18 **Key Points**

19 • High-frequency *S*-coda and long-period Rayleigh waves from repeating earthquakes reveal velocity

20 changes since the 2004 Sumatra Earthquake

21 • *S*-coda velocity changes underwent steady recovery from 2005 to 2015, while Rayleigh wave

22 velocities decreased significantly in late 2007

23 • Temporal differences in *S*-coda and Rayleigh velocity changes can delineate slow deformation at

24 depth and healing of the surface damage zone

25

26 **Abstract**

27   Temporal changes in the subsurface seismic velocity structure reflect the physical processes

28 that modulate the properties of the media through which seismic waves propagate. These processes,

29 such as healing of the surface damage zone and deep crustal deformation, are described by similar

30 functions and operate on similar timescales, making it difficult to determine which process drives the

31 observed changes. We examine earthquake-induced velocity changes using the measured lag-time

32 time series $\tau(t)$ of the repeating earthquake sequences since the 2004 M_w 9.2 Sumatra and 2005 M_w

33 8.6 Nias earthquakes. The *S*-coda velocity changes (δV_S, equivalent to $-\tau_S$) recover steadily during

34 the 2005−2015 period. The Rayleigh wave velocity changes (δV_{LR}, or $-\tau_{LR}$) undergo transient

35 recovery, followed by a strong δV_{LR} reduction in late 2007. δV_S recovery is most likely driven by

36 deep processes, whereas the temporal breaks in δV_{LR} recovery in 2007 reflect surface damage and

37 healing induced by the strong ground motions of the 2004 M_w 9.2, 2005 M_w 8.6, 2007 M_w 8.4 and

38 M_w 7.9 Bengkulu, and 2008 M_w 7.3 Simeulue earthquakes. The observed differences between the

39 temporal variations in δV_S and δV_{LR} can distinguish deep processes from healing of the surface

40 damage zone.

2

41

Plain language summary

Earthquake slip leads to stress relaxation in the crust, whereas healing of the damage induced by strong ground motion predominantly occurs in the near-surface. Temporal changes in the seismic velocity structure after large earthquakes can be driven by diverse mechanisms, such as aseismic slip or fault zone healing, but the timescales governing these processes are very similar, making them difficult to distinguish. We detect temporal velocity changes in the crust since the great 2004 Sumatra and 2005 Nias earthquakes using the high-frequency late-arriving scattered waves after the S phase and long-period Rayleigh waves of repeating earthquakes. We find that the temporal velocity changes in the scattered waves exhibit steady logarithmic recovery from 2005 to 2015, whereas the Rayleigh-wave velocity recovery was interrupted by several large earthquakes after late 2007. The difference between these two temporal trends in velocity change is the key to distinguishing between a damage/healing/re-damage cycle near the surface and slow deformation (e.g., afterslip, post-seismic relaxation) at depth. Rayleigh waves are highly sensitive to the near-surface damage and healing after the 2004/2005 events, and also the repeated damage induced by the 2007 and 2008 earthquakes. Steady velocity recovery of the scattered waves primarily corresponds to slow deformation at depth.

57

1. Introduction

Long-term monitoring of temporal seismic-velocity variations in the crust is an important and long-sought goal in geophysics because these temporal changes can be proxy measures for the mechanical processes and timescales of crustal responses to earthquake slip. Numerous studies have suggested that these temporal velocity changes are often associated with the peak ground velocity (PGV) or acceleration (PGA) that is induced by the strong ground motion (GM) of an earthquake [*Rubinstein and Beroza*, 2004a; *Schaff and Beroza*, 2004; *Y. G. Li et al.*, 2006; *Rubinstein et al.*, 2007;

3

65 *Wegler et al.*, 2009; *Takagi et al.*, 2012; *T. Yu and Hung*, 2012; *Hobiger et al.*, 2016]. Strong GM

66 damages the subsurface sediment layer, which is subjected to low confining pressures of only a few

67 tens of MPa [*Wu et al.*, 2009; *Zhao and Peng*, 2009; *Sawazaki et al.*, 2015; *L. Li et al.*, 2017]. The

68 subsequent velocity recovery, which probably reflects healing of the subsurface damage zone, is

69 typically characterized by a logarithmic time dependence (so-called "slow dynamics") [*TenCate et*

70 *al.*, 2000; *Peng and Ben-Zion*, 2006; *Brenguier et al.*, 2008; *Snieder et al.*, 2017].

71

72   These temporal velocity changes may also be associated with aseismic slip (or slip rate), post-

73 seismic afterslip [*Rivet et al.*, 2011; *W. Yu et al.*, 2013a], and viscoelastic relaxation in the bulk crust.

74 Post-seismic transients due to afterslip and dilatancy recovery occur adjacent to the earthquake slip

75 zone, and can modulate the crack density and pore pressure, yielding recoveries in S-wave velocity

76 and Poisson's ratio [*Peltzer et al.*, 1996; *Fialko*, 2004; *Fielding et al.*, 2009]. Viscoelastic relaxation

77 mainly occurs in the lower crust and upper mantle over longer timescales, and can restore the stress

78 perturbation induced by co-seismic slip [*Barbot and Fialko*, 2010; *Qiu et al.*, 2018; *Tang et al.*, 2019].

79 Post-seismic transient processes due to dilatancy recovery [*Jónsson et al.*, 2003; *Fialko*, 2004],

80 afterslip [*Froment et al.*, 2013], and viscoelastic relaxation all follow similar logarithmic decay

81 patterns. However, it is difficult to unambiguously associate an observed logarithmic velocity

82 recovery with a specific physical mechanism and/or depth [*Obermann et al.*, 2013; *Obermann et al.*,

83 2016; *Yang et al.*, 2019] since all of the processes that influence the subsurface damage zone and

84 post-seismic transients operate on similar timescales. For example, both the healing of the fault zone

85 [*Y. G. Li et al.*, 1998] and decay time of post-seismic deformation [*Fialko*, 2004] are on the order of

86 several years for the 1992 M_w 7.3 Landers Earthquake.

87

4

88   *W. Yu et al*. [2013b; a] detected repeating earthquakes (REs) near the Sumatra Subduction Zone

89   and used these repeaters to probe the temporal changes in seismic velocity induced by the 2004 M_w

90   9.2 Sumatra and 2005 M_w 8.6 Nias earthquakes during 2005–2008. They found that the temporal

91   velocity changes in the high-frequency (HF, 0.5−2.0 Hz) *S*-wave codas (δV_S) and long-period (LP,

92   0.03−0.1 Hz) Rayleigh waves (δV_{LR}) followed similar logarithmic recovery timescales after the 2004

93   and 2005 earthquakes that were potentially linked to strong GM-induced surface damage or/and post-

94   seismic afterslip. However, the ability to distinguish the velocity changes induced by deep processes

95   from healing of the subsurface damage zone remains a challenge, as mentioned above.

96

97   Cracks produced by a previous earthquake can multiply within the subsurface damage zone as

98   a result of the strong GM induced by subsequent earthquakes [*Rubinstein and Beroza*, 2004a]. If the

99   logarithmic velocity recovery reflects healing of the subsurface damage zone, then the re-damage

100   process from subsequent large earthquakes could result in further reduction of the seismic velocity,

101   reversing the established recovery pattern [*Vidale and Li*, 2003; *Rubinstein and Beroza*, 2004a;

102   *Sawazaki et al.*, 2018]. However, velocity recovery is likely to continue without reversal if it is driven

103   by post-seismic afterslip or other deep processes, even in the event of another earthquake. Therefore,

104   the ability to detect such a bifurcation in the temporal velocity recovery patterns would help

105   discriminate between the healing of surface damage zones and slow deformation in the crust.

106

107   The 2004 M_w 9.2 Sumatra Earthquake [*Ammon et al.*, 2005; *Park et al.*, 2005; *Subarya et al.*,

108   2006; *Chlieh et al.*, 2007] has been followed by a series of large earthquakes that have occurred in

109   the proximity of the 2004 rupture zone and in the Wharton Basin, northeast Indian Ocean (Fig. 1; see

110   Table S1 for the event IDs). Examples of the former include the 2005 M_w 8.6 Nias Earthquake [*Hsu*

111   *et al.*, 2006; *Ishii et al.*, 2007; *Konca et al.*, 2007], 2007 M_w 8.4 and M_w 7.9 Bengkulu double

112   earthquakes [*Konca et al.*, 2008; *Tsang et al.*, 2016], 2008 M_w 7.3 Simeulue Earthquake [*Morgan et*

113   *al.*, 2017], and 2010 M_w 7.8 Banyak Earthquake, and examples of the latter include the 2012 M_w 8.6

114   and M_w 8.2 double earthquakes [*Yue et al.*, 2012; *Wei et al.*, 2013; *Hill et al.*, 2015]. The strong GM

115   generated by these large earthquakes can repeatedly damage the surface layer and interrupt healing,

116   whereas the large post-seismic afterslip from the 2004 M_w 8.8 Sumatra and 2005 M_w 8.2 Nias events

117   [*Hsu et al.*, 2006; *Chlieh et al.*, 2007; *Hoechner et al.*, 2011; *Feng et al.*, 2015] (Fig. 1), among other

118   slow deformation processes, potentially drives continuous velocity changes. The main goal of this

119   work is to examine how seismic-velocity change measurements from different attributes can help

120   differentiate between these concurrent processes.

121

122   We extend our previous work [*W. Yu et al.*, 2013a] by incorporating seven additional years of

123   regional seismic waveform data, which expands our RE dataset to the 2005–2015 time period. We

124   discuss the data processing procedures, and summarize the observed temporal velocity changes in

125   δV_S and δV_{LR} in the following sections, where we highlight a clear bifurcation in the δV_S and δV_{LR}

126   patterns: δV_S follows a monotonic logarithmic recovery, while δV_{LR} deviates from the background

127   recovery rate in late 2007. We then investigate the sensitivity of the seismic velocity model to the

128   first-order pattern of the observed lag-time time series $\tau(t)$ of the HF S-coda and LP Rayleigh waves

129   using a series of perturbed velocity models.

130

131   **2. Seismic data, and $\tau(t)$ and δV measurements**

132   **2.1 Repeating earthquakes recorded by seismographic station PSI**

133   The procedural details for the RE detection and relative location assessment within a given

134   earthquake sequence have been discussed in previous studies [*Wen*, 2006; *W. Yu and Wen*, 2012; *W.*

6

135 *Yu*, 2013; *W. Yu et al.*, 2013b]. Several previously identified RE sequences continued to occur in the

136 afterslip zones of the 2004 and 2005 earthquakes until the end of 2015 (Fig. 1). The high-precision

137 relative hypocenter locations of these REs (relative to the estimated rupture area of the selected RE

138 sequences) are presented in the Supporting Information (Text S1, Fig. S1, and Table S2).

139 Seismographic station PSI, which was installed in Parapat, Sumatra, Indonesia, in 1993, is equipped

140 with a Streckeisen STS-2 broadband sensor. Station PSI detected the REs immediately after the 2004

141 and 2005 mainshocks, and it is in an advantageous position to potentially detect the δV induced by

142 the 2005 event since the seismic waves from the RE sequences associated with the 2005 event

143 propagated through the main slip and surface damage zones of the 2005 event as they traveled to

144 station PSI.

145

146 **2.2 $\tau(t)$ measurements using coda wave interferometry**

147 Coda wave interferometry is used to measure the $\tau(t)$ of the HF *S*-coda and LP Rayleigh waves

148 relative to the direct *P*-wave onset in a given RE sequence [*Poupinet et al.*, 1984; *Snieder et al.*, 2002;

149 *Snieder*, 2006]. The HF waveforms are convolved using a zero-phase two-pole Butterworth bandpass

150 filter with 0.5 and 2.0 Hz corner frequencies, and the LP Rayleigh waves are bandpass filtered

151 between 0.03 and 0.1 Hz. The reference event of a given RE sequence is chosen as the last event

152 before late 2007, when the onset of an additional increase in the Rayleigh-wave lag times (τ_{LR}) is

153 detected (to be discussed in Section 3). We measure the differential time of the first 4-s HF *P*-wave

154 between the target and reference events via the cross correlation (CC) of each RE pair. We adopt 4-

155 and 40-s sliding windows for the HF coda and LP surface waves, respectively, with a 95% overlap

156 between successive time windows for both waves. The $\tau(t)$ for the HF *S*-coda and LP Rayleigh waves

157 are computed as the time differences between either the HF *S*-coda or LP Rayleigh waves, and the

158 HF *P*-wave onset using a sliding-window CC approach. A 50-ms sampling interval of the original

159 time series is interpolated to a 5-ms sampling interval to achieve subsample precision in time. Note

7

160 that the subsample precision can also be attained by interpolating the resulting CC time series. We

161 find that the $\tau(t)$ calculated via CC of the interpolated time series is identical to that obtained via

162 interpolation of the resulting CC time series. The $\tau(t)$ for the HF S-coda waves (τ_S) can be expressed

163 as follows:

164 $$t_S = (t_{S\text{-}coda}^{trg} - t_{S\text{-}coda}^{ref}) - (t_{HFP}^{trg} - t_{HFP}^{ref}), \tag{1}$$

165 where t refers to the arrival times (or lapse times) of the 4-s HF P- (subscripted "HF P") and S-coda

166 (subscripted "S-coda") waves between the target (superscripted "trg") and reference (superscripted

167 "ref") events of a given RE pair. The $\tau(t)$ for the 20-s dominant period (LP) Rayleigh waves (τ_{LR}) can

168 be expressed as follows:

169 $$t_{LR} = (t_{20sLR}^{trg} - t_{20sLR}^{ref}) - (t_{HFP}^{trg} - t_{HFP}^{ref}). \tag{2}$$

170 The $\tau(t)$ measurements can eliminate the uncertainties due to the relative origin time error of the event

171 catalog and Global Positioning System (GPS) clock drift error between the two events in a given RE

172 pair. The earthquake-induced crustal velocity reduction could also influence the arrival time of the

173 direct P-wave from the target events and introduce a bias in $\tau(t)$. The direct P-wave is insensitive to

174 the medium changes compared with the later part of the coda [*Poupinet et al.*, 1984; *Snieder et al.*,

175 2002] and Rayleigh waves since it has the shortest propagation path. Figures 2a and 2c display

176 example HF coda and LP Rayleigh waveforms from the N1 RE sequence that were recorded by

177 station PSI, respectively, with the waveforms of the target events aligned via CC of the 4-s HF P-

178 wave between the target and reference events. Figures 2b and 2d display the calculated $\tau(t)$ of the HF

179 coda and LP Rayleigh waves from the corresponding waveforms displayed in Figures 2a and 2c,

180 respectively. Signal-to-noise ratios (SNRs) are used to sort the time segments with sufficient signal

181 strength, and are defined as follows: the noise amplitude is measured as the maximum amplitude in

182 the 5–15-s time window before the P-wave arrival, and the signal amplitude is measured as the

183 maximum amplitude in a given time window. *W. Yu et al.* [2013a] previously adopted SNR

184 thresholds of 5 for HF S-coda waves and 10 for LP Rayleigh waves. However, a minimum threshold

185 of SNR = 10 with this new data set would exclude many τ_{LR} measurements, yielding few temporal

Field Code Changed

186 samples for the RE sequences. Therefore, we explore suitable SNR thresholds for the LP Rayleigh

187 waves of smaller events. We find that a threshold requiring at least 80% of the 40-s lapse time

188 segments (i.e., 32 s) to satisfy SNR of ≥ 5, and a CC coefficient of ≥ 0.9 between each waveform pair

189 yields a reasonable number of τ_{LR} measurements and stable τ_{LR} values. We acquire 471 $\tau(t)$

190 measurements from the HF S-coda and LP Rayleigh waves using the above-mentioned SNR and CC

191 thresholds.

192

193 **2.3 δV_S and δV_{LR} measurements and uncertainties**

194   The assumption of a spatially homogenous velocity reduction relative to the background

195 velocity allows the δV centered at lapse time t to be estimated as follows [*Snieder et al.*, 2002]:

196 $$dV = -\frac{t(t)}{t}. \tag{3}$$

197 The observed $\tau_S(t)$ for the 2005 Nias Earthquake RE sequences is stretched in the later part of the

198 coda waves, similar to previous findings [*Poupinet et al.*, 1984; *Lobkis and Weaver*, 2003]. A

199 fractional seismic-velocity change in the S-wave coda (δV_S) of the RE pair can be approximated by

200 a negative $\tau_S(t)$ slope (dashed lines in Fig. 2b). Linear regression is used to estimate the parameters

201 of the slope b ($-\delta V_S$) and intercept a whose τ_S values that meet the SNR and CC coefficient thresholds.

202 The 2σ standard deviations in δV_S are twice the computed root mean square (RMS) of $\tau_{iS} - \widehat{\tau_{iS}}$,

203 where $\widehat{\tau_{iS}} = a + bt_i$, which is the predicted value based on the inferred a and b values. However, τ_{LR}

204 is constant for the entire wave packet (Fig. 2d). The fractional velocity change for the LP Rayleigh

205 wave (δV_{LR}) is computed as follows:

206 $$dV_{LR} = -\frac{\overline{t_{LR}}}{t_{LR}}, \tag{4}$$

207 where $\overline{t_{LR}}$ is the mean of the τ_{LR} lapse time segments that satisfy the SNR and CC coefficient

208 thresholds, and t_{LR} is the Rayleigh-wave arrival time. The 2σ standard deviations in δV_{LR} are twice

209 the computed RMS of $t_{iLR} - \overline{t_{LR}}$ (Fig. 3 and the following figures).

210

211 We emphasize that δV_S and δV_{LR} are used to highlight the time-dependent discrepancy in late

212 2007. If the upper crust experiences partial or uniform velocity perturbations induced by earthquake

213 slip, then one would anticipate detectable changes in both the *P*- and *S*-coda waves. We observe that

214 the τ_P values are smaller than the τ_S values and only detectable immediately after the Nias Earthquake

215 (see Section 3). Therefore, we only focus on δV_S and δV_{LR} in our analysis. We consider the effect of

216 fractional changes in both the *P*- and *S*-wave velocities of the crust and how the velocity model

217 perturbations influence the synthetic $\tau(t)$ results (see Section 4).

218

219 **3. Temporal changes in δV_S and δV_{LR}: observations of bifurcation**

220 We examine the $\tau_S(t)$ from the N1 sequence at station PSI to determine the decade-long

221 temporal evolution of δV_S and δV_{LR} (Figs. 2 and 3). The τ_S values of the first target event (15 April

222 2005) increase monotonically to $\tau_S = +0.07$ s (light-blue curve in Fig. 2b) relative to the 9 October

223 2006 reference event, which is equivalent to $\delta V_S = -0.1\%$ (dashed black line in Fig. 2b). The slope

224 of τ_S decreases with time. However, the τ_S values for the 2 July 2008 target event decrease to about

225 -0.02 s (red curve in Fig. 2b), which is equivalent to $\delta V_S = +0.02\%$ (dashed light-red line). δV_S

226 exhibits a continuous recovery between 2005 and 2011 that amounts to ~0.14% (Fig. 3a).

227

228   The τ_{LR} value for the first target event (15 April 2005) is about +0.16 s (light-blue curve in Fig.

229   2d), and then decreases to +0.11 s for the 3 December 2005 event. However, the τ_{LR} values increase

230   to +0.44 s for the subsequent 2 July 2008 and 29 March 2011 target events (red and blue curves in

231   Fig. 2d, respectively). δV_{LR} recovered from −0.13% to −0.09% between 15 April 2005 and 3

232   December 2005, but then decreased to −0.36% between 9 October 2006 and 2 July 2008, which is

233   almost three times greater than the change in δV_{LR} in the three weeks following the 2005 Nias

234   mainshock. These observations therefore include a clear break from the observed recovery trend after

235   the 2007 Bengkulu and 2008 Simeulue earthquakes (Fig. 3b).

236

237   Similar discrepancies between τ_S and τ_{LR} are consistently detected among all of the Sumatra

238   and Nias RE sequences at station PSI after late 2007 (Fig. 4). Note that the $\tau(t)$ values for the S1 and

239   S4 Sumatra RE sequences possess smaller values and fluctuate around zero for the HF coda waves

240   (Fig. 4e and g). The monotonic increase in the HF P-wave coda lag times (τ_P) only holds for the target

241   events that occurred within the first week following the 2005 Nias Earthquake, with calculated τ_P

242   values of up to +0.03 s (thick light-blue curves in Figs. 4c and 5b−g). Because the τ_P values are a

243   factor of two smaller than the τ_S values (e.g., Fig. 3a of *W. Yu et al.* [2013a]) to begin with, given the

244   same decay rate, the τ_P values largely decreased to zero after the first week following the 2005

245   mainshock (Figs. 4a and 5a).

246

247   We use a kernel density estimation [*Parzen*, 1962] with adequate bandwidths that are adopted

248   to both assess the overall distribution of the δV_S and δV_{LR} measurements whose time separations are

249   longer than half a year, and establish the consistency and robustness of the observed δV_S and δV_{LR}

250   trends (Fig. 3c and d). The kernel density estimation is a representation of the probability density

251   function and can be formulated as follows:

11

$$\widehat{f}_h(x) = \frac{1}{n}\sum_{i=1}^{n}K(\frac{x-x_i}{h}),\qquad(5)$$

where x_i is the i-th δV data of the total sample size n, h is the bandwidth value that controls the smoothness of the resulting probability density curve, and $K(x_i, h)$ is the kernel expressed in Gaussian function:

$$K(x_i,h) = \frac{1}{h\sqrt{2\rho}}e^{-\frac{1}{2}(\frac{x-x_i}{h})^2}.\qquad(6)$$

The peaks correspond to the maximum likelihood values for each set of δV data. Note that the break from the δV_{LR} recovery after late 2007 is likely caused by both the 2007 and 2008 earthquakes (to be discussed in Section 5). We adopt the timing of the 2007 Bengkulu earthquakes to sort the δV values into two groups, before (blue curve, group 1) and across the 2007 earthquakes (red curve, group 2); the 2007 earthquakes were simply chosen for this division since they occurred first. We observe a noticeable contrast between the group 1 and group 2 δV values. The peak δV_S value changes from −0.04% in group 1 to +0.007% in group 2, indicating continuous velocity recovery (Fig. 3c), whereas the peak δV_{LR} value changes from −0.16% in group 1 to −0.25% in group 2, indicating an additional velocity reduction and minimum recovery after 2007 (Fig. 3d). The post-2007 δV_{LR} values (group 2) are typically a factor of two larger than those measured earlier in the time series (group 1). The steady δV_S recovery at station PSI after the 2004/2005 earthquakes is consistent among all of the Sumatra and Nias RE sequences (left panels of Figs. 6 and 7). The δV_{LR} values consistently exhibit substantial offsets of −0.3 to −0.6% for all of the RE sequences across the late 2007 timeframe (right panels of Figs. 6 and 7). We conclude that this is a robust observation of clear bifurcation in the temporal δV_{LR} and δV_S variations.

4. Finite-difference synthetics and $\tau(t)$ examination

274   The finite-difference (FD) method [*Helmberger and Vidale*, 1988; *Vidale and Helmberger*, 1988]

275   is used to compute the synthetic seismograms. Our goal is to explore the seismic velocity model

276   parameters that are sensitive to the first-order pattern of the observed τ_S and τ_{LR} trends. Our one-

277   dimensional (1D) reference velocity model, termed "mST2", is a combination of the ST2 model

278   (upper 50 km) [*Lange et al.*, 2010] and isotropic Preliminary reference Earth model (PREM; 50–370

279   km depth) [*Dziewonski and Anderson*, 1981]. The ST2 velocity model is derived from regional *P*-

280   and *S*-wave travel times whose phases sampled the Sumatra Subduction Zone. Here we perturb the

281   *P*-wave velocity (α), *S*-wave velocity (β), and layer thickness of the mST2 model for our sensitivity

282   analysis (Fig. 8a and b). Random media are adopted for all of the models, which are defined by

283   Gaussian correlation functions with RMS perturbations and correlation lengths in the *x*- and *z*-

284   directions (*clx* and *clz*, respectively) [*Frankel and Clayton*, 1986]. A two-dimensional (2D) random-

285   media reference velocity model is formed from the 1D mST2 velocity model using the following

286   parameters: RMS = 10%, *clx* = 0.5 km, and *clz* = 0.5 km (isotropic, with an aspect ratio *clx*/*clz* = 1;

287   see Table 1). We consider two end-member models, "deep layer" (DL) and "surface" (SF). The

288   settings for the DL models include superposed background velocity $d\alpha$ and $d\beta$ perturbations, and

289   variations in the *clx*/*clz* aspect ratio and RMS in the upper 1–16 km of the crust, whereas the settings

290   for the SF models include superposed $d\beta$ perturbations, *clx*/*clz*, and RMS variations that are confined

291   to the uppermost 0.5–1.0 km. The perturbed parameters for each model are presented in Table 1.

292

293   We consider the geometry of the N1 sequence recorded at station PSI for most of the

294   computations, with a 22-km focal depth for the N1 RE sequence and 267-km epicentral distance from

295   station PSI. The dimensions of the FD regime are 500 km × 220 km (*x*-direction × *z*-direction), and

296   the length of the time window is 170 s, with a 0.0625-km grid spacing and 3.125-ms time step used

297   during the computation. The source is positioned at *x* = 100 km and *z* = 22 km. The random-media

298   regime extends from *x* = 101.5 km to *x* = 500 km and from *z* = 0 km to *z* = 1 km for SF models, and

13

299   from $z = 1$ km to $z = 16$ km for DL models (Fig. 8c). The FD synthetics are accurate up to 6.0 Hz.

300   We also present two examples where we consider the geometry of the S1 sequence at station PSI,

301   with a 48-km focal depth for the S1 RE sequence and 534-km epicentral distance from station PSI.

302   The dimensions of the FD regime are 900 km × 370 km (*x*-direction × *z*-direction) for the S1–PSI

303   geometry, and the length of the time window is 280 s, with a 0.125-km grid spacing and 6.25-ms

304   time step. The source is positioned at $x = 100$ km and $z = 48$ km. The precision of the synthetic

305   seismograms for S1 is accurate up to 3.0 Hz. *clz* is fixed at 0.5 km, meaning each scatterer includes

306   four and eight grid cells in the *z*-direction for the S1–PSI and N1–PSI regimes, respectively. We use

307   a dip-slip focal mechanism and 1-s triangle source time function. The HF synthetic seismograms are

308   bandpass filtered between 0.4 and 1.6 Hz. The synthetic $\tau(t)$ values that are computed from the

309   synthetic seismograms are based on the perturbed models relative to the reference model using a

310   sliding-window CC approach, which is identical to the approach used to obtain the observed $\tau(t)$

311   values.

312

313   The heterogeneous regions that can produce the observed time-dependent time delay include a

314   localized velocity reduction near either the source or station, and a velocity reduction in the bulk of

315   the upper crust. We first examine the effect of a localized velocity reduction near either the source

316   or station. The N1 DL-LSRC1 model produces τ_P values of up to +0.05 s and null τ_S values for a

317   localized velocity reduction near the source (orange curve in Fig. 9a), whereas the N1 SF-LSRC1

318   model produces null τ_P and τ_S values (light-blue curve in Fig. 9a). The N1 SF-LSTN1 model produces

319   null τ_P and τ_S values for a localized velocity reduction near the station (thick green curve in Fig. 9a),

320   and the S1 SF-LSTN1 model produces oscillating τ_P and τ_S values between −0.05 s and +0.05 s for

321   the S1–PSI path (thick green curve in Fig. 10a). Amplifying the localized *S*-wave velocity reduction

322   near the station from $d\beta = -4\%$ to -16% produces a linear increase in $\tau_S(t)$ values, with increases of

323   +0.075 s (N1 SF-LSTN2; thick yellow curve in Fig. 9a) and +0.15 s (S1 SF-LSTN2; thick yellow

14

324 curve in Fig. 10a), respectively, for the N1 and S1 sequences recorded by station PSI. Two lines of

325 argument suggest that the observed $\tau(t)$ values of the HF S-coda waves are not caused by a localized

326 near-surface velocity reduction at station PSI. (1) The perturbed models with localized velocity

327 perturbations near the station produce a linear increase in τ_S values, even at different distance ranges,

328 whereas the observed τ_S values for the S1 sequence at station PSI does not exhibit an increase in $\tau_S(t)$

329 (light-blue curve in Fig. 4e). (2) A monotonic increase in τ_P values is detectable for the target events

330 that occurred within the first week following the Nias mainshock (Figs. 4b and 5b−g), but the smaller

331 τ_P values largely diminished to zero after the first week following the Nias Earthquake. The observed

332 τ_P and τ_S values suggest that the velocity reduction occurs in the bulk part of the upper crust. Moreover,

333 the localized velocity reduction near either the source or station produces null τ_{LR} values (Figs. 9c

334 and 10c).

335

336   Here we discuss how the velocity reduction parameters, RMS perturbations, and clx/clz aspect

337 ratio for the SF and DL models influence the synthetic $\tau(t)$ values for the HF S-coda and Rayleigh

338 waves. The following FD synthetics computations employ the N1–PSI source–receiver geometry.

339 Figure 11 displays the synthetic test results where an individual parameter is moderately perturbed,

340 such that the sensitivity of each perturbed parameter can be assessed. Models SF1, SF2, and SF3

341 have a 3% RMS amplification, increase in the clx/clz ratio from one to ten, and additional $d\beta = −4\%$

342 perturbation relative to the reference model, respectively. The synthetic $\tau(t)$ values for the HF S-coda

343 waves that propagated through these models all exhibit subtle fluctuations around zero, with episodic

344 oscillations at 10, 20–30, and 47–52 s (Fig. 11a). Models DL1, DL2, and DL3 have a 3% RMS

345 amplification, increase in the clx/clz aspect ratio from one to ten, and additional $d\alpha = −0.06\%$ and $d\beta$

346 $= −0.12\%$ perturbations relative to the reference model, respectively. The 3% RMS amplification

347 also produces subtle fluctuations in the τ_P and τ_S values (DL1, light-blue curve in Fig. 11c). However,

348 increasing the clx/clz aspect ratio from one to ten produces a negative τ_S value of −0.07 s at ~50 s

15

349   (DL2, orange curve in Fig. 11c), and the $d\alpha = -0.06\%$ and $d\beta = -0.12\%$ perturbations produce an

350   increase in the τ_S value of up to +0.13 s (DL3, pink curve in Fig. 11c). Model DL4, which includes

351   all of the perturbations in models DL1, DL2, and DL3, produces a monotonic increase in τ_P, as well

352   as smaller τ_S values at ~50 s (green curve in Fig. 11c). The smaller τ_S values mimic the negative τ_S

353   values in the DL2 model at 47–52 s due to the increase in the *clx*/*clz* aspect ratio.

354

355   We now consider the effects of RMS amplification and perturbing several parameters within a

356   given velocity model. A monotonic increase in both $\tau_P(t)$ and $\tau_S(t)$ is still better approximated by the

357   DL models for the HF *P*- and *S*-wave codas (DL5 and DL6 in Fig. 12c). The SF models with a strong

358   *S*-wave velocity reduction ($d\beta = -16\%$) produce oscillating $\tau_P(t)$ and $\tau_S(t)$ values with peaks at 10,

359   20−30, and 47−52 s (SF5 and SF6 in Fig. 12a). The DL models with RMS = 25%, $d\alpha = -0.06\%$, $d\beta$

360    $= -0.12\%$ perturbations, and *clx*/*clz* = 1 produces linear increases of up to +0.072 and +0.147 s in τ_P

361   and τ_S, respectively (DL5, light-blue curve in Fig. 12; the 2D $d\beta$ profile is displayed in Fig. 8d). The

362   τ_P values increase by a factor of 1.5 when the *clx*/*clz* aspect ratio is increased to ten, with a value of

363   up to 0.11 s; the τ_S values are larger up to +0.138 s over the 40−45-s window, but then decrease over

364   the 47−52-s window (DL6, orange curve in Fig. 12c; the 2D $d\beta$ profile is displayed in Fig. 8e). This

365   τ_S pattern of an increase followed by a drop over the 47−52-s window is similar to that observed for

366   models DL3 and DL4 (Fig. 11c). The heterogeneous region in model DL7 only spans 50% of that in

367   model DL5; its predicted τ_P values exhibit an increase over the 10−20-s window to +0.025 s, followed

368   by a drop over the 20−30-s window to −0.03 s, whereas the τ_S values exhibit a monotonic increase

369   up to +0.1 s (DL7, pink curve in Fig. 12c). The combined perturbations of the SF and DL models

370   produce τ_P and τ_S values that are similar to those based calculated from the DL models, with larger

371   τ_P and smaller τ_S values often obtained (Fig. 12e; the 2D $d\beta$ profile of model SF4+DL7 is displayed

372   in Fig. 8f).

16

373

LP Rayleigh waves are sensitive to $d\beta$ reductions and RMS amplification in the bulk crust, with models SF3, SF4, DL3, and DL4 producing τ_{LR} values of +0.087, +0.087, +0.038, and +0.05 s, respectively (Figs. 11e, f, and 12g). Models SF5 and SF6 produce τ_{LR} values in the +0.244 to +0.431 s range (Fig. 12g). Models DL5–DL7 have fixed RMS = 25%, $d\alpha = -0.06\%$, and $d\beta = -0.12\%$ perturbation; an increase in the clx/clz aspect ratio from one to ten produces an increase in τ_{LR} from +0.125 s (DL5) to +0.150 s (DL6), whereas a reduction in the heterogeneous region in model DL7 produces a maximum τ_{LR} value of only +0.056 s (Fig. 12h). Combinations of the SF4 model and various DL models have also been used to produce synthetic τ_{LR} values, with τ_{LR} values of +0.219, +0.250, and +0.156 s obtained for models SF4+DL5, SF4+DL6, and SF4+DL7, respectively (Fig. 12i).

384

Our modeling results indicate that a strong S-wave velocity reduction in the near-surface substantially contributes to the large τ_{LR} values, but has a minimal effect on the observed τ_P and τ_S pattern. A subtle S-wave velocity reduction in the upper crust is necessary to account for the observed τ_P and τ_S patterns, and can also partially contribute to the τ_{LR} pattern. Our preferred explanation is as follows. The observed τ_S and τ_{LR} patterns after the 2004/2005 earthquakes may reflect the combination of a strong S-wave velocity reduction in the near-surface and a subtle S-wave velocity reduction in the upper crust. However, the τ_{LR} amplification after late 2007 predominantly reflects another substantial S-wave velocity reduction in the near-surface, given the null τ_S constraint (red curves in Fig. 4). The medium changing from isotropic ($clx/clz = 1$) to vertically transverse isotropic ($clx/clz = 10$) and amplifying the RMS can influence S-coda and Rayleigh-wave propagation, thereby altering the τ_S and τ_{LR} values. We discuss the likely scenarios that can potentially explain these observations and modeling results in the following section.

17

397

5. Discussion and Conclusions

5.1 δV_S recovery after the 2004 and 2005 earthquakes

Obermann et al. [2013] positioned the source and receiver at the surface in their coda wave computations, and suggested that the later part of the coda waves were predominantly sensitive to the bulk velocity heterogeneities of the media, with the sensitivity of these waves to the source depth being approximately bounded by the length scale of the mean free path. Here we position the source and receiver at 22 km depth and the surface, respectively, in our FD simulations. Our FD synthetic tests reveal that the DL models with subtle *S*-wave velocity perturbations that are confined to the upper 1–16 km produce characteristics that are consistent with a monotonic increase in τ_S (Fig. 12c), whereas the SF models with near-surface velocity perturbations (confined to the uppermost 0.5−1.0 km) cannot reproduce this key feature (Fig. 12a). Although the source–receiver geometries of the two modeling approaches are different, our inferences on the sensitivity of the later part of the coda waves to the bulk heterogeneities of the media are consistent with those in *Obermann et al*. [2013].

411

The δV_S observations show continuous recovery from 2005 to 2015. It is unlikely that the δV_S induced by co-seismic slip would be sustained for several years, even though the deformation induced by large earthquake co-seismic slip can produce structural changes in the bulk crust and time-varying δV_S behavior. Additional independent arguments suggest that the continuous δV_S recovery from 2005 to 2015 was predominantly controlled by deep post-seismic afterslip or/and viscoelastic relaxation processes. The REs associated with the 2004 and 2005 earthquakes are located close to the afterslip zones, at depths of about 50 and 25 km, respectively (Fig. 1 and Table S2). The post-seismic displacement time series recorded by GPS stations UMLH and LEWK, and the GPS normalized displacement time series relative to the concurrent δV_S values are provided in Figures S2 and S3,

18

421 respectively, for comparison. Note that the details of the GPS data processing can be found in *Feng*

422 *et al.* [2015]. The logarithmic recovery of δV_S corresponds to the post-seismic deformation time

423 series reasonably well. *Feng et al.* [2015] suggested that viscoelastic relaxation was essential for

424 explaining the long-term geodetic measurements. *Qiu et al.* [2018] recently estimated a background

425 upper mantle viscosity of 10^{17}–10^{19} Pa-s beneath the Sumatra region, which would indicate relaxation

426 timescales (days to years) that are similar to our observed timescales of δV_S recovery.

427

5.2 Multiple δV_{LR} reductions induced by the 2004, 2005, 2007, and 2008 earthquakes

429   The observed δV_{LR} values at station PSI from late 2007 to early 2008 exhibit a remarkable

430 reduction of at least −0.3%, which is a factor of two larger than the reductions caused by the 2004

431 and 2005 earthquakes (Figs. 3, 6, and 7). These new data reveal that the δV_{LR} reduction after the 2004,

432 2005, 2007, and 2008 earthquakes progressively increases, i.e., $\delta V_{LR}^{2007/2008} > \delta V_{LR}^{2005} > \delta V_{LR}^{2004}$.

433 Note that substantial δV_{LR} reductions are likely caused by the 2007 M_w 8.4 and M_w 7.9, and 2008

434 earthquakes. It is difficult to assess the temporal resolution of δV_{LR} using the RE sequences due to

435 the undersampling during the five-month period when the 2007 and 2008 earthquakes occurred.

436 Previous studies have suggested that earthquake-induced velocity reduction is often associated with

437 high PGV [*Rubinstein and Beroza*, 2004b; *Hobiger et al.*, 2016]. We examine the PGV of the large

438 earthquakes recorded by station PSI in the 0.5–2.0 Hz frequency band (Table S3). The PGV

439 amplitude of the 2005 M_w 8.6 earthquake is larger than that of the 2004 M_w 9.2 event, and the PGV

440 amplitudes of the 2007 M_w 8.4 and M_w 7.9, and 2008 M_w 7.3 earthquakes are smaller than those of

441 the 2005 M_w 8.6 event, even though a stronger δV_{LR} reduction that is associated with the 2007 and

442 2008 earthquakes is detected. We speculate that the strong GM induced by the 2004 and 2005 events

443 made the subsurface cracks and fractures more susceptible to the GM induced by the 2007 and 2008

444 earthquakes, resulting in another substantial velocity reduction.

19

445

5.3 Temporal changes in δV during 2005−2015

447   REs discretely sample δV with a limited temporal resolution. However, concurrent δV_S and

448   δV_{LR} observations, and the differences in their temporal patterns offer new insights into the diverse

449   processes that modulate media properties. Figure 13 summarizes the decadal δV_S and δV_{LR}

450   observations, and illustrates our inferences on the evolution of the crustal seismic-velocity structure

451   along the Banda Aceh−Nias−Simeulue segment of the Sumatra Subduction Zone. A subtle −0.1%

452   δV_S reduction due to the 2004 and/or 2005 earthquakes is followed by steady recovery, with no

453   noticeable disruption from 2005 to 2015 (δV_S in Fig. 13). However, a −0.1% δV_{LR} reduction is

454   induced by the 2004 earthquake, and a slightly larger −0.1 to −0.3% reduction is induced by the 2005

455   event. We find that δV_{LR} experiences recovery until late 2007, with the GM from the 2007 and 2008

456   earthquakes then inducing a substantial δV_{LR} reduction (−0.3 to −0.6%) that possibly occurred in

457   multiple steps. We speculate that any δV_{LR} caused by the 2010 Banyak Earthquake may have gone

458   undetected due to the limited temporal resolution of the data, resulting in the observed gentle velocity

459   recovery trend.

460

461   In summary, the differences in the temporal δV_S and δV_{LR} behaviors that are inferred from

462   REs are a powerful tool for discriminating between the mechanisms that drive seismic-velocity

463   changes after great earthquakes. Steady δV_S recovery is consistent with the logarithmic time

464   dependence inferred from post-seismic GPS data (Figs. S2 and S3), which predominantly reflects

465   afterslip that occurred in the updip and downdip sections of the rupture area [*Feng et al.*, 2015] (Fig.

466   1) and/or viscoelastic relaxation after the 2004 and 2005 earthquakes. Furthermore, FD synthetics

467   computations demonstrate that the monotonic increase in the observed τ_S values can be explained by

468   a subtle velocity reduction of $d\beta = -0.12\%$ at 1−16 km depth (DL5 in Fig. 12c). However, δV_{LR}

20

469 displays additional drops after the large earthquakes during the 2007−2008 time period, breaking the

470 pattern of monotonic recovery. The model with a subtle *S*-wave velocity reduction at 1−16 km depth

471 can partly account for the observed τ_{LR} pattern after the 2004/2005 events, but it is insufficient in

472 producing values that are comparable to the observed τ_{LR} pattern after late 2007. Strong *S*-wave

473 velocity reductions of $d\beta = -4$ and −16% that are confined to the uppermost 0.5−1.0 km can account

474 for the observed τ_{LR} values after 2005 and late 2007, respectively (Fig. 12g). These sudden changes

475 are primarily associated with a cycle of damage, healing, and re-damage in the subsurface layer

476 [*Vidale and Li*, 2003; *Sawazaki et al.*, 2018].

List of Figure Captions

677

678   **Figure 1.** Regional seismicity map of the Sumatra Subduction Zone. The epicenters of several major

679   earthquakes ($M_w \geq 7.3$) are shown as either large open white or black stars that are labeled with their

680   respective event ID or M_w values, respectively (Table S1). The repeating earthquake (RE) sequences

681   are represented by small stars, and the background seismicity is represented by the gray dots, all of

682   which is superimposed on the modeled co-seismic slip (contours) and post-seismic afterslip (colored

683   area) of the 2004 Sumatra [*Chlieh et al.*, 2007] and 2005 Nias [*Hsu et al.*, 2006] earthquakes. Note

684   that color scales for the afterslip values of the 2004 and 2005 events are different. The double arrows

685   show the rupture extents of the 2004 and 2005 events on the map. The REs that were selected for the

686   relative locations and temporal velocity change analyses (Table S2) are indicated by small yellow

687   stars, whereas the REs with high cross-correlation (CC) coefficients and no further relocation

688   analysis are indicated by small white stars; the source parameters of the latter are not provided. The

689   REs are located near the afterslip zones of the 2004 and 2005 events [*Chlieh et al.*, 2007]. The solid

690   and dotted black lines indicate the trench [*Bird*, 2003] and slab depths at 50-km intervals

691   [*Gudmundsson and Sambridge*, 1998], respectively. The seismic and GPS stations used in this

692   analysis are indicated by the open triangle and open squares, respectively. An enlarged map near the

693   Nias, Banyak, and Simeulue Islands is provided to better present the 2005 Nias Earthquake RE

694   locations, with the dotted gray box indicating the location of the displayed region in the main figure.

695

696

28

Figure 2. (a, c) Waveforms and (b, d) lag-time time series $\tau(t)$ for the N1 RE sequence recorded at station PSI. The vertical-component data are shown for the (a, b) high-frequency (HF) coda waves, bandpass filtered between 0.5 and 2.0 Hz, and (c, d) long-period (LP; 0.03–0.1 Hz) Rayleigh waves. The $\tau(t)$ values for the target event are computed relative to the reference event (black trace, 9 October 2006) and labeled "target event ID–ref". The amplitudes of the filtered waveforms in each selected time window are normalized to the maximum amplitude in that window. The shaded regions correspond to the waveform segments with signal-to-noise ratios (SNR) of ≥ 5 and cross-correlation (CC) coefficients of ≥ 0.9, which are used to compute δV. The unstable and oscillatory $\tau(t)$ values at the beginning of each lower plot are due to low SNR values. The dashed black and light-red lines in (b) correspond to the $-\delta V_S$ values that are estimated from the observed $\tau_S(t)$ of the target events: 15 April 2005 (light-blue line) and 2 July 2008 (red line), respectively. The arrival times of the P-, S-, and LP Rayleigh waves are labeled "P", "S", and "LR", respectively.

Figure 3. Temporal velocity changes in (a) δV_S and (b) δV_{LR}, and their respective standard deviations (error bars) for the N1 RE sequence recorded at station PSI during the 2005−2011 time period, beginning after the 2005 event. The reference event is indicated by the open black triangle and placed on the zero line (baseline). The 2σ standard deviations in δV_S and δV_{LR} are discussed in the text. The vertical dotted lines correspond to the major earthquakes near the Sumatra Subduction Zone, including the 2004, 2005, 2007, 2008, 2010 Banyak, 2010 Mentawai, and 2012 earthquakes (earthquake details listed in Table S1). The (c) δV_S and (d) δV_{LR} distributions, measured from the REs that have been relocated (Table S2) and possess high CC coefficients, and determined using Eqs. (5) and (6). The contrast in δV before and across the 2007 Bengkulu earthquakes, which is inferred from the probability density function for all of the data, resembles the δV distributions constructed from the individual RE sequences.

722 **Figure 4.** Observed $\tau(t)$ for the selected target events from four RE sequences, recorded at station

723 PSI: (a, b) N1, (c, d) N11, (e, f) S1, and (g, h) S4. The HF τ_P and τ_S, and LP τ_{LR} are displayed in the

724 left and right panels, respectively. The epicentral distance between each RE sequence and station PSI

725 (in km) is displayed in the titles. The light-blue and green curves are the measured $\tau(t)$ for the target

726 events that occurred after the 2004 and 2005 earthquakes, respectively, whereas the red curve is the

727 measured $\tau(t)$ for the target events that occurred after the 2007 and 2008 earthquakes. The measured

728 $\tau(t)$ for the 3 April 2005 target event of the N11 sequence in (c) indicates detectable τ_P values that are

729 highlighted by the thick light-blue curve. This figure is similar to Figure 2b and d.

730

731 **Figure 5.** Observed $\tau(t)$ of the HF coda waves for the selected target events from seven Nias RE

732 sequences recorded at station PSI: (a) N4, (b) N15, (c) N16, (d) N2, (e) N3, (f) N9, and (g) N10. The

733 thick light-blue curves indicate detectable τ_P values, which are mostly detectable for the target events

734 that occurred within the first week following the 2005 Nias Earthquake. This figure is similar to the

735 left panels of Figure 4.

736

737 **Figure 6.** Temporal δV_S (gray circles) and δV_{LR} (red circles), and their respective standard deviations

738 (black error bars) for six Nias RE sequences recorded at station PSI: (a, b) N4, (c, d) N11, (e, f) N13,

739 (g, h) N15, (i, j) N16, and (k, l) N17, displayed over the 2005–2015 time period to highlight the

740 consistency in both the δV_S recovery and temporal break in δV_{LR} recovery after late 2007. The vertical

741 dotted lines indicate the origin times of the 2004, 2005, 2007, 2008, and 2010 Banyak, 2010

742 Mentawai, and 2012 earthquakes (Table S1), and the open triangles indicate the reference event for

743 each RE sequence, which are placed at zero (baseline). The 2σ standard deviations in δV_S and δV_{LR}

744 are discussed in the text.

30

745 **Figure 7.** Computed δV_S and δV_{LR} for the Sumatra RE sequences recorded at station PSI: (a, b) S1,

746 (c, d) S3, and (e, f) S4 over the 2005–2015 time period. The figure symbols are same as in Figure 6.

747

748 **Figure 8.** One-dimensional (a) *P*-wave velocity (α) and (b) *S*-wave velocity (β) structures of the

749 mST2 reference velocity model (gray line), which is modified from the ST2 (dotted black line)

750 [*Lange et al.*, 2010] and PREM [*Dziewonski and Anderson*, 1981] models; the upper 100 km of the

751 velocity model is displayed here. (c–f) Lateral $d\beta$ perturbations of several two-dimensional random-

752 media models: (c) reference model, (d) DL5, (e) DL6, and (f) SF4+DL7. The presented models are

753 adopted for simulating wave propagation from the N1 RE sequence to station PSI. The source (star)

754 and receiver (triangle) in (c) are positioned at (100, 22) and (367, 0), respectively, and the FD regime

755 is displayed from $x = 98$ to 373 km and $z = 0$ to 25 km. The FD regime in (d–f) is displayed from x

756 $= 100$ to 240 km and $z = 0$ to 18 km. Note that color scales for $d\beta$ perturbations of (e) the DL6 model

757 are different from those of (c, d, f) other models. The perturbed parameters of each presented model

758 are listed in Table 1.

759

760

Figure 9. (a) Synthetic $\tau(t)$ that were calculated from (b) the HF (0.4–1.6 Hz) FD synthetic seismograms of the N1 sequence recorded at station PSI using models with localized velocity perturbations near either the source or station PSI. The computed synthetic seismograms that are based on the reference model are indicated by the black traces, whereas the computed synthetic seismograms that are based on the perturbed models are indicated by the colored traces and superimposed on the reference synthetic seismograms. The *P*- and *S*-coda time windows are plotted separately to highlight the *P*-codas due to their relatively low amplitudes. The amplitude scales for both the *P*- and *S*-waves are displayed. (c) LP (0.03–0.1 Hz) synthetic τ_{LR} based on the same perturbed models, with the synthetic seismograms based on the reference model (black) and model N1 SF-LSTN2 (yellow) displayed in the inset. The perturbed parameters of each presented model are listed in Table 1.

Figure 10. FD synthetic seismograms and corresponding $\tau(t)$ of the S1 sequence at station PSI based on two models with a localized velocity perturbation near station PSI. The perturbed parameters of each presented model are listed in Table 1. This figure is similar to Figure 9.

Figure 11. HF FD synthetic seismograms and corresponding $\tau(t)$ using several velocity models: (a, b) "surface" (uppermost 1.0 km, denoted as "SF") and (c, d) "deep layer" (1–16 km depth, denoted as "DL") with various RMS, correlation length, $d\alpha$, and $d\beta$ perturbations in the random media. Synthetic LP τ_{LR} based on various (e) SF and (f) DL model perturbations. The LP synthetics in (f) that are computed based on the reference model and model DL4 are indicated by black and green traces, respectively. The perturbed parameters of each presented model are listed in Table 1. This figure is similar to Figure 9.

32

Figure 12. FD synthetic seismograms and corresponding $\tau(t)$ for additional (a, b, g) SF, (c, d, h) DL, and (e, f, i) SF4+DL models. The perturbed parameters of each presented model are listed in Table 1. This figure is similar to Figure 11.

Figure 13. Interpretation of the observed temporal changes in δV_{LR} and δV_S induced by the 2004, 2005, 2007, 2008, 2010, and 2012 earthquakes along the Banda Aceh−Nias−Simeulue segment of the Sumatra Subduction Zone. δV_{LR} recovery occurs until it is interrupted by the 2007 and 2008 events. A question mark is placed next to the drop associated with the 2010 Banyak Earthquake to reflect undersampling. The observations indicate an apparent static offset in δV_{LR} without recovery after the 2007 and 2008 events (dashed dark-gray lines). δV_S is reduced by the 2005 event, and undergoes steady recovery during the 2005−2015 time period, in contrast to the complex time-varying δV_{LR} behavior.

797 **Table 1.** List of models used for the finite-difference synthetics computations, and the associated

798 parameters that were modified to perturb the mST2 reference velocity model.

Model ID	Parameters that were modified to perturb the mST2 reference velocity model
Reference random-media model	RMS = 10%, clx = 0.5 km, and clz = 0.5 km over the 0−1 and 1−16 km depth ranges for the surface (SF) and deep layer (DL) models, respectively
N1 SF-LSRC1 (Surface)	$d\beta$ = −4%, RMS = 25%, clx = 0.5 km, and clz = 0.5 km over the 0–1 km depth range, localized to within 25 km of the source
N1 DL-LSRC1 (Deep Layer)	$d\alpha$ = −0.06%, $d\beta$ = −0.12%, RMS = 25%, clx = 0.5 km, and clz = 0.5 km over the 1−16 km depth range, localized to within 25 km of the source
N1 SF-LSTN1 (Surface)	$d\beta$ = −4%, RMS = 25%, clx = 0.5 km, and clz = 0.5 km over the 0–1 km depth range, localized to within 10 km of the station
N1 SF-LSTN2 (Surface)	$d\beta$ = −16%, RMS = 25%, clx = 0.5 km, and clz = 0.5 km over the 0–1 km depth range, localized to within 10 km of the station
S1 SF-LSTN1	Similar to N1 SF-LSTN1, but with a 48-km focal depth and 534-km epicentral distance
S1 SF-LSTN2	Similar to N1 SF-LSTN2, but with a 48-km focal depth and 534-km epicentral distance
SF1 (Surface)	RMS = 13%, clx = 0.5 km, and clz = 0.5 km over the 0–1 km depth range; i.e., a 3% increase in the RMS perturbation relative to the reference random-media model
SF2 (Surface)	RMS = 10%, clx = 5 km, and clz = 0.5 km over the 0–1 km depth range; i.e., a ten-fold increase in the clx/clz aspect ratio relative to the reference random-media model
SF3 (Surface)	$d\beta$ = −4%, RMS = 10%, clx = 0.5 km, and clz = 0.5 km over the 0–1 km depth range; i.e., an additional $d\beta$ perturbation relative to the reference model
SF4 (Surface)	$d\beta$ = −4%, RMS = 25%, clx = 0.5 km, and clz = 0.5 km over the 0–1 km depth range
SF5 (Surface)	$d\beta$ = −16%, RMS = 10%, clx = 0.5 km, and clz = 0.5 km over the 0–0.5 km depth range
SF6 (Surface)	$d\beta$ = −16%, RMS = 10%, clx = 0.5 km, and clz = 0.5 km over the 0–1 km depth range
DL1 (Deep Layer)	RMS = 13%, clx = 0.5 km, and clz = 0.5 km over the 1−16 km depth range; i.e., a 3% increase in the RMS perturbation relative to the reference random-media model
DL2 (Deep Layer)	RMS = 10%, clx = 5 km, and clz = 0.5 km over the 1−16 km depth range; i.e., a ten-fold increase in the clx/clz aspect ratio relative to the reference random-media model
DL3 (Deep Layer)	$d\alpha$ = −0.06%, $d\beta$ = −0.12%, RMS = 10%, clx = 0.5 km, and clz = 0.5 km over the 1−16 km depth range; i.e., additional $d\alpha$ and $d\beta$ perturbations relative to the reference random-media model
DL4 (Deep Layer)	Combination of the DL1, DL2, and DL3 models
DL5 (Deep Layer)	$d\alpha$ = −0.06%, $d\beta$ = −0.12%, RMS = 25%, clx = 0.5 km, and clz = 0.5 km over the 1−16 km depth range
DL6 (Deep Layer)	$d\alpha$ = −0.06%, $d\beta$ = −0.12%, RMS = 25%, clx = 5 km, and clz = 0.5 km over the 1−16 km depth range
DL7 (Deep Layer)	$d\alpha$ = −0.06%, $d\beta$ = −0.12%, RMS = 25%, clx = 0.5 km, and clz = 0.5 km over the 1–16 km depth range that is within 130 km of the source

SF4+DL5	Combination of the SF4 and DL5 models
SF4+DL6	Combination of the SF4 and DL6 models
SF4+DL7	Combination of the SF4 and DL7 models
