, Oklahoma, and Montana have the lowest exposures because all of their major components  
348 under exposure are ranked very low in comparison to the other States.

349

### 350 *Sensitivity*

351 Second, we assess the degree to which each State is affected by wildfires by investigating the  
352 sensitivity contributing factor. The results for sensitivity (left panel in figure 6) show California as  
353 the most sensitive State to wildfires (0.84). This is followed by Texas, with a sensitivity of 0.66.  
354 Montana and Wyoming are the least sensitive. California, Texas, and Florida are the most sensitive  
355 to wildfires because they yield the highest values of each major component under sensitivity  
356 (*demographic*, *ignition causes*, and *environmental index*) (right panel in figure 6). *Demographic*  
357 comprises sub-components, such as the wildland-urban interface (WUI) and population. States  
358 with greater areas of WUI or populations within WUI would be more sensitive to wildfires because  
359 they are within a region more exposed to wildfire events. *Ignition causes* attributed to outdoor  
360 activities such as campfires and smoking would also increase the potential inception of human-  
361 caused fires. In addition, States that experience poorer air quality and more drought will be more  
362 sensitive during and after wildfire events and seasons. The *environmental index* remains relatively  
363 constant among all States (yellow). However, California and Texas are the most sensitive States  
364 because they are driven primarily by the major components of *ignition causes* (red) and  
365 *demographic* (blue). The least sensitive State is Montana (0.08) because, in comparison to the  
366 other States, all its major components are ranked relatively low.

367

368 *Adaptive Capacity*

369 Third, we assess the ability of each State to withstand or recover from wildfires by analyzing the  
370 contributing factor of adaptive capacity. Our results indicate that California, Texas, and Florida  
371 exhibit the greatest adaptive capacity to wildfires (0.69, 0.67, and 0.48, respectively) while  
372 Oregon, Idaho and Montana are the least adaptive (0.15, 0.12, 0.12, respectively) (left panel in  
373 figure 7). The reasons for the adaptive capacity disparities among the States have to do with the  
374 major components (or capitals) each State has (*natural, physical, human, social network, and*  
375 *financial*) Table 1.

376

377 What drives the adaptive capacity to be relatively high for California, and to a slightly lesser extent  
378 Texas, are their *social network* (green) *physical capital* (red) and *financial capital* (orange) (right  
379 panel in figure 7). These two States have social structures in place to facilitate safety measures in  
380 times of wildfires such as allocating firefighters and first responders to wildland fire emergencies.  
381 These States are also more equipped with transportation accessibilities, such as closer airports and  
382 access to public roads, in case of major wildfires. California and Texas also have greater access to  
383 communication within their households, including internet signals for receiving warning alerts,  
384 both of which can be beneficial to one's livelihood during the State of an emergency wildfire  
385 evacuation. These States also rank highly in financial capital, such as having relatively higher  
386 household incomes and fire management assisted grants, which can lend financial support during  
387 wildland fire emergency hazards. Additionally, Florida also has a high adaptive capacity that is  
388 primarily driven by its *natural capital*. It has the greatest water area of all the States analyzed,  
389 thereby providing the State with water resources for fire suppression.

390 In contrast to the States with the highest adaptive capacity, Montana, Idaho, and Oregon rank very  
391 low in all capitals. Also, while some States rank high in one major component, it suffers in others,  
392 thereby driving down the rank of its overall adaptive capacity value. For example, New Mexico  
393 has a relatively high human capital in comparison to other States, which corresponds to residential  
394 density and occupation; however, all its other capitals are negligible, resulting in an overall low  
395 adaptive capacity to wildfires. This emphasizes the need to evaluate all the contributing factors in  
396 adaptive capacity to get a holistic view of the allotted resources available to aid in wildfire's  
397 resiliency measures. Adaptive capacity is one of the most important determining factors in risk  
398 assessment, as highlighted by Davies et al. (2018) who show that wildfire hazard potential can be  
399 reduced once the adaptive capacity of the State is taken into consideration.

413 **4. Discussion**

414

415 Assessing each contributing factor and its respective major components and subcomponents have  
416 provided an in-depth analysis of why the livelihood vulnerability of some States to wildfires are  
417 higher than others. Many media and scientific reports constantly show California as the State with  
418 the most dangerous and destructive wildfires, especially in recent years. The NIFC report showed  
419 that California had the highest acres burned and maximum damages in 2018 among all the  
420 American States. According to the 2019-2020 California Budget Summary, approximately ten of  
421 the most destructive wildfires in California have occurred since the year 2015. Thus, one might  
422 think that California, with the highest exposure, would have the highest LVI. Our study indicates  
423 that while California is the most exposed, and sensitive to wildfires (figure 8), it has a very high  
424 adaptive capacity to help offset its livelihood vulnerability. The California Administration has  
425 implemented solutions and recommendations to reduce wildfire risk to improve the State's  
426 emergency preparedness, response, and recovery capacity; and to further protect vulnerable  
427 communities. The 2019-2020 State budget includes 918 million dollars in additional funding to  
428 comply with these efforts. For these reasons, it is evident why California is one of the States that  
429 exhibits a lower livelihood vulnerability to wildfires.

430

431 Similarly, Texas has the lowest LVI of all the States analyzed. Despite its high sensitivity, its  
432 exposure to wildfire is relatively lower than more than 25% of the other States and has the second-  
433 highest adaptive capacity. Texas is highly sensitive to wildfires. According to Texas A&M Forest  
434 Service (2020), there have been over 150,000 wildfires consuming more than 9 million acres since  
435 2005 with 71,499 wildfires in 2017 alone. Ninety percent of wildfires in Texas are human caused

436 as a result of debris burning, sparks from welding and grinding equipment, poorly discarded  
437 smoking materials, vehicles' exhaust systems, and arson. Moreover, according to Headwater  
438 Economics (2018) parts of Texas that are experiencing the fastest population growth are spatially  
439 correlated with regions of highest wildfire threat and greater proportions of vulnerable people.  
440 These factors explain why Texas is highly sensitive to wildfires. However, we suggest that similar  
441 to California, Texas has a very high adaptive capacity, which drastically influences its livelihood  
442 vulnerability to wildfires. This high adaptive capacity is driven primarily by social network,  
443 physical capital, and financial capital. According to the Texas A&M Forest Service (2020), Texas  
444 has resources to deploy wildfire risk information and create awareness about wildfire concerns  
445 across the State through using a Texas Wildfire Risk Assessment Portal (TxWRAP). Furthermore,  
446 data produced from this portal is part of the Texas Wildfire Risk Assessment Project (WRA) that  
447 has further positioned the Texas Forest Service as a national leader in wildfire protection planning.  
448 These resources have positioned Texas to help withstand natural hazards pertaining to wildfires.

449  
450 Additional considerations should also be taken into account for States like Arizona that exhibit a  
451 high LVI, as well as for States like California that exhibits a high exposure, but low LVI. Arizona  
452 has high biophysical exposures of wildfires and high sensitivity to environmental indices such as  
453 drought and poor air quality. According to the U.S. Census Bureau, Arizona is among the top three  
454 States with highest rates of population growth in the nation. There have been more than 120,000  
455 new residents (doubled California's 50,635 new residents) in the 2018-2019 time period alone,  
456 with a projected population of over 10 million people by 2050, according to the Arizona Commerce  
457 Authority. It can be assumed that with such growth, urbanization, transportation, and  
458 communication services will increase, thereby, making Arizona more sensitive to wildfire risk, as

459 9 out of 10 wildland fires are started by humans according to the Arizona Department of Forestry  
460 and Fire Management.

461

462 There is also future concerns for the State of California, despite having a low LVI. Its resultant  
463 exposure to wildfire is the highest amongst all States, thereby requiring continuous observations  
464 and monitoring. According to Miller et. al. (2020), the increased number of fires in California is  
465 due to a combination of climate change that has heightened hot and dry conditions and fire  
466 suppression policies that have allowed the accumulation of fuels in the landscape. As stated by  
467 numerous dependencies in the California Forest Carbon Plan in 2018, wildfire emissions are  
468 projected to increase by 19%-101% using the 1961-1990 years as the baseline period. If current  
469 forest management techniques and global greenhouse gas emissions continue, wildfire smoke will  
470 increase, only exacerbating these emissions and worsening the current health impacts. Therefore,  
471 looking to the future, mitigation and resilience strategies need to be developed and adopted for the  
472 high LVI States, such as Arizona; and continued efforts are required for, relatively, low LVI but  
473 high exposure States such as California in order to facilitate and provide resources to help adapt  
474 to biophysical wildfire hazards in the future.

475

476 Actions are being taken to address wildfire impact across California and the United States by the  
477 Environmental Protection Agency (EPA), the US Forest Service, and other agencies. EPA recently  
478 published a Wildland Fire Research Framework coordinating its wildland-fire-related research  
479 across multiple national research programs that will be implemented in the 2019-2022 Strategic  
480 Research Action Plans (EPA, 2019). This framework has different roles for multiple federal  
481 agencies to collaborate with the EPA Office of Research and development. The US Forest Service

482 has a network of fire labs and research stations that focus on understanding and modeling fire  
483 processes. Other agencies, such as The National Weather Service focuses their efforts on smoke  
484 plume modeling and hazard mapping. The National Aeronautics and Space Administration  
485 (NASA), promotes the use of Earth observations and models focused on addressing issues  
486 pertaining to wildland fire in support of management strategies, business practices, and policy  
487 analysis and decision support. According to EPA (2019), other agencies across the United States  
488 that are involved in wildfire assessment include, but not limited to: the Fire Research Division by  
489 the National Institute of Standards and Technology (NIST); Centers for Disease Control and  
490 Prevention (CDC); National Institute of Environmental Health Sciences (NIEHS), the U.S. Fire  
491 Administration by the Federal Emergency Management Agency (FEMA); the Division of  
492 Atmospheric and Geospace Sciences by the National Science Foundation (NSF); the Atmospheric  
493 System Research (ASR) Program by the U.S. Department of Energy (DOE); the Office of  
494 Wildland Fire (OWF) by the U.S. Department of Interior; The Fire Ecology and Research and  
495 Wildland Fire Program by the National Park Service (NPS); the Fire and Aviation Program by the  
496 Bureau of Land Management (BLM), and the Wildland Fire Science and Wildfire Hazards  
497 program by the U.S. Geological Service (USGS). However, despite these efforts, fire management  
498 practices and policies need to continue to evolve. This is because policies used in the past are not  
499 necessarily the ones required moving forward.

500

501 The need to adopt contemporary practices are beneficial for resiliency and mitigation methods.  
502 For example, following a massive fire that burned 3 million acres in Montana, Idaho, and  
503 Washington, Silcox, (1910), policies focusing on fire suppression and prevention became  
504 dominant in the early 1900s and was the foundation of California's economic theory of wildfire

505 management (Headley et al., 1916; Rideout et al. 2008). However, according to the recent  
506 California Policy Center (2017), fire suppression techniques only worked as short term solutions,  
507 resulting in over one-hundred million dead or dying trees, overgrown forests, and fuel  
508 accumulation, increasing the risk for dangerous wildland fires. Thus, the continued need for  
509 evolving and enhancing fire management techniques and practices is essential for accurately  
510 monitoring and improving wildfire risk assessments.

511  
512 One fire management practice is the implementation of prescribed burns. Prescribed fires are a  
513 technique used to manage fuels in forests in a coordinated and planned manner (McCaw, 2012),  
514 and policymakers recognize the critical importance prescribed burns have on reducing the impact  
515 of large and damaging wildfires (York et al., 2020). However, more implementation of prescribed  
516 burns is currently needed. While 1 billion dollars in California state-wide funding is aimed at  
517 reducing the century-long buildup of forest fuels in the next five years, only a small fraction of  
518 prescribed burns are being conducted. For instance, although the California Carbon plan has a goal  
519 of treating 500 000 acres of private land each year, in 2017-2018 only 33 000 acres of private land  
520 were managed (Newsom, 2019; York et al., 2020). Private landowners own approximately half of  
521 the mixed-conifer forests in California, and prescribed burns can help protect their property and  
522 contribute to reducing the impact of large wildfires to the broad public. Another caveat, however,  
523 is the need for burn permits, which are significantly challenging to obtain by landowners (York et  
524 al., 2020). Thus, while progress is being made to adopt mitigation and resilience strategies to  
525 addressing wildfire risk, issuing and obtaining burn permits are still problematic. Therefore, we  
526 emphasize the need for constant re-evaluations to policies and management practices in wildfire

527 assessment risk, especially during the rapidly changing climate and land-use/land-cover conditions  
528 that will inevitably impact communities' livelihood vulnerability to wildfire events.

571 **5. Conclusions**

572

573 Across the United States, wildfires can produce great environmental and socio-economic risks. To  
574 quantify these risks across multi-scale, socio-economic, and biophysical variables, we produce a  
575 framework to compute a livelihood vulnerability index for the top 14 American States that are  
576 most at risk for wildfires. Our framework comprises contributing factors (exposure, sensitivity,  
577 and adaptive capacity), major components, sub-components, and indicator variables. Our  
578 framework was further justified by performing a principal component analysis to provide  
579 additional confidence in our approach.

580

581 Our results indicate that the States of Arizona and New Mexico experience the greatest livelihood  
582 vulnerability, with an LVI of 0.57 and 0.55, respectively and California, Florida, and Texas  
583 experience the least livelihood vulnerability to wildfires (0.44, 0.35, 0.33, respectively). LVI is  
584 weighted strongly on the contributing factors. For example, while California has a high exposure  
585 and sensitivity to wildfires, it has high adaptive capacity capitals that offset these concerns.  
586 Additionally, livelihood vulnerability depends largely on sensitivity indicator variables, such as  
587 population density. We acknowledge that with Arizona's high LVI, and steady population growth,  
588 that continued wildfire risk management and urban planning strategies are essential for reducing  
589 the biophysical and socio-economic impact of wildfires in the future and to further avoid an  
590 increase in its LVI.

591

592 The results from this study are critical to researchers, government and policymakers, in identifying,  
593 allotting, and providing better resiliency and adaptation measures to support the American States

594 that are most vulnerable to wildfires. Further research can be conducted, following the same  
595 framework for each of the State's geo-political subdivisions in order to better understand the risk  
596 and vulnerability of growing wildland-urban interface zones and to determine what urban-  
597 boundary limitations should be considered for risk assessment studies. Moreover, additional  
598 research can be conducted to assess future LVI scenarios by employing high-resolution forecast  
599 models to help guide future wildland fire exposure projections in vulnerable communities within  
600 the United States.

632 **Table 1.** LVI terminology definitions, colour coordinated by major components in each  
633 contributing factor: adaptive capacity (green), exposure (red) and sensitivity (blue). Gray  
634 highlights denote terms that are frequently used in livelihood vulnerability literature  
635

Terminology	Definition
Contributing factor	Overarching biophysical and socio-economic factors used to calculate LVI (exposure, adaptive capacity, and sensitivity)
Adaptive capacity	The system's (State's) ability to withstand or recover from the exposure (wildfire)
Exposure	The magnitude and duration of the climate-related exposure such as a drought or change in precipitation
Sensitivity	The degree to which the system/community is affected by the exposure (wildfire)
Major component	The first level of divisions within each contributing factor
Financial capital	Considers financial resources a system (State) has to help adapt to an exposure (wildfire) e.g. grants, income
Human capital	Considers human resources a system (State) has to help adapt to an exposure (wildfire) e.g. Occupation type
Natural capital	Considers natural resources in a system (State) that helps a system adapt to an exposure (wildfire) e.g. Lakes, forests
Physical capital	Considers materials and resources that a system (State) has to help adapt to an exposure (wildfire) e.g. Transportations and communication types
Social network	Considers social constructs that are in place by a system (State) to help adapt to an exposure (wildfire) e.g. Safety practices

Wildfire Occurrence	Considers metrics used to quantify the number of wildfires in a State, e.g. wildfire occurrence, loss of wildland
Topography	Considers metrics used to quantify topography of landscape, e.g. elevation height
Weather	Considers the meteorological metrics that influences wildfire behavior, e.g. air temperature
Weather Extreme Events	Considers metrics that quantifies extreme environmental conditions conducive for wildfires e.g. extreme heat
Demographic	Considers metrics that describe population structure of a State, e.g. population density
Ignition causes	Considers metrics pertaining to potential ignition sources for the onset of a wildfire, e.g. smoking
Environment Indices	Indices that compute a potential risk related to wildfires, e.g. an air quality index
Subcomponent	The second level of divisions within each major component
Indicator variables	Measurable units of data for each sub-component
Livelihood vulnerability index (LVI)	A vulnerability assessment tool to address issues of sensitivity, exposure and adaptive capacity to climate change (wildfire) in fire-prone communities

638 **Figure. 1** Description of the framework developed for the LVI (box 1 and the central gray circle).  
 639 LVI is represented by contributing factor (box 2). The contributing factors are sensitivity (blue),  
 640 exposure (red), and adaptive capacity (green). The contributing factors are further divided into  
 641 major components (box 3). The major components are color-coordinated with the contributing  
 642 factors. The major components for sensitivity (blue) are demographic, ignition causes, and  
 643 environmental index (light blue); for exposure (red) are wildfire occurrence, topography, weather,  
 644 weather extreme events (light red); for adaptive capacity (green) are social network, natural,  
 645 physical, human, and financial capital (light green). Major components are divided into sub-  
 646 components (box 4) and represented by the sub-components in the outermost part of the circle.  
 647 The sub-components are further divided into indicators (box 5) and not shown in this figure. Refer  
 648 to Table 2 for each indicator variable.

651 **Table 2.** LVI framework with a description of the contributing factors, major components, sub-  
652 components, indicator variables and their corresponding justifications for being included in the  
653 framework. The headings of red, green, and blue represent the contributing factors of exposure,  
654 adaptive capacity, and sensitivity, respectively. Highlighted indicators represent values that  
655 contribute negatively to the contributing factor, and the inverse value is computed for input into  
656 the LVI calculation  
657

EXPOSURE						
Major Components	Sub-Components	Indicator Variables	Justification	Units	Year	Data Source
Wildfires	Wildfire occurrence	Number of wildfires (2019)	States that have experienced more wildfires will have vulnerable residents	number in 2019	2019	<a href="https://www.iii.org/fact-statistic/facts-statistics-wildfires#Wildfires%20By%20State,%202019">https://www.iii.org/fact-statistic/facts-statistics-wildfires#Wildfires%20By%20State,%202019</a>
	Loss of wildland	Number of acres burnt to wildfires in 2019	Changes in land cover can have negative environmental knock-on effects such as flash flooding; loss of wildland means more investments required to restore forests and structures lost in these regions	Acres	2019	<a href="https://www.predictiveservices.nifc.gov/intelligence/2019_statussumm/fires_acres19.pdf">https://www.predictiveservices.nifc.gov/intelligence/2019_statussumm/fires_acres19.pdf</a>

<b>Major Components</b>	<b>Sub-Components</b>	<b>Indicator Variables</b>	<b>Justification</b>	<b>Units</b>	<b>Year</b>	<b>Data Source</b>
<b>Natural Capital</b>	Forest	Acres of forests	Greater the number of forests the greater the potential fuel source	acres	2016	<a href="https://www.fs.usda.gov/sites/default/files/fs_media/fs_document/publication-15817-usda-forest-service-fia-annual-report-508.pdf">https://www.fs.usda.gov/sites/default/files/fs_media/fs_document/publication-15817-usda-forest-service-fia-annual-report-508.pdf</a>
	Lakes/water bodies	Water area	Greater the number of water bodies the more water resources are available to help with fire suppression	square miles	2016	<a href="https://www.usgs.gov/special-topic/water-science-school/science/how-wet-your-state-water-area-each-state?qt-science_center_objects=0#qt-science_center_objects">https://www.usgs.gov/special-topic/water-science-school/science/how-wet-your-state-water-area-each-state?qt-science_center_objects=0#qt-science_center_objects</a>
		Area of lakes	Greater the number of water bodies the more water resources are available to help with fire suppression	acres	2010	<a href="https://www.uslakes.info/">https://www.uslakes.info/</a>

<b>Physical Capital</b>	Transportation	Miles of public road	Greater the miles of public roads available, the better equipped states are to assist with evacuation routes	miles	2020	<a href="https://www.bts.gov/content/state-transportation-numbers">https://www.bts.gov/content/state-transportation-numbers</a>
		Major airports	Greater the number of airports, the better suited states are to assist with evacuation routes	number	2020	<a href="https://www.bts.gov/content/state-transportation-numbers">https://www.bts.gov/content/state-transportation-numbers</a>
	Communication	Households with a computer	Greater the number of computers will there by help with accessing warning information	number	2014-2018	<a href="https://www.census.gov/quickfacts/fact/map/CA,US/HSG445218">https://www.census.gov/quickfacts/fact/map/CA,US/HSG445218</a>
		Households with broadband internet connection	Greater the number of households with internet will thereby help with accessing warning information	number	2014-2018	<a href="https://www.census.gov/quickfacts/fact/map/CA,US/HSG445218">https://www.census.gov/quickfacts/fact/map/CA,US/HSG445218</a>

<b>Human Capital</b>	Residential density	Persons per households	Damages due to wildfire, how many people in household are affected	Number	2019	<a href="https://www.census.gov/quickfacts/fact/table/US#">https://www.census.gov/quickfacts/fact/table/US#</a>
----------------------	---------------------	------------------------	--	--------	------	---

	Occupation	Timber/wood labour	The number of people actively involved in the forestry industry, with lower numbers suggesting less people impacted by potential wildfires	number	2019	<a href="https://data.bls.gov/oes/#/geoOcc/Multiple%20occupations%20for%20one%20geographical%20area">https://data.bls.gov/oes/#/geoOcc/Multiple%20occupations%20for%20one%20geographical%20area</a>
<b>Social Network</b>	Safety	Firefighters	Greater the number of firefighters, greater the resources to help with fire suppression	number	2019	<a href="https://data.bls.gov/oes/#/geoOcc/Multiple%20occupations%20for%20one%20geographical%20area">https://data.bls.gov/oes/#/geoOcc/Multiple%20occupations%20for%20one%20geographical%20area</a>
		First responders (EMTs)	Greater the number of firefighters, greater the resources to help with fire suppression	number	2019	<a href="https://data.bls.gov/oes/#/geoOcc/Multiple%20occupations%20for%20one%20geographical%20area">https://data.bls.gov/oes/#/geoOcc/Multiple%20occupations%20for%20one%20geographical%20area</a>
<b>Financial Capital</b>	Income	Median household income	Greater the income, the more resources, and capacity they have to adapt and respond to exposure	dollars	2018	<a href="https://www.census.gov/library/visualizations/interactive/2018-median-household-income.html">https://www.census.gov/library/visualizations/interactive/2018-median-household-income.html</a>
	Grant	Fire management assistance grants	Greater the number, the better assistance for fire suppression efforts	number	2017	<a href="https://fas.org/sgp/crs/misc/R44966.pdf">https://fas.org/sgp/crs/misc/R44966.pdf</a>

SENSITIVITY						
Major Components	Sub-Components	Indicator Variables	Justification	Units	Year	Data Source
<b>Demographic</b>	WUI	WUI area	Area most at risk for wildfires	km2	2010	<a href="https://www.fs.fed.us/nrs/pubs/rmap/rmap_nrs8.pdf">https://www.fs.fed.us/nrs/pubs/rmap/rmap_nrs8.pdf</a>
		Number of houses within WUI zones	Houses at high and extreme risk from wildfire in the most wildfire-prone states	Number	2010	
		Population at risk in WUI Zones	Densely populated areas are more exposed and require more resources during wildfire natural disaster	Number	2010	
	Population	Population density (2019)	May require more assistance and at-risk during wildfire event	Number	2019	<a href="https://www.census.gov/quickfacts/fact/map/CA,US/HSG445218">https://www.census.gov/quickfacts/fact/map/CA,US/HSG445218</a>

		Housing units	The greater urbanization sprawl, the more it can infringe on forested regions	Number	2019	<a href="https://www.census.gov/quickfacts/fact/table/US#">https://www.census.gov/quickfacts/fact/table/US#</a>
--	--	---------------	---	--------	------	---

<b>Ignition Causes</b>	Outdoor Activities	Number of camping sites	Campsites may have campfires and might be ignition sources	Number	2019	<a href="https://camping-usa.com/campgrounds/">https://camping-usa.com/campgrounds/</a>
	Smoking	Number of smokers	Smokers are considered individuals likely to start a fire by accident	Million People	2019	<a href="https://www.americahealthrankings.org/explore/annual/measure/Smoking/state/CA">https://www.americahealthrankings.org/explore/annual/measure/Smoking/state/CA</a>

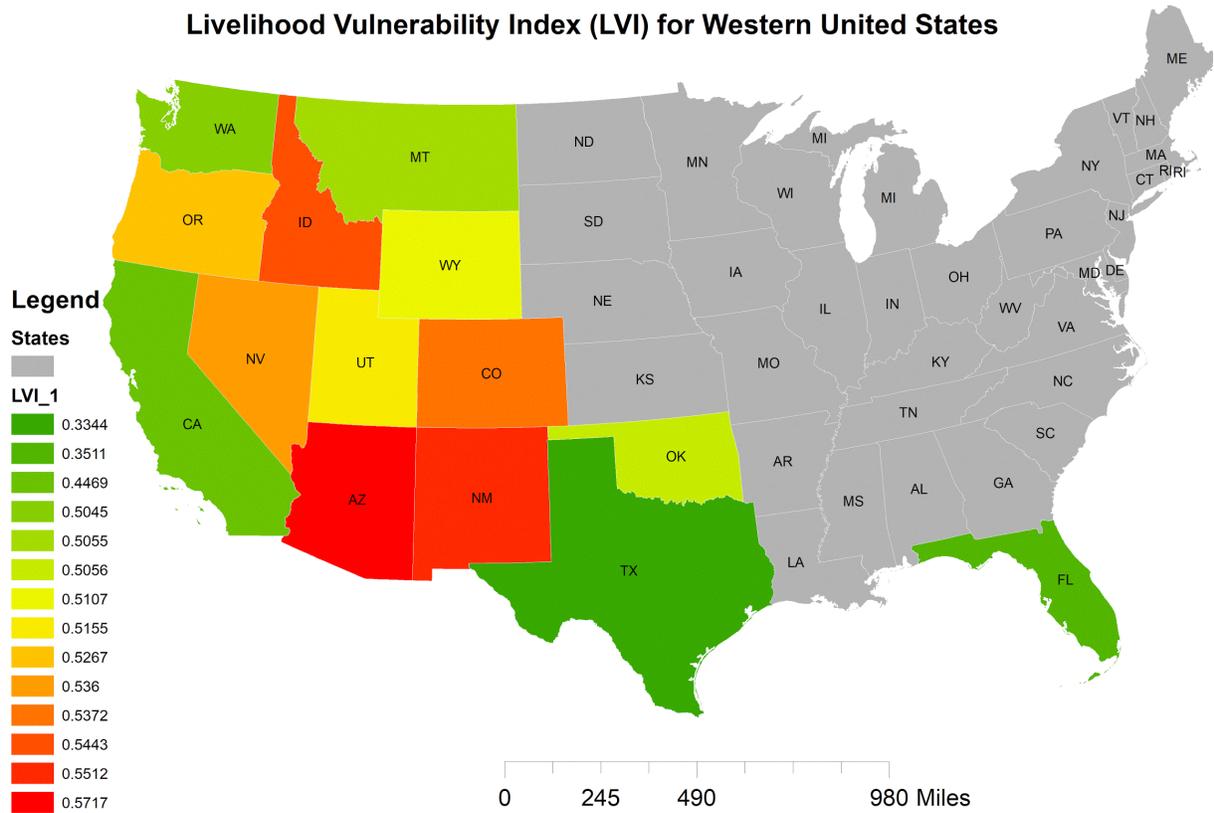

<b>Environmental Index</b>	Index (PDMI)	2019 Annual PDMI	Uses temperature and precipitation to estimate relative dryness. (Palmer Modified Drought Index)	Number	2019	<a href="https://www.ncdc.noaa.gov/temp-and-precip/drought/nadm/indices/palmer/div#select-form">https://www.ncdc.noaa.gov/temp-and-precip/drought/nadm/indices/palmer/div#select-form</a>
	Index (AQI)	Annual AQI	Population that is likely to experience increasingly severe adverse health effects.	Number	1999-2009	<a href="http://www.usa.com/rank/us--air-quality-index--state-rank.htm?hl=CA&amp;h1st=CA">http://www.usa.com/rank/us--air-quality-index--state-rank.htm?hl=CA&amp;h1st=CA</a>

689 **Figure. 2** Map of the United States with the States analyzed shaded in orange and states not  
 690 considered shaded in gray. The states considered were selected based on the 2019 Wildfire Risk  
 691 report on the acreage size burnt in 2018 and 2019, indicated by the red circles, ranging from the  
 692 smallest circle (burn area less than 90 000 acres) to the largest circle (burn area exceeding 1 million  
 693 acres). Note, while Alaska was a top State for burnt area, it was removed from the LVI analysis  
 694 due to lack of available data.
