## Key Points:

- Alaska glacier elevation changes are generated from TOPEX/Poseidon and Jason-2 altimeter observations and by a glacier-threshold method
- The rates of time-lapsed glacier elevations during 1993–2016 were largely negative, but some rates were positive, depending on regions
- Topography, regional environmental setting and Pacific decadal oscillation may lead to Alaska's heterogenous glacier elevation changes

## 24    **Abstract**

25    Satellite radar altimeters have been used to monitor sea level changes and ice sheet elevation changes  
26    for more than 3 decades. Over mountain glaciers, radar altimetry has limited applications due to  
27    contaminated radar waveforms caused by complex glacier surfaces and steep terrains. In this study, we  
28    develop a glacier-threshold method (GTM) to determine glacier elevation changes over mountain  
29    glaciers in Alaska. The GTM can detect and remove invalid elevation observations from the  
30    TOPEX/Poseidon (T/P) and Jason-2 (J2) altimeters, creating usable elevation observations from 16–  
31    92% of the raw observations. The selected elevations are used to construct long-term time series of  
32    Alaskan glacier elevation changes over 1993–2002 (T/P) and 2008–2016 (J2) at 47 sites. A crossover  
33    analysis and a Lidar comparison confirm the result from T/P and J2. Our finding shows that most of  
34    the Alaskan glaciers studied have continued to decline in recent years. The largest declining rate is -  
35     $11.06 \pm 0.35$  m/yr over Klutlan Glacier, followed by Chitina Glacier at  $-8.82 \pm 0.12$  m/yr. Glacier  
36    thickening occurred in some accumulation zones, such as Hubbard Glacier and Logan Glacier, and  
37    also at some glacier terminuses. The mechanisms of these elevation changes are discussed using  
38    climate datasets. It is suggested that changes in environmental factors such as precipitation, air  
39    temperature and sea water temperature influence the shifts in the trends of glacier elevation changes.  
40    A sophisticated processing system and altimeter data from repeat missions can facilitate long-term  
41    monitoring of small-scaled glaciers for a better understanding of glacier dynamics.

42

## 43    **Plain Language Summary**

44    Satellite radar altimetry is an important observation technology to determine changes in surface  
45    elevations. However, altimeter measurement accuracy is very sensitive to terrain complexity,  
46    especially over mountain glaciers. Here we present a glacier-threshold method (GTM) to investigate  
47    the glacier elevation changes in Alaska, using TOPEX/Poseidon (T/P) and Jason-2 (J2) altimeter

48 measurements. Internal and external accuracy assessments show the GTM enables us to retrieve  
49 precise changes in glacier elevations and improve the usable rate of original radar observations. During  
50 the recent study period, the vast majority of Alaska glaciers are rapidly declining. The maximum  
51 declining rate reached  $11.06 \pm 0.35$  m/yr near Klutlan Glacier. But in some glacier accumulation areas  
52 and glacier tongues, the glacier elevations were rising. A climate factor analysis shows that the changes  
53 in precipitation, air temperature and sea water temperature are responsible for the asynchronously  
54 spatio-temporal glacier elevation changes. All these findings from the repeat-track radar altimetry and  
55 the GTM help to improve our knowledge about Alaska glacier processes.

58 retracking

59

## 60 1 Introduction

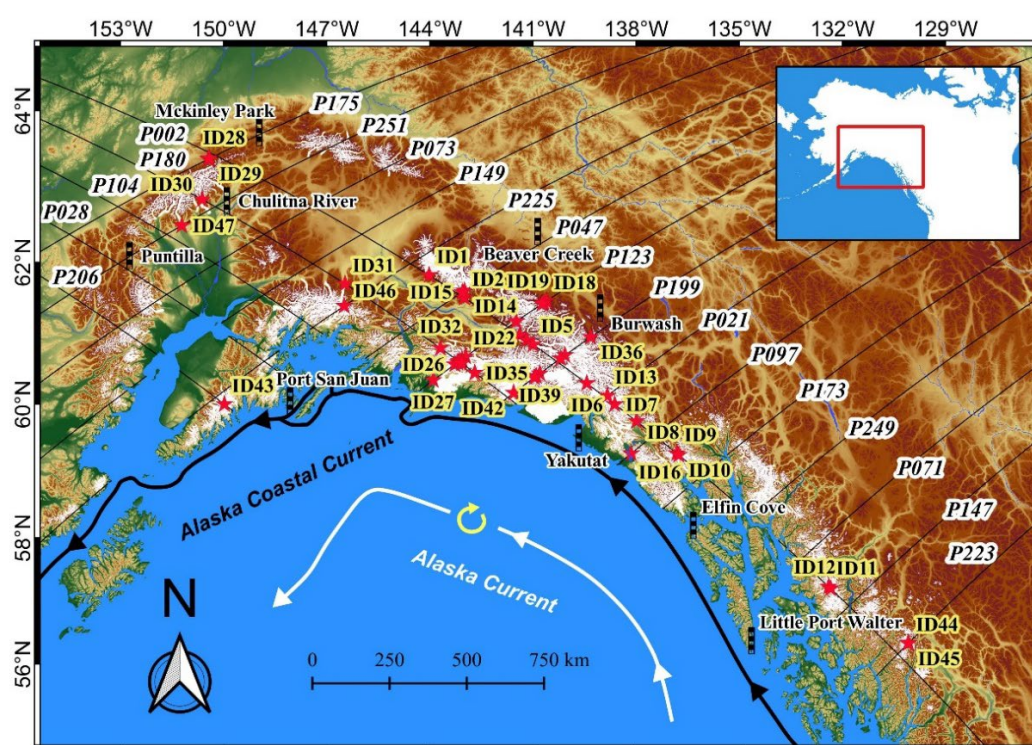

61 There are more than 10,000 glaciers in Alaska, 98% of which are retreating and thinning (*Molnia*,  
62 2007). Glaciers in Alaska began to retreat as early as in the 18th century, and some small glaciers have  
63 disappeared in the 20th century (*Molnia*, 2008). A recent study shows that Alaska's rapidly melting  
64 glaciers contributed to one third of the global sea level rise over the past half century (*Zemp et al.*,  
65 2019). Mass losses associated with Alaska glacier melting have been detected by the Gravity Recovery  
66 and Climate Experiment (GRACE) data. *Luthcke et al.* (2008); (2013) first used GRACE mascon  
67 solutions to confirm significant mass losses in Alaska, similar to the results from the solutions using  
68 spherical harmonic expansions (*Jacob et al.*, 2012; *Gardner et al.*, 2013; *Wouters et al.*, 2019). The  
69 latest time-varying gravity observations of GRACE and GRACE Follow-On show that the glacier-  
70 induced mass losses are intensifying with a loss rate of  $-72.5 \pm 8$  Gt/yr (*Ciraci et al.*, 2020). However,  
71 the GRACE gravimetry data over the Alaska mountain glaciers reflect only large-scale mass changes  
72 due to its coarse spatial resolution ( $\sim 350$  km) (*Wang et al.*, 2012). In contrast, satellite imagery can  
73 provide small-scale, two-dimensional and three-dimensional changes of mountain glaciers, which can  
74 play a critical role in quantifying glacier discharge and the mass balance here (*Berthier et al.*, 2010;  
75 *Heid and Kääb*, 2012; *Brun et al.*, 2017; *Dussaillant et al.*, 2019). However, the temporal resolution  
76 of satellite imagery can be easily altered by cloud covers, resulting in incomplete seasonal observations  
77 of glacier dynamics, and potentially incorrect long-term trends. In order to detect glacier changes at a  
78 smaller scale than GRACE, and to ensure the establishment of a continuous and robust time series, a  
79 different sensor, such as satellite altimetry, becomes necessary.

80 At present, there are two types of satellite altimeters, namely laser and radar altimeters. A laser  
81 altimeter, such as Ice, Cloud, and land Elevation Satellite (ICESat), has a small illuminating footprint  
82 of about 70 m, which is less affected by rough terrains compared to radar altimeters. The ICESat  
83 altimeter can measure glacier heights at a near-repeat spot for about 3–4 times a year, but only limited  
84 observations has been made over Alaska (*Muskett et al.*, 2008). *Kääb et al.* (2012) measured the

85 variations in mountain glacier elevations over the Himalayas using ICESat. *Gardner et al.* (2013)  
86 estimated glacier mass changes using ICESat and showed the contribution of global glacier melting to  
87 sea level rise. Current studies using GRACE or ICESat showed that most mountain glaciers in Alaska  
88 were melting during 2003–2009. ICESat-2, launched in 2018, continues ICESat observations to extend  
89 the elevation records of global glaciers (*Neumann et al.*, 2019). Despite the high-accuracy heights in  
90 mountainous areas from ICESat/ICESat-2, the rates of glacier elevation change estimated from the two  
91 altimeters still contain large uncertainties due to their non-repeat ground tracks.

92       An altimeter with an exact repeat orbit (but subject to roughly 1-km offset relative to the nominal  
93 orbit) is typical for oceanographic applications. Examples of exact-repeat altimeters are Geosat, ERS-  
94 series of altimeters and TOPEX/Poseidon (T/P)–series of altimeters. The T/P-series altimeters include  
95 the T/P, Jason-1, 2 and 3 altimeters, which measure surface elevations along their repeated ground  
96 tracks every 10 days. In theory, the exact-repeat radar altimeters can provide long-term and continuous  
97 observations for glacier monitoring. However, radar altimeters have much larger footprints than those  
98 of ICESat/ICESat-2, despite the recent improvement using the delay Doppler technique (*Raney*, 1998)  
99 that can result in a 300-m resolution in the along-track direction (*McMillan et al.*, 2019). Such large  
100 footprints make most radar-based altimeters difficult to observe precise elevations over mountain  
101 glaciers, where the terrain can be rugged and sloping, and radar signals can suffer from volume  
102 scattering and radar penetration (*Lee et al.*, 2013). These surface conditions over glaciers can  
103 contaminate radar waveforms to result in low-precision range measurements over mountain glaciers.  
104 Retracker for remedying contaminated waveforms include offset center Gravity retracker (*Wingham*  
105 *et al.*, 1986), beta retracker (*Martin et al.*, 1983), ICE-2 retracker (*Legresy and Remy*, 1997), threshold  
106 retracker (*Davis*, 1997), modified threshold retracker (*Lee et al.*, 2008) and sub-waveform threshold  
107 retracker (*Yang et al.*, 2012). Improved radar ranges over glaciers have been used to calculate glacier  
108 heights and their changes (*Wingham et al.*, 2009; *Lee et al.*, 2013; *Forsberg et al.*, 2017). In particular,  
109 *Lee et al.* (2013) showed that the glacier elevation change from T/P and Envisat are able to detect the  
110 1993–1995 and 2008–2011 surge events over Alaska glaciers.

111 The objective of this paper is to demonstrate the implementation of a glacier-threshold method  
 112 (GTM) to generate precise elevation measurements from T/P and J2 radar altimeters, then detect and  
 113 analyze trends of elevation change of glaciers at 47 sites (Figure 1 and Table A1) in Alaska. This paper  
 114 is organized as follows. Section 2 shows the satellite altimetry data, airborne Lidar data and the digital  
 115 elevation model (DEM). Section 3 presents the GTM and demonstrates the method step by step.  
 116 Section 4 shows the long-term glacier elevation changes detected by GTM, which are then verified  
 117 and analyzed, taking into account the impact of regional Alaska environmental factors on glacier  
 118 changes. Section 5 concludes this study.

119  
 120 **Figure 1.** Ground tracks (black fine lines) of T/P and J2 over Alaska glaciers, with the  
 121 pass numbers (P). An ID is a glacier site with elevation changes from the altimeters. Here  
 122 only selected glacier IDs are shown (see Table A1 for the full list of glacier names, longitudes,  
 123 latitudes and elevations).

## 124    **2 Data**

### 125        **2.1 TOPEX/Poseidon and Jason-2 altimeter data**

126        The main measurements to detect elevation changes over Alaska mountain glaciers are T/P and  
127    J2. T/P and J2 belong to a family of radar altimeters, and repeat the same ground tracks every 10 days  
128    on 254 passes. Figure 1 shows the ground tracks of the 21 passes of the two satellites. Each of the T/P  
129    data records contain 10-Hz elevation measurements, spaced at an interval of 660 m. The orbit heights,  
130    range measurements, and geophysical corrections were acquired from the geophysical data records  
131    (GDRs), and 64-sample radar waveforms are acquired from the sensor data records (SDRs). Following  
132    the approach of *Lee* (2008), we re-sampled the original 128 waveforms of T/P into 64 waveforms for  
133    retracking. The T/P mission lasted from October 1992 through August 2002 (cycles 1–364). Unlike  
134    T/P, the J2 dataset contains 20-Hz measurements, corresponding to an interval of 330 m. The orbit  
135    heights, range measurements, geophysical corrections, and the 104-sample waveforms were acquired  
136    from sensor geophysical data records (SGDRs).

137        Due to the design of the Jason-1 satellite radar altimeter, and several problems in data processing,  
138    the elevation measurements of Jason-1 over land are not usable (*Frappart et al.*, 2006; *Hwang et al.*,  
139    2016). Therefore, we only used the measurements from T/P and J2. Jason-3 are not used because of  
140    the limited time of research. The altimeter-derived elevation time series span two periods: 1992-2002  
141    (T/P) and 2008-2016 (J2). Over Alaska’s mountain glaciers, the wet tropospheric delays were corrected  
142    using the European Center for Medium-Range Weather Forecasts (ECMWF) model. All the altimeter  
143    data used in this paper were downloaded from the web site of the French Archiving, Validation and  
144    Interpretation of Satellite Oceanographic data (AVISO) at <http://www.aviso.altimetry.fr/>.

### 145        **2.2 IceBridge UAF Lidar data**

146        We used airborne Lidar datasets to verify the altimeter-derived Alaskan glacier elevation time  
147    series. The Lidar dataset is obtained from the Airborne University of Alaska Fairbanks (UAF) Glacier

148 Lidar System and contains surface elevations of Alaskan glaciers. The dataset is a result from the  
149 NASA Operation IceBridge program. The Lidar observations were collected using laser ranging to  
150 glacier surfaces on a fixed wing aircrafts that was positioned by the Global Positioning System with  
151 attitude corrections from the inertial measurement unit (GPS/IMU) (*Larsen, 2010*). The footprint of a  
152 laser pulse is about 20 centimeters in diameter. The average along-track and cross-track spacings are  
153 1 m by 1 m. The average accuracy of the elevation measurements is better than 30 cm. We used high-  
154 resolution and high-precision repeated elevation observations from this dataset to assess our altimeter  
155 result. The web site of the Lidar data is <https://nsidc.org/data/ILAKS1B/versions/1>.

### 156 **2.3 Digital elevation model**

157 A digital elevation model (DEM) is needed when applying the GTM method in this paper. The  
158 DEM was used to correct for the terrain gradient effect and remove erroneous land surface heights  
159 (LSH) from the altimeters. The DEM used in this paper is from SRTM\_plus (*Becker et al., 2009*),  
160 which is on a 15"×15" grid. This DEM was constructed from the measurements of the Shuttle Radar  
161 Topography Mission (SRTM), augmented by elevation data from other satellite missions. Note that  
162 there are several versions of DEM from SRTM with the finest spatial resolution being 3"×3" (90 m).  
163 However, the SRTM DEMs provide elevations only within latitudes  $\pm 55^\circ$  without covering Alaska  
164 mountain glaciers ( $> 55^\circ\text{N}$ ). To use a unified DEM, we decided to choose the SRTM\_plus DEM. We  
165 converted the elevations from T/P and J2 to the elevations with respect to the WGS84 ellipsoid (used  
166 by the SRTM\_plus), based on the differences in the ellipsoidal parameters for T/P and the WGS84.  
167 The SRTM\_plus DEM was downloaded from [ftp://topex.ucsd.edu/pub/srtm15\\_plus/](ftp://topex.ucsd.edu/pub/srtm15_plus/).

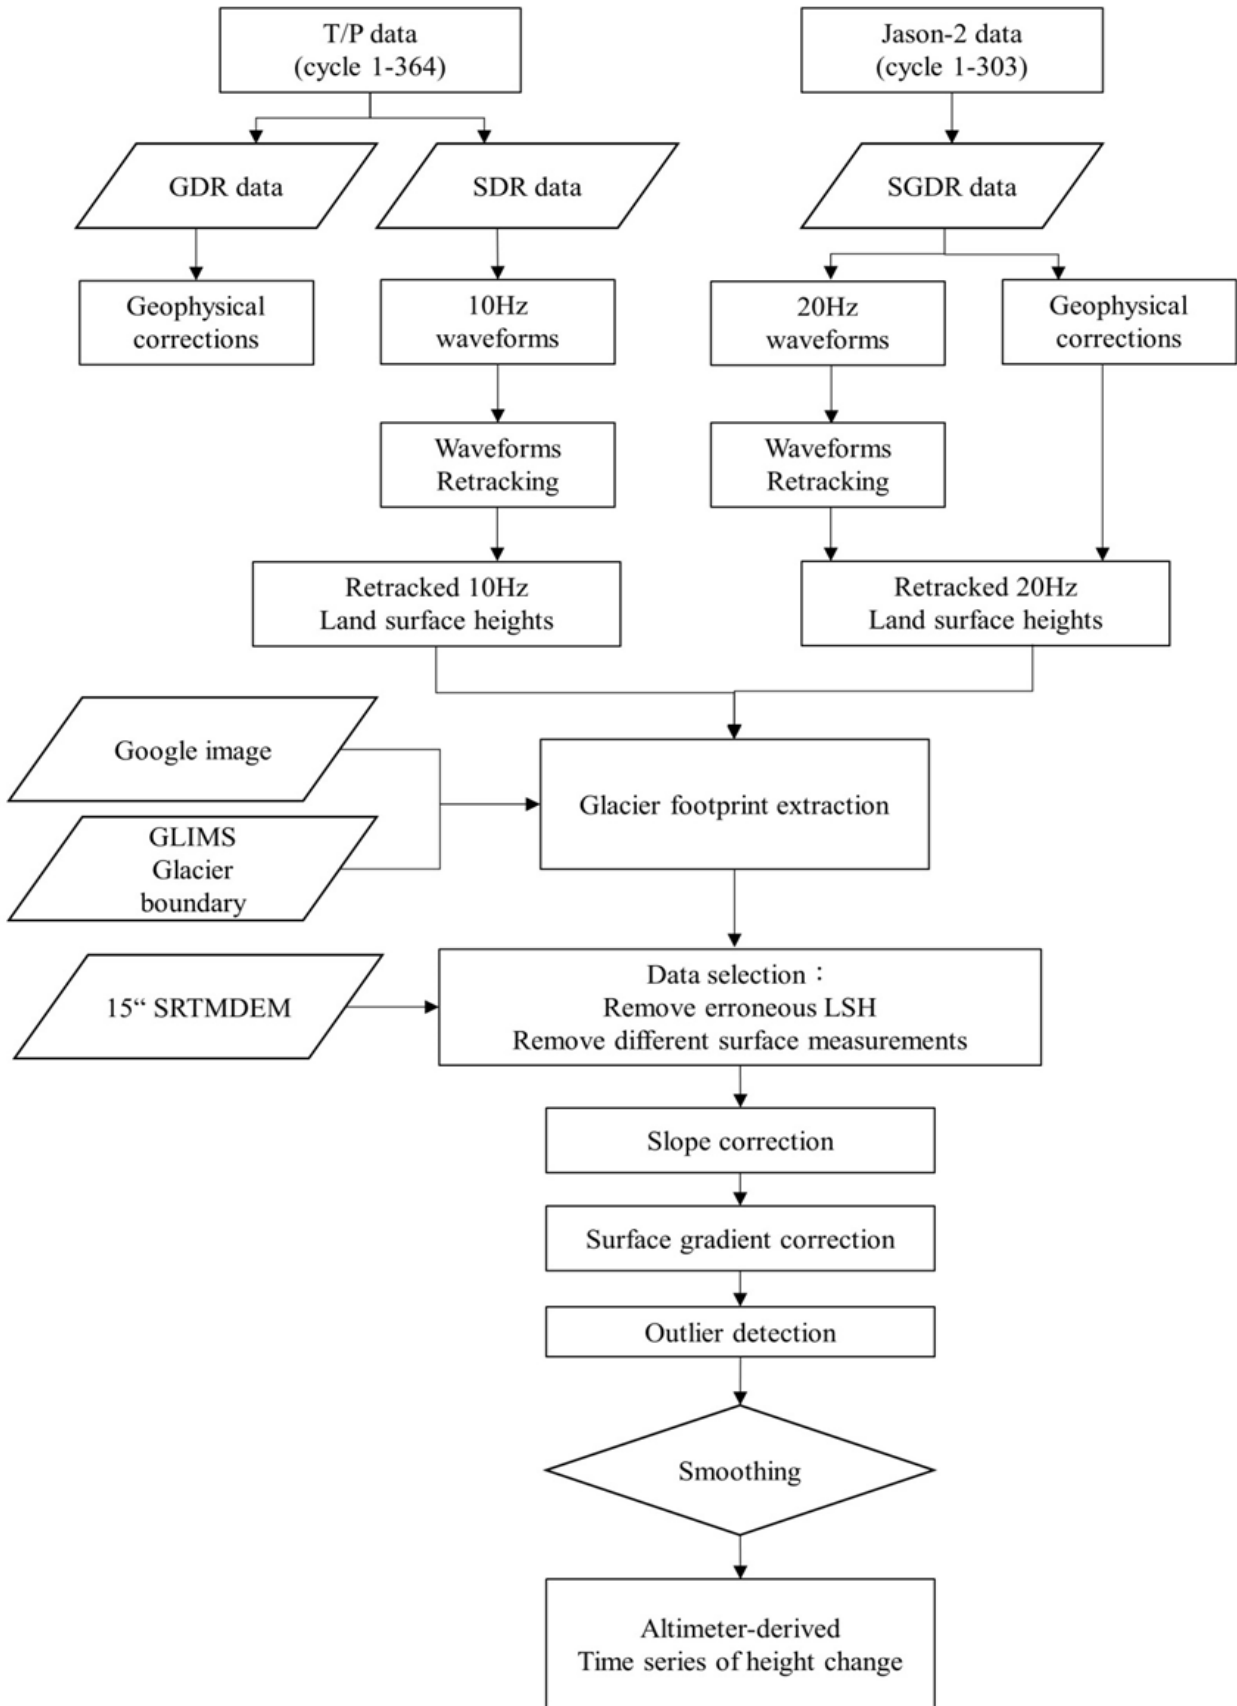

## 168 **3 Methods**

169 A radar altimeter can measure precise glacier elevations over flat, open areas in polar ice sheets,  
170 but not in mountain glaciers without careful data processing. In the study, we present the glacier-  
171 threshold method (GTM) to generate robust glacier elevation changes over Alaska mountain glaciers.

172 The procedure of the GTM for T/P and J2 data is shown in Figure 2. Some of the steps in the procedure  
173 were shown in (*Hwang et al.*, 2021). To avoid repetitions, the steps given by (*Hwang et al.*, 2021) will  
174 only be briefly described in the following subsections. The five steps in the GTM are:

- 175 a) Determine the optimal waveform retracking algorithm to retrack waveforms;
- 176 b) Select valid altimetry observations;
- 177 c) Correct terrain slope and terrain gradient effect;
- 178 d) Calculate the linear trend of each site laying on glaciers;
- 179 e) Assess the detected elevation change by crossover analysis.

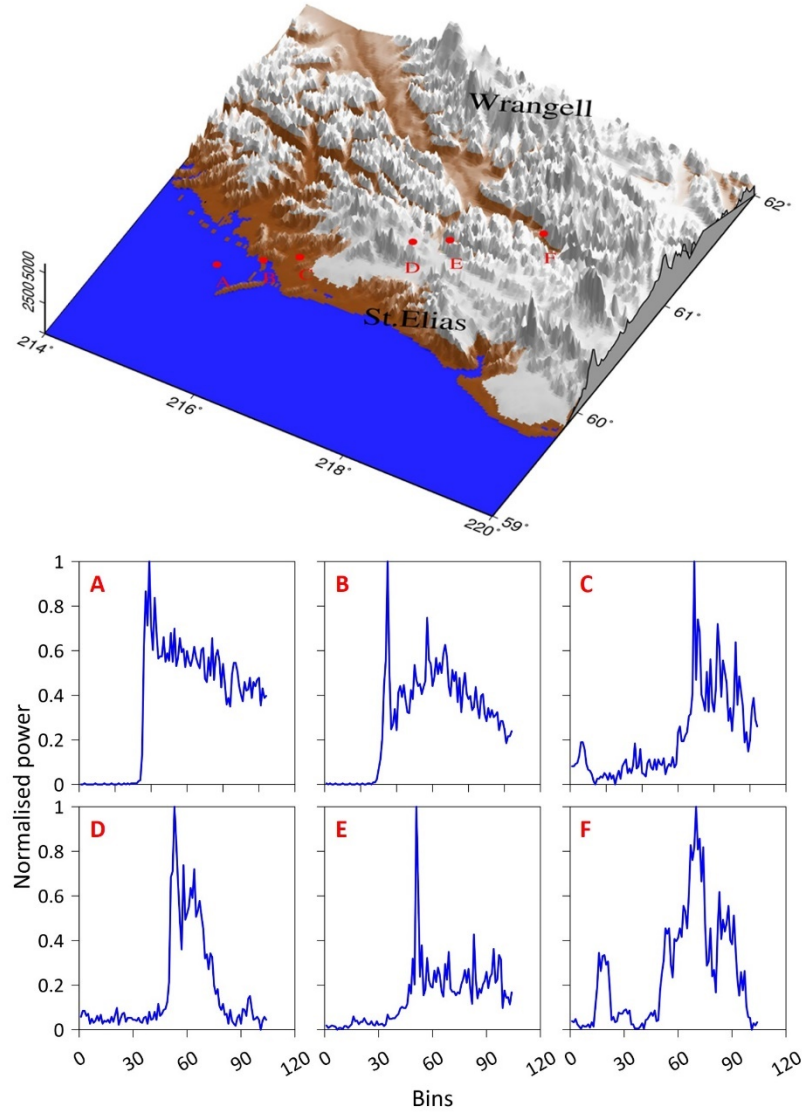

**Figure 2.** Flowchart of the GTM for retrieving precise glacier elevation changes.

### 3.1 Waveform Retracking

The glacier elevation ( $H_{glacier}$ ) from altimeter measurements at a given nadir point can be expressed as:

$$H_{glacier} = H_{sat} - H_{alt} - H_{cor} - H_{terrain} - H_{retrack} \quad (1)$$

where  $H_{glacier}$  is the height of glacier;  $H_{sat}$  is the satellite altitude;  $H_{alt}$  is the range measurement (for T/P and J2);  $H_{cor}$  is the integration of geophysical corrections (in the GDR product of the T/P satellite and the SGDR product of the Jason-2);  $H_{terrain}$  is the terrain correction, which will be described in subsection 3.4;  $H_{retrack}$  is the range correction from waveform retracking.

**Figure 3.** Glaciers over Alaska (top, white-shaded areas) and radar altimeter waveforms A-F over different surface types along pass 123 of J2.

193 Altimeter radar waveform retracking is an important part for generating precise range  
194 measurements from complex waveforms. A radar altimeter generated returned waveforms from the  
195 reflecting radar pulses to determine the two-way travel times for range measurements. Over a rough  
196 or uneven land surface, returned waveforms of radar altimeters can be different from the default Brown  
197 model (*Brown, 1977*). Figure 3 shows sample J2 waveforms along pass 123 over six different types of  
198 surfaces in Alaska: ocean (A), coastal area (B), flat terrain(C), ice (D), steep slope (E), and complex  
199 terrain (F, mixed rock and ice). The waveform the ocean surface is the closest to the Brown model (see  
200 waveform A in Figure 3). As the altimeter approaches land from the oceans, the waveforms become  
201 irregular due to waveform contamination. In particular, the waveforms become more complex over  
202 rough ice surfaces (see waveform D and F in Figure 3) or steep-sloped terrains (see waveform E in  
203 Figure 3).

204 We retrack waveforms to detect the gates of the actual midpoint of the waveform leading edge to  
205 correct for range errors over Alaskan mountain glaciers. For a given waveform, range correction from  
206 waveform retracking is:

$$207 \quad H_{retrack} = (G_r - G_t) \times 0.46875 \quad (2)$$

208 where  $G_r$  is the retracked gate,  $G_t$  is the default tracking gate (the default is 24.5 and 32.5 for T/P and  
209 J2, respectively, unitless), and 0.46875 m is the length of a gate for the Ku-band altimeter.

210 Several algorithms for waveform retracking can improve the precision of radar range  
211 measurement, such as off-center of gravity (*Wingham et al., 1986*), the threshold algorithm (*Davis,*  
212 *1997*), and the Sub-waveform algorithm (*Yang et al., 2012*). To determine the optimal algorithm of  
213 waveform retracking in this study, we experimented with these three algorithms (including various  
214 threshold values) for waveform retracking. The best retracker used in this paper is described and  
215 assessed in Section 3.5.

216

**Table 1.** Rates of glacier elevation change (in m/yr) from J2 data at the crossover of passes 123 and 180 from different retracking methods

Retracking algorithm	Pass		Difference
	123	180	
OCOG	-2.54	-1.88	0.66
Threshold (50%)	-2.47	-1.72	0.75
Sub-waveform (10%)	-1.87	-1.56	0.31
Sub-waveform (20%)	-2.18	-1.8	0.38
Sub-waveform (30%)	-1.5	-1.7	0.2
Sub-waveform (50%)	-1.57	-1.56	0.01

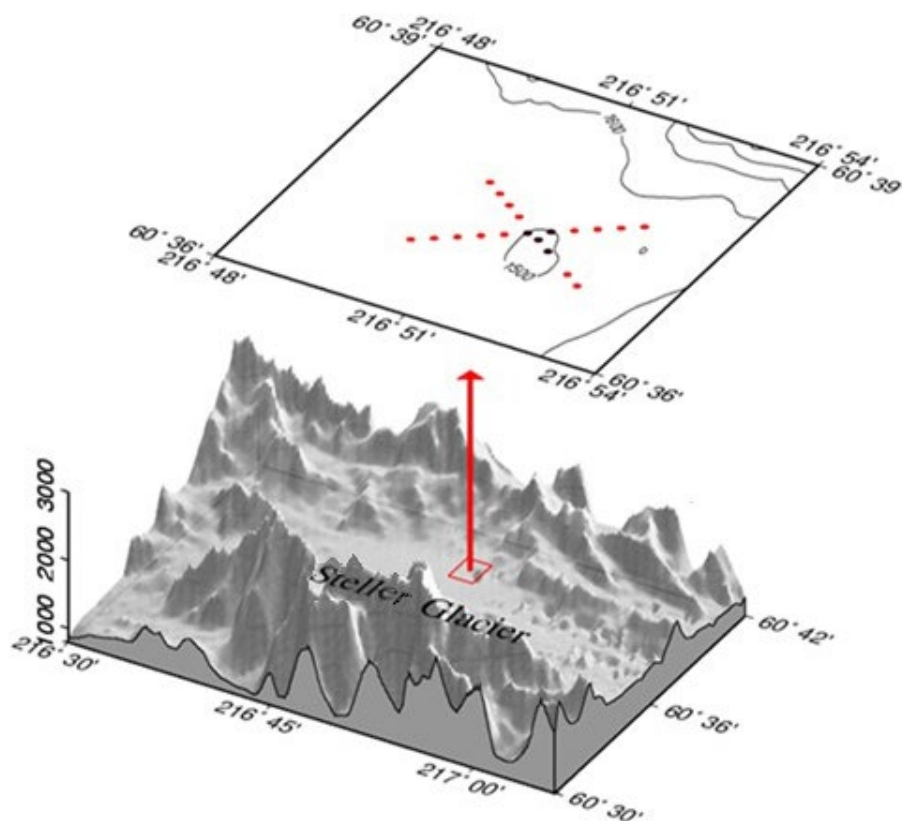

### 3.2 Altimeter data selection

Selecting usable waveforms and retracking them for precise elevations is a crucial part of the GTM. We follow the selection criteria presented in (Hwang *et al.*, 2021) to select the needed waveforms. The waveforms over Alaska glaciers are specular like the D waveform in Figure 3, consistent with the view of Lee (2008) and other studies over ice sheets and glaciers. A returned waveform is not only related to characteristics of the radar-illuminated surface, but also to the distance between the radar altimeter and the surface. Over ice surfaces, the automatic gain control (AGC) onboard T/P and J2 can theoretically help to maintain suitable returned powers (Fu and Cazenave, 2000), but the AGC cannot guarantee preventing the return powers from becoming fully saturated. Hwang *et al.* (2016) showed that the range errors can reach 100 m if altimeter radar waveforms were damaged by complex surface.

Therefore, we first identify whether altimetry footprints are over glaciers by using Global Land Ice Measurements from Space (GLIMS) and Google Earth images. The criterion for the identification is that the measurements are within the polygons of glaciers defined by GLIMS and also over an ice/snow surface on Google Earth images. We then classify the waveforms to identify valid waveform

234 measurements and for each waveform we computed the peak power of waveform, and removed the  
235 value of peak power smaller than 1.8. More details can be found in *Peacock and Laxon* (2004), *Lee*  
236 (2008), and *Yang et al.* (2012). Additionally, we applied a cluster analysis method and the algorithm  
237 of *Dabo-Niang et al.* (2007) to distinguish between useful and bad waveforms. But it turns out that  
238 glacier heights corrected by waveform retracking cannot automatically yield useful time series of  
239 glacier elevation change without further data screening. Therefore, we used the SRTM\_plus DEM to  
240 remove outliers of measurement over mountain glaciers: The LSH is regarded as an outlier when the  
241 difference between the LSH and the DEM elevation exceeds 150 m (*Hwang et al.*, 2021).

242 It is challenging to obtain precise LSHs from radar altimeters over steep slopes due to high  
243 uncertainty (*Brenner et al.*, 2007), and the rate of elevation change is not consistent at different  
244 altitudes. For example, over the Greenland Ice sheet, the elevation changes from the Envisat altimeter  
245 (2002-2010) varied with altitude. The results represent positive trend in high altitude area, and  
246 represent negative trend in low altitude area (*Forsberg et al.*, 2017). Thus, for a given site in this paper  
247 we used 15"×15" SRTM to select suitable altimeter measurements in a bin with a 1-km radius, centered  
248 at the location of a reference point. The reference point is determined by individual inspections of all  
249 sites. In this step, the altimeter measurements falling into the 100 m contour (like the red points in  
250 Figure 4) are candidate measurements for a bin. Figure 4 shows an example of how altimetry  
251 measurements are selected over different altitudes (black points) in a bin.

**Figure 4.** An example showing selected altimeter measurements (red dots) from J2 around Sites 24 and 33 (see Table A1 for coordinates) near the crossover of passes 123 and 180. The selected measurements have elevations ranging from 1500 to 1600 m over a gently sloping glacier surface, where the effects of lateral offset in repeated tracks and terrain gradient can be reliably corrected. Compared to a rugged surface, the measurements at the black points are over steep slopes (rugged terrain) and thus are excluded.

### 3.3 Correction for terrain effect

Corrections for terrain effect include the slope correction and terrain gradient correction. The slope-induced error is caused by the difference between sub-satellite point and the closest point on a sloping surface (Brenner *et al.*, 1983). The terrain gradient error due to the lateral shift of repeated tracks in the cross-track direction (about  $\pm 1$  km). Below we show how these corrections are applied.

#### (a) Outlier removal, elevation adjustment

First, we fitted the following least-squares model to the selected measurements from repeat cycles

266 at a bin (*Hwang et al.*, 2021):

$$267 \quad H_i^j(\varphi, \lambda, t) + v_i^j = a_0 + a_1(t - t_0) + a_2(\varphi - \varphi_0) + a_3(\lambda - \lambda_0) + \quad (3)$$

$$a_4(\varphi - \varphi_0)^2 + a_5(\lambda - \lambda_0)^2 + a_6(\varphi - \varphi_0)(\lambda - \lambda_0)$$

268 where  $H_i^j(\varphi, \lambda, t)$  is the LSH from altimeter at geodetic latitude ( $\varphi$ ), longitude ( $\lambda$ ), and measured time  
 269 ( $t$ ), included range correction from waveform retracking,  $j$  is the repeat cycle,  $i$  is the  $i$ th measurement  
 270 from repeat cycle  $j$  at this bin,  $v_i^j$  is the residual of  $H_i^j(\varphi, \lambda, t)$ ,  $\varphi_0$  and  $\lambda_0$  represent the location of  
 271 reference point in this bin,  $a_0$  is the mean height at this bin,  $a_1$  is the initial rate of elevation change,  
 272  $a_2$ ,  $a_3$ ,  $a_4$ ,  $a_5$  and  $a_6$  are coefficients of 2<sup>nd</sup> order surface fitting from all repeat cycles at this bin.

273 In the least-squares adjustment, the weight of an observation is the inverse distance between the  
 274 measurement point and reference point. After the first-round of adjustment, the residuals ( $v_i^j$ ) for all  
 275 measurements and the a posteriori variance of unit weight is computed. If a residual ( $v_i^j$ ) is two times  
 276 larger than the squared root of the a posteriori variance, we need to remove the corresponding  
 277 measurement and perform the next-round of adjustment without the removed measurements and stop  
 278 the adjustment when no measurements are removed. According to *Flament and Rémy* (2012), the  
 279 coefficients of 2<sup>nd</sup> order surface can reduce the effects of terrain. More details of the coefficients of 2<sup>nd</sup>  
 280 order surface also can be found in *Remy and Parouty* (2009) and *Hwang et al.* (2021). An adjusted,  
 281 outlier-free elevation can be expressed as:

$$282 \quad \hat{H}_i^j(\varphi, \lambda, t) = H_i^j(\varphi, \lambda, t) + v_i^j \quad (4)$$

### 283 (b) Correction for lateral offset of ground track

284 As mentioned earlier, the actual tracks of the satellite do not repeat exactly. This can introduce  
 285 the terrain gradient effect. Before retrieving glacier elevation changes at each site, the along-track  
 286 heights should be reduced to the heights along reference tracks. Here, we use a 15'' $\times$ 15'' SRTM to  
 287 correct the terrain gradient as (*Lee*, 2008):

$$288 \quad H_i^j(\varphi_0, \lambda_0, t) = \hat{H}_i^j(\varphi, \lambda, t) + DEM(\varphi_0, \lambda_0) - DEM(\varphi, \lambda) \quad (5)$$

289 where  $H_i^j(\varphi_0, \lambda_0, t)$  is the  $i$ th LSH after terrain gradient correction at reference point ( $\varphi_0, \lambda_0$ )  
 290 from repeat cycle  $j$  in this bin,  $DEM(\varphi_0, \lambda_0)$  and  $DEM(\varphi, \lambda)$  are the elevations from the 15'' $\times$ 15''

DEM at the reference point and the observation point.

### 3.4 Altimeter-derived elevation changes

After the elevation measurements from all cycles in a bin were treated using the methods described in Section 3.2-2.4, for each cycle we averaged the measurements to form a representative height:

$$\bar{H}^j(\varphi_0, \lambda_0, t) = \frac{\sum_{i=1}^n H_i^j(\varphi_0, \lambda_0, t)}{n} \quad (6)$$

where  $\bar{H}^j(\varphi_0, \lambda_0, t)$  is the representative height at reference point  $(\varphi_0, \lambda_0)$  for cycle  $j$ ,  $n$  is the number of measurements in the bin.

In order to reduce high-frequency noises, a Gaussian filter was used to smooth the time series of glacier elevation change. Then, we compute the trend of elevation changes at  $(\varphi_0, \lambda_0)$  from the altimeter-derived time series by the model as follows:

$$\Delta \bar{H}^j(\varphi_0, \lambda_0, t) = a + bt + c \cos(2\pi\omega t) + d(2\pi\omega t) \quad (7)$$

where  $\Delta \bar{H}^j(\varphi_0, \lambda_0, t)$  is the altimeter-derived elevation change of mountain glacier,  $t$  is the time relative to the average time,  $a$  is the mean,  $b$  is a linear trend (rate of elevation change),  $\sqrt{c^2 + d^2}$  is the amplitude of the annual oscillation, and  $\omega$  is the annual frequency (one cycle per year).

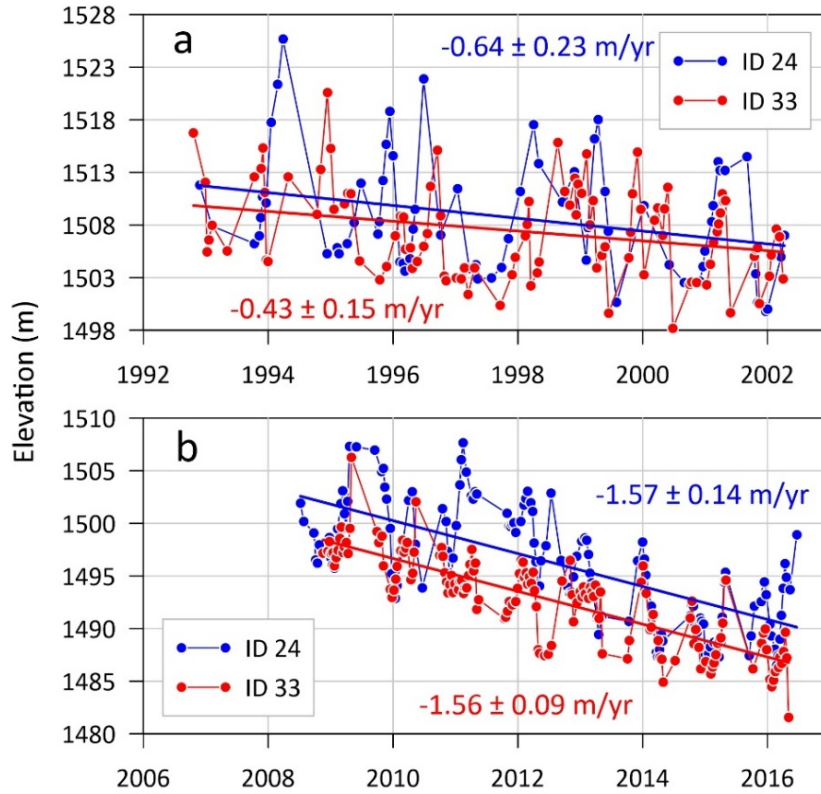

A robust least-squares method is used to estimate the four parameters ( $a$ ,  $b$ ,  $c$ , and  $d$ ), with equal weights for all measurements. We also estimated the uncertainty of rate ( $b$ ) in Eq. 7. In this paper, an estimated rate of elevation change is accepted only when it meets the following two criteria: 1) The absolute value of elevation change rate is larger than its standard error; 2) The ratio between the number of elevation measurements in a time series and the number of all cycles is larger than 15% (see column 3 of Table A2 and Table A3). This ratio is also defined as the usable data percentage in this study.

### 3.5 Method validation by an internal accuracy assessment at a crossover

Due to a lack of in situ glacier elevation measurements (such as elevations from GPS, total station and Lidar observations), it is challenging to assess the uncertainties of elevation changes from T/P and

315 J2 over Alaska glaciers. Here, we use a crossover analysis to assess the “internal” accuracies of  
316 elevation changes from the T/P and J2 altimeters. An external accuracy analysis using Lidar  
317 measurements is made in Section 4.1. The selected crossover point is at the intersection of pass 123  
318 (ascending track) and pass 180 (descending track), located around ID 24 and ID 33 (Figure 1 and Table  
319 A1). Here, we compare two time series of glacier elevation change from pass 123 and 180. We  
320 experimented with different waveform retracking algorithms to obtain different elevation change rates  
321 at this crossover point. As shown in Table 1, the sub-waveform algorithm with a 50-% threshold results  
322 in a minimum difference between the elevation change rates from pass 123 and 180.

323 Figure 5a and b compares the time series from T/P and J2 for pass 123 and 180, resulting from  
324 the use of the sub-waveform retracker with a 50-% threshold value. From the T/P data (1992–2002),  
325 the difference between the rates from the two passes is 0.21 m/yr and the difference is 0.01 m/yr from  
326 the J2 data (2008–2016). The patterns of elevation change from pass 123 and 180 at this crossover are  
327 consistent, despite some differences in the two time series. These differences may be caused by spatial  
328 and temporal factors, such the 2-day difference between the time of measurement from 123 and that  
329 from 180. Another explanation may be that the automatic gain control (AGC) reacted to the surface  
330 elevations differently for pass 123, which traveled from ocean to land pass and for pass 180, which  
331 traveled from land to ocean.

**Figure 5. (a)** The time series of glacier elevation change and their rates from T/P data at the crossover point, corresponding to ID 24 if data from pass 123 are used (blue dots), to ID33 if data from pass 180 are used (red dots), **(b)** same as (a), but from J2 data. The elevations are corrected by the sub-waveform retracking with a 50% threshold (Table 1).

## 4 Results and Discussion

### 4.1 External assessment using Lidar measurements

An external accuracy assessment of the glacier elevation changes determined in this study is made using the airborne Lidar data described in Section 2.3. In order to avoid the impact of the systematic bias between the Lidar measurements and the altimeter measurements (J2 only), we calculated the differences of elevations detected by the two kinds of sensors, named  $D_L$  (the difference of the elevations at a spot from the two airborne Lidar surveys) and  $D_{J2}$  (similar to  $D_L$ , but from J2 with a slightly different time span). At a given site, the  $D_L$  and  $D_{J2}$  value and their associated time spans can be used to compute the rates of elevation change in the respective time spans (the time spans are nearly the same), and the difference between the two rates is called  $D_r$ . At a given site, the elevation from

347 Lidar is defined as the mean of the elevations within a radius of 300 m to the site (*Trantow and Herzfeld,*  
348 2016), and the elevation from J2 is obtained by spline interpolation from the J2-derived time series.  
349 Due to the rapid seasonal and interannual changes of glaciers, only the sites with dense and robust time  
350 series of J2 are used for comparison with the Lidar measurements. Ultimately, we selected seven sites  
351 (ID 4, 5, 18, 20, 31, 37 and 47) over six glaciers (Walsh, Logan, Klutlan, Tazlian, Hubbard and Kahiltna  
352 Glacier) for this comparison.

353 Table 2 shows the values of  $D_L$ ,  $D_{J2}$  and  $D_r$  at the seven sites. From Table 2, in general the patterns  
354 (signs) of the glacier elevation changes from Lidar ( $D_L$ ) and J2 ( $D_{J2}$ ) at each site are consistent, but  
355 with varying discrepancies from one site to another. At Site 31 and Site 47, the  $D_r$  values are the  
356 smallest because of the stable change of glaciers, dense time series of J2, and the flat terrains at these  
357 sites. The largest  $D_r$  (absolute value) occurs at Site 5, followed by Sites 4, 18 and 20. Because the time  
358 spans for each  $D_L$  and  $D_{J2}$  are only slightly different, temporal glacier variabilities around the sites  
359 with large differences ( $D_r$  values) are unlikely to be a dominant for the large differences. Table 2 shows  
360 the  $D_r$  values are correlated with the slopes. This correlation may result from relatively large  
361 uncertainties in the Lidar and J2 elevation measurements over glaciers with large slopes. In general,  
362 the Lidar elevation measurements confirm the elevation changes from J2, but the result in Table 2  
363 shows a mean discrepancy of 1.15 m/yr (average of absolute  $D_r$ ) and a standard deviation of 0.84 m/yr  
364 in the differences of the rates from Lidar and J2 at the seven sites. Both the Lidar and J2 measurements  
365 show rising glacier elevations at Site 37, despite a discrepancy in the two rates. At Site 5, the rate of  
366 elevation change from Lidar is -20.22 m/year, compared to -12.48 m/year from J2. Thus, both Lidar  
367 and J2 show large glacier elevation drops near Site 5 in the 2010s.

**4.2 Patterns of glacier elevation changes from T/P and J2**

374

375

376

377

378

379

380

The T/P and J2 altimeter observations spanned nearly two decades (from January 1993 to 2016 in this paper), resulting in various patterns of glacier changes over Alaska. Here we classify the 47 sites to three categories of patterns: (I) those with similar trends in glacier elevation changes with evident elevation discontinuities (Figure 6), (II) those with reverse trends and evident elevation discontinuities (Figure 7), (III) those with similar trends and no clear elevation discontinuities (Figure 8). Evident elevation discontinuities might be caused by a number of factors, including T/P-J2 inter-altimeter biases, terrain effect, and changes in climate pattern.

381

382

383

384

385

386

387

388

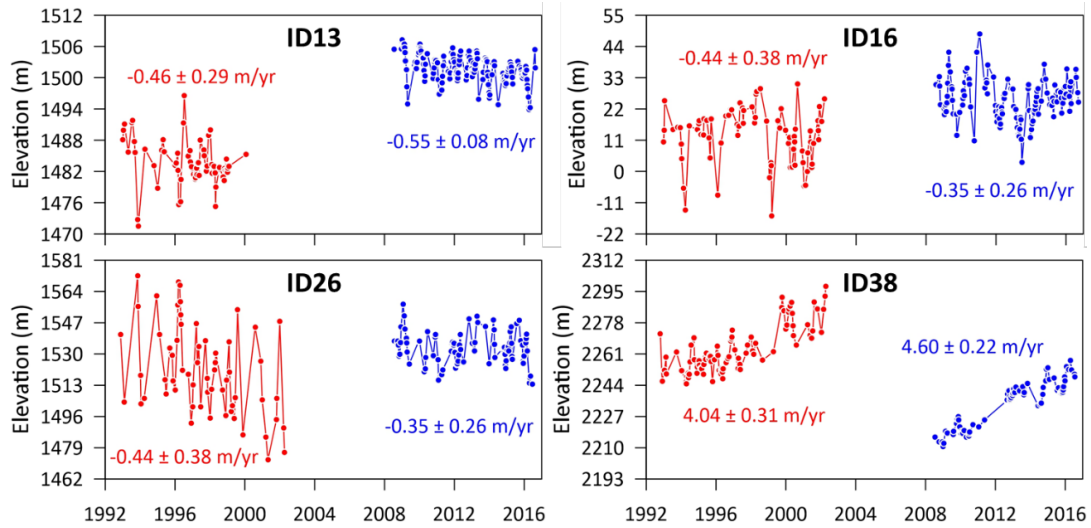

Previous studies showed that there are inter-altimeter biases in monitoring inland water and ocean dynamics using similar types of radar altimeters (*Beckley et al.*, 2004; 2010; *Hwang et al.*, 2016). Such systematic differences are associated with the different levels of measurement accuracy and topographic complexity. In some cases, constants were applied to correct for the biases (*Wingham et al.*, 2006; *Fricker and Padman*, 2012). However, over ice surfaces, inter-altimeter biases usually have distinct spatial patterns (*Frappart et al.*, 2016). The inter-altimeter biases of a tandem mission can be estimated through a collinear difference of simultaneous measurements at a small scale (*Wingham et al.*, 2006; *Schröder et al.*, 2019). Since J2 was launched several years after T/P and they used different

altimeters, identifying range biases over glacier surfaces between them is difficult. A method based on long-term rate reference has been used to eliminate this offset (*Schröder et al.*, 2019), but the premise of a stable trend of glacier elevation change must be met. For the sites with similar trends but with evident elevation discontinuities (Figure 6), the rate-reference correction method seems feasible for bias corrections. However, the method is invalid for the sites with reverse trends and evident elevation discontinuities (Figure 7). Because of the lack of reliable reference observations, it is challenging to remove the biases between the glacier elevations from T/P and J2. Thus, we decide not to correct for any potential inter-altimeter biases between T/P and J2, and the result in this paper genuinely reflects the capabilities of T/P and J2 in observing glacier elevation changes over Alaska.

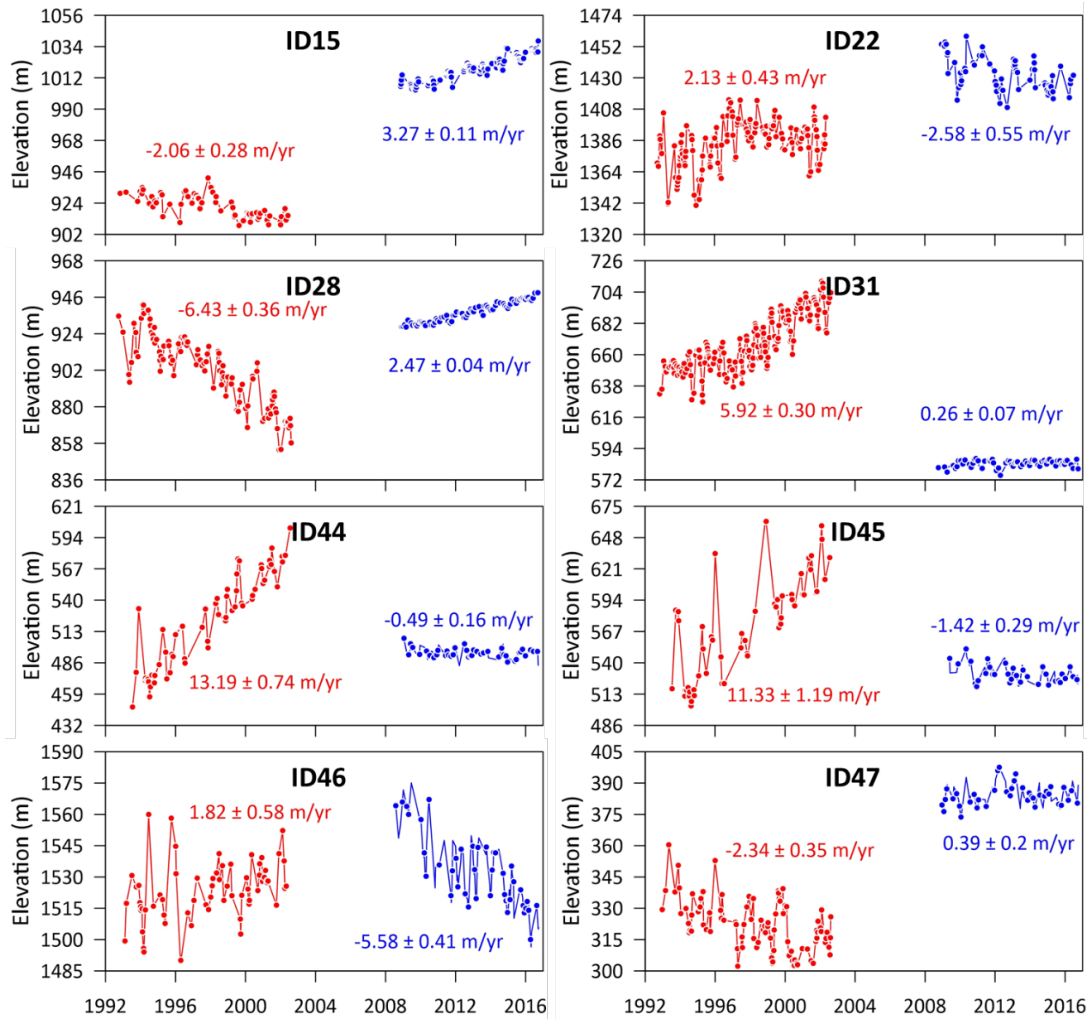

J2 obtains elevations at a frequency of 20 Hz with an along-track spacing of ~330 m, which is half that of T/P. Terrain undulations within the footprints of T/P and J2 can also cause different ranging biases that introduce elevation discontinuities between the two altimeters. Moreover, the inherent different ranging techniques of the radar altimeters used by T/P and J2 can result in different usable data rates at a given glacier site. For example, the J2 altimeter (called Poseidon-3 altimeter) used an open-loop tracker mode that can successfully track backscatter signals over rapidly varying terrains (*Martin-Puig et al.*, 2016). Furthermore, large terrain slopes can introduce greater uncertainties in the observed glacier elevation changes. In this study, the SRTM\_plus was employed to reduce the error of terrain effect. The ice topography from this DEM product results from different ICESat acquisitions in different seasons and years (*Becker et al.*, 2009), and the profiles measured by ICESat represents the full topography.

During the study period (1993–2016), the changes in the rates of glacier elevation change in Figure 6, 7 and 8 may also reflect shifts in climate pattern. *Wendler et al.* (2017) showed that the Pacific Decadal Oscillation (PDO) had substantial impacts on the climate of Alaska. After 1998, the PDO has changed from a positive phase to a negative phase, leading to colder temperatures and lower precipitations. The inter-annual fluctuation in the PDO index in the negative phase has lasted for decades before the index changed from negative values to positive ones in 2014. These inter-decadal

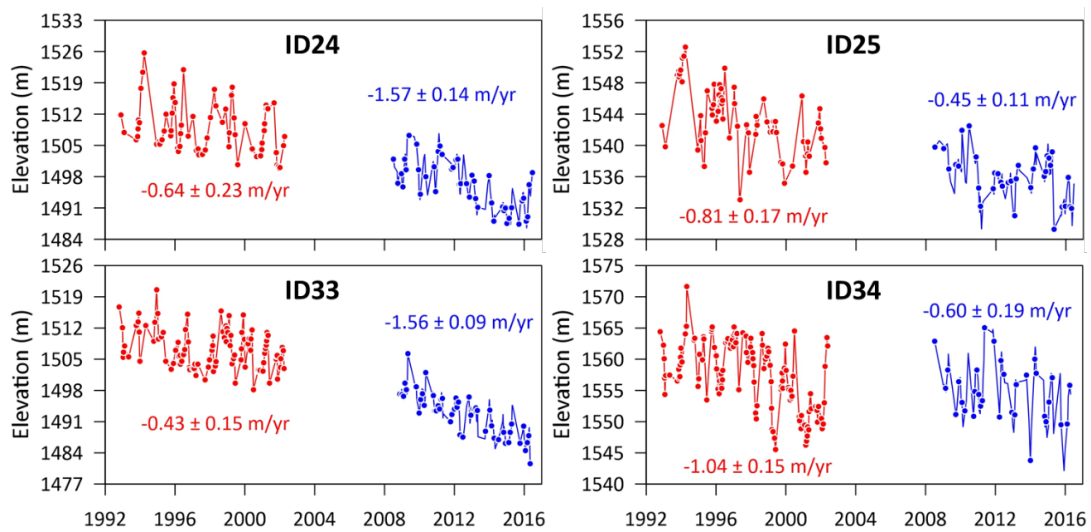

415 climate phase shifts occurred just across the mission period of T/P and J2 (1993–2016). More analyses  
 416 about the spatially heterogeneous responses of Alaskan glaciers to PDO will be discussed in Section  
 417 4.4.

**Figure 6.** Glacier elevation changes at Sites 13, 16, 26 and 38, with similar trends but with evident elevation discontinuities.

**Figure 7.** Glacier elevation changes at Sites 15, 22, 28, 31, 44, 45, 46 and 47, with reverse trends and evident elevation discontinuities.

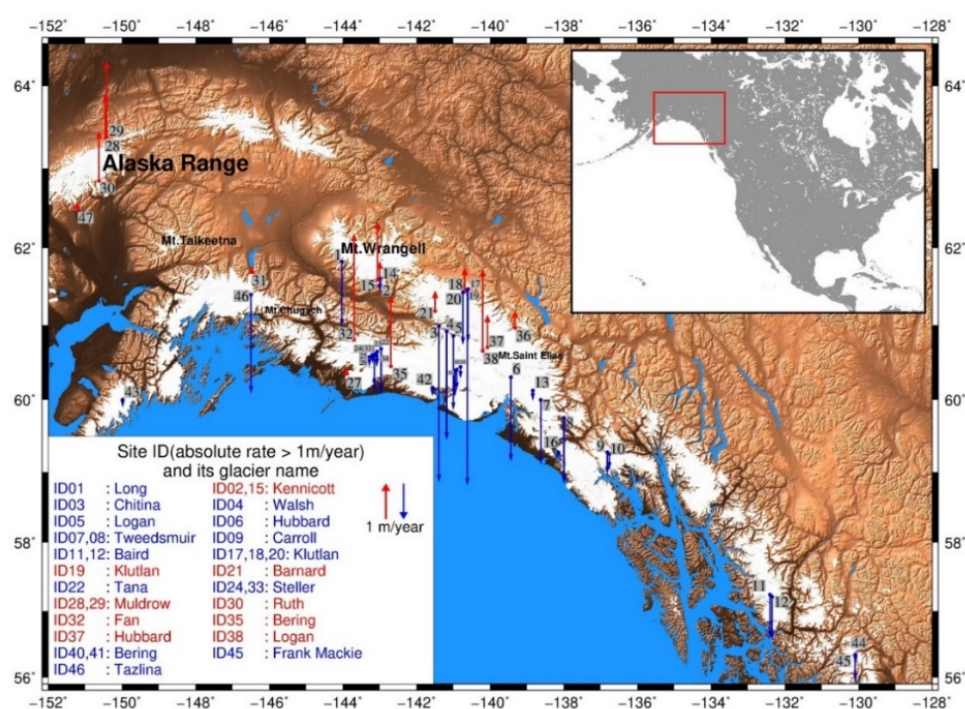

**Figure 8.** Glacier elevation changes at Sites 24, 25, 33 and 34 with similar declining trends and negligible elevation discontinuities.

### 4.3 Recent rates of Alaska glacier elevation changes from J2

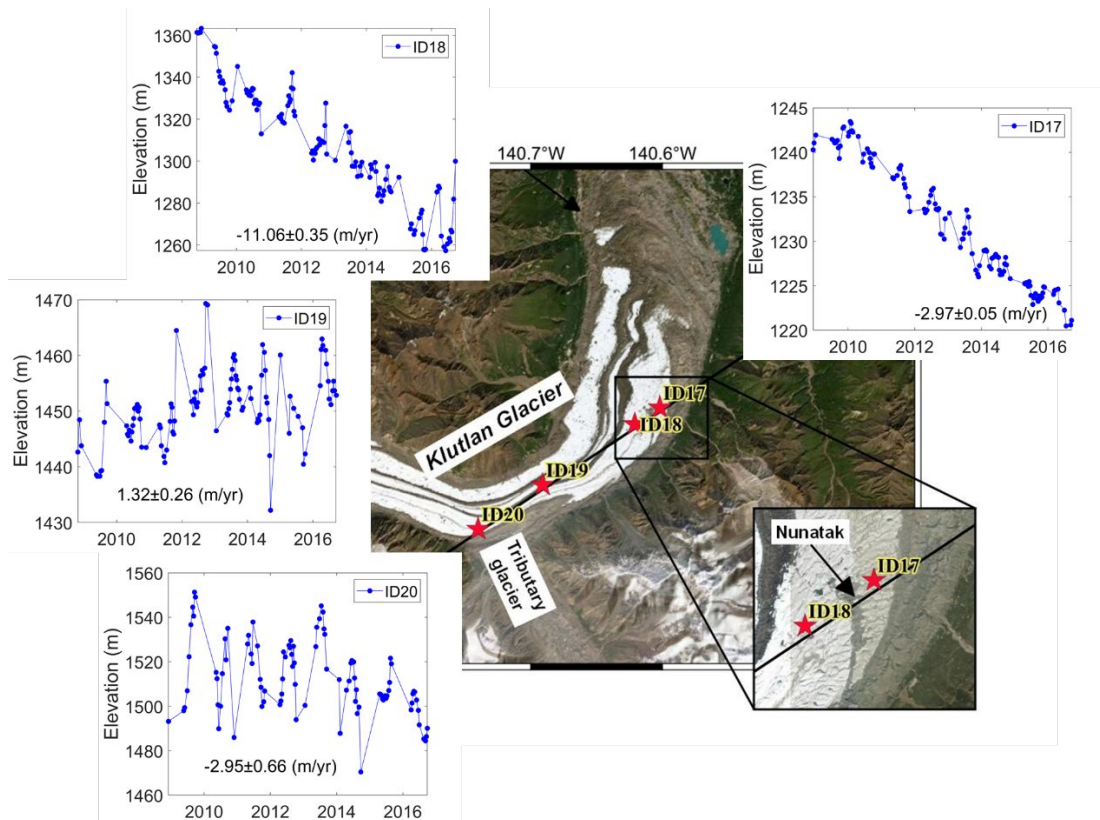

Here, we discuss recent glacier elevation changes rates over Alaska glaciers using the J2 result over 2008–2016. Figure 9 shows the rates at the 47 sites from J2 given in Table A3. In total, 25 glaciers are included (Sites 24 and 33 are at a crossover point, thus the same glacier). Most sites are located in St. Elias mountains, Kenai Mountains, Chugach Range, Coast Range and Wrangell Mountains. Glaciers thinning and retreat in these regions contributed 90% of the freshwater discharge into the Gulf of Alaska (Neal *et al.*, 2010). Few sites are distributed in central Alaska range. At most sites, the glacier elevations were falling (negative rates of elevation change), but at some sites the glacier elevations experienced positive rates. The varying patterns of glacier elevation changes may be caused by glacial dynamics, atmospheric circulation and climate sensitivity (Berthier *et al.*, 2010; Menounos *et al.*, 2019). Below we analyze selected groups of glaciers to discuss such heterogeneous elevation changes.

**Figure 9.** Rates of glacier elevation change from J2 over 2008–2016. Red (blue) arrows show positive (negative) rates. The inserted chart shows the site IDs and glacier names with absolute rates > 1 m/year (see Table A1).

Klutlan Glacier (Figure 10) is located in the St. Elias Mountains and has experienced repeated

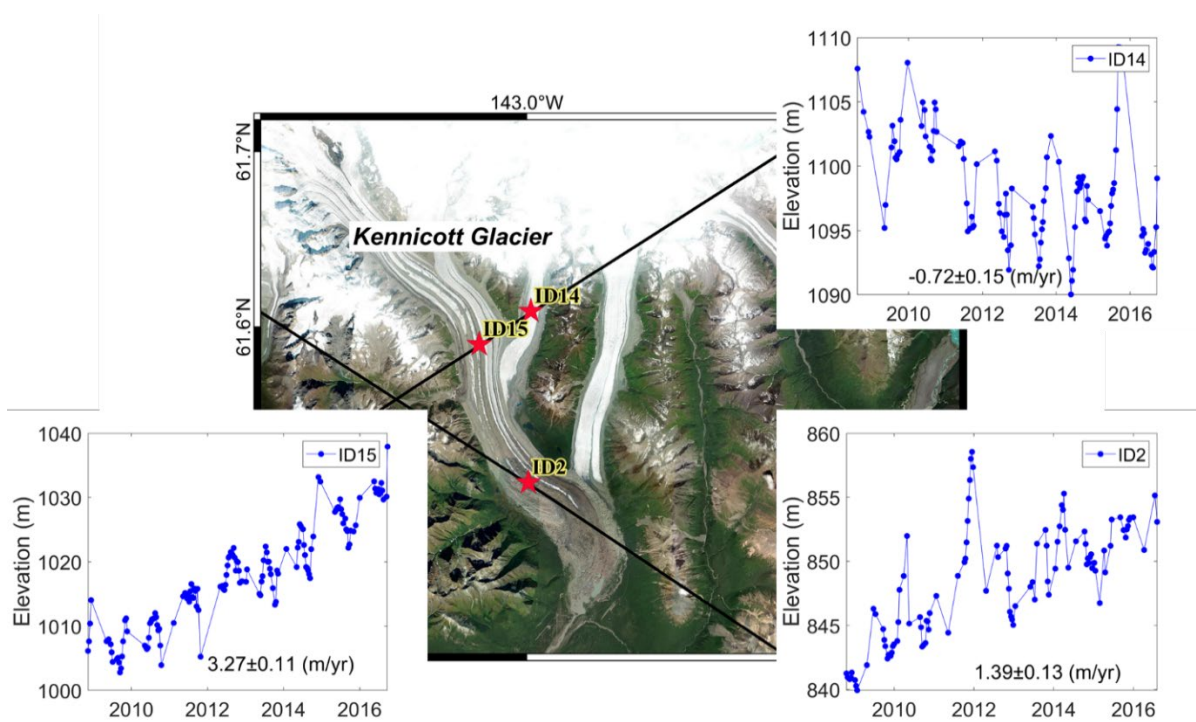

443 surges during the past hundreds of years (*Wright, 1980*) and in recent times (*Altena et al., 2019*). Thus,  
 444 this glacier is highly dynamic. Four Sites (Sites 17, 18, 19 and 20 in Figure 10) are near the terminus  
 445 of Klutlan Glacier. At Sites 17 and 20, the rates of elevation change are about -3 m/yr, but the rate at  
 446 Site 18 is much larger, reaching -11 m/yr. Potential causes of the large thinning rate at Site 18 and the  
 447 positive rate at Site 19 (1.32 m/yr) can be explained as follows. A large tributary joins Klutlan Glacier  
 448 near Sites 19 and 20. At the junction of glaciers, debris flows from the tributary have deposited near  
 449 Site 19 to raise the elevations. Furthermore, between Sites 18 (altitude 1260 m) and 17 (altitude 1237  
 450 m), there is a nunatak at an altitude of about 1320 m. Site 17 is located in the northern side of the  
 451 nunatak and is less affected by glacier surges. Thus, the presence of the nunatak results in a large  
 452 difference between the rates at Site 17 and 18. Although the glacier thinning rates at Site 17 and Site  
 453 20 are close, the thinning patterns at the two sites are different. The annual variation of glacier elevation  
 454 changes at Site 20 are much larger than that at Site 17.

455  
 456 **Figure 10.** Glacier elevation changes at Sites 17, 18, 19 and 20 near Klutlan Glacier

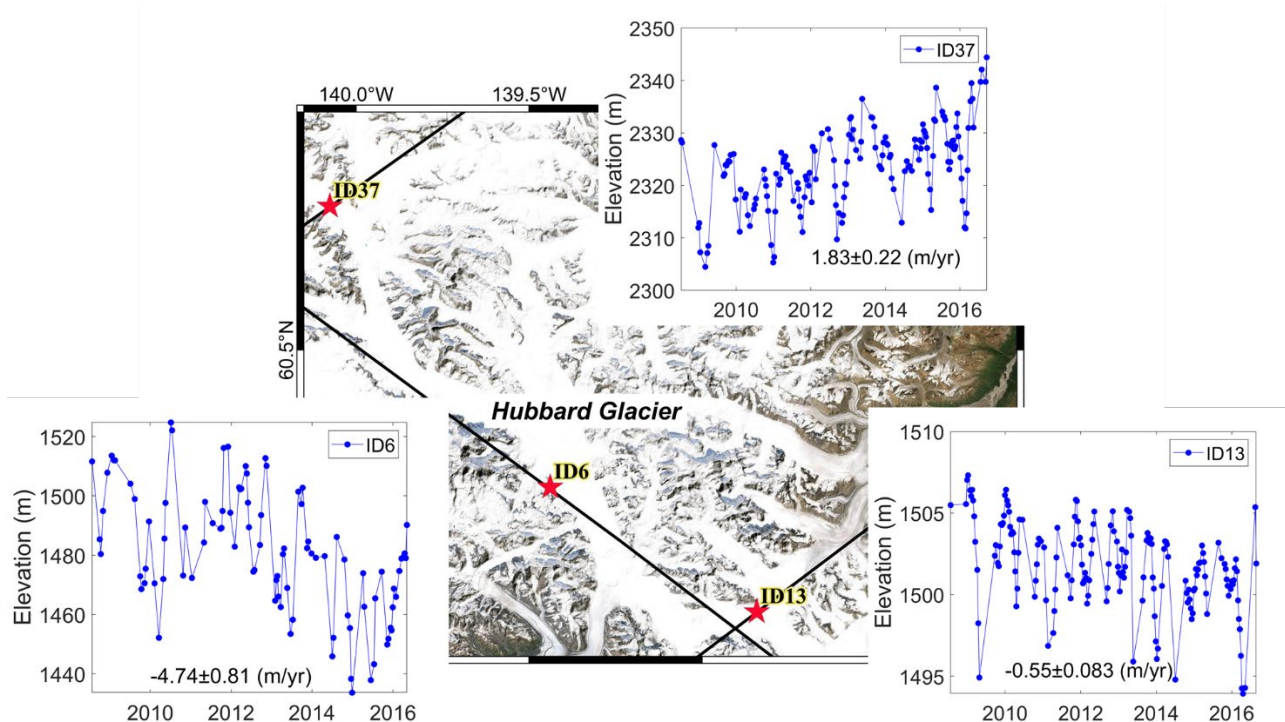

457 Kennicott Glacier is the largest glacier in the Wrangell Mountains, covered with continuous debris

458 (Anderson *et al.*, 2019). Figure 11 shows the J2-derived elevation changes at Sites 2, 14 and 15 around  
 459 this glacier. The elevations experience seasonal fluctuations with rapid increases in the thickness of  
 460 glacier increases in spring and summer, and decreases in autumn and winter. Compared with the  
 461 terrains in the upstream tributaries, the terrain around Sites 2 and 15 is flat. Armstrong *et al.* (2016)  
 462 showed that, the glacier velocity of Kennicott in the early summer is the highest, and the velocity  
 463 begins to slow down from autumn onward. The glacier growth in the lower reaches at Sites 2 and 15  
 464 should be mainly caused by the ice discharge from the upstream glaciers. At the same elevation zone,  
 465 there are significant differences in the elevation change of the glaciers measured on different tributaries  
 466 (Das *et al.*, 2014). The J2-derived declining rate of glacier elevations at Site 14 ( $-0.72$  m/year) is larger  
 467 than that of the entire Kennicott Glacier during 2000-2007 (Das *et al.*, 2014).

468 **Figure 11.** Glacier elevation changes at Sites 2, 14 and 15 near Kennicott Glacier  
 469

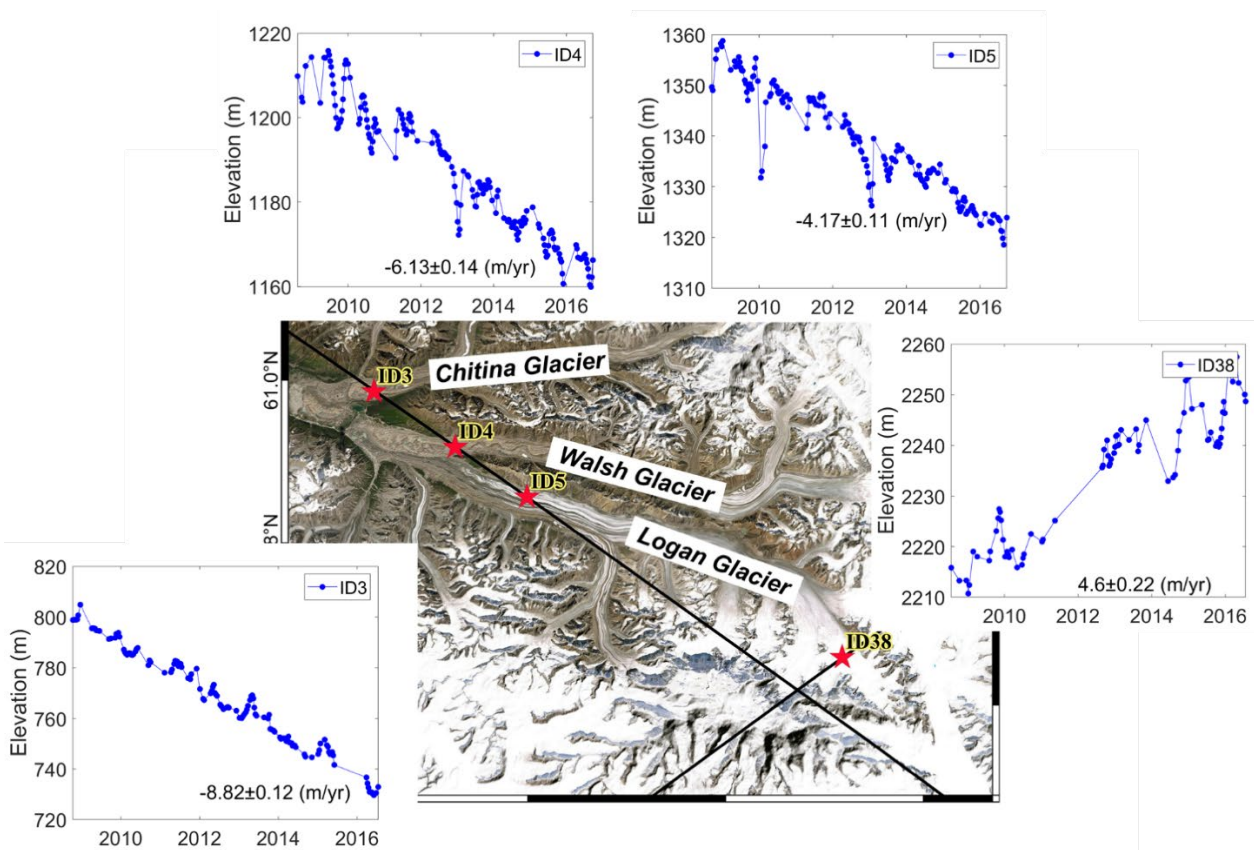

**Figure 12.** Glacier elevation changes at Sites 6, 13 and 37 near Hubbard Glacier

Hubbard Glacier is the largest temperate tidewater glacier spanning 123 km from North to South, and the glacier changes here are asynchronous with respect to the ice losses at its nearby glaciers (Trabant *et al.*, 2003a; Stearns *et al.*, 2015). Figure 12 shows that, the upstream of Hubbard Glacier thickened at a rate of 1.83 m/yr (Site 37), which was closely related to climate forcing (Motyka and Truffer, 2007; Ritchie *et al.*, 2008). In contrast to the previous understanding, the glacier elevations at the middle and lower reaches of Hubbard declined significantly (the rate at Site 6 is -4.74 m/yr), and the glaciers at the west end of Hubbard tend to thin slightly (the rate at Site 13 is -0.5 m/yr). The J2 results show a local variability of the glacier around Hubbard Glacier not reported in earlier studies.

Logan Glacier, Walsh Glacier and Chitina Glacier are tributaries of a large trunk that occupies the upper Chitina River Valley. More than 40 years ago, these glaciers and Anderson Glacier (next to Chitina Glacier) were connected to each other (Ommanney, 2002). In recent years, a large number of glaciers around this region have shrunk, leading to the retreats of glacier terminuses for up to tens of kilometers. As shown in Figure 13, the glacier elevations at Sites 3, 4 and 5 declined at the maximum rate of up to -8.82 m/yr at the terminuses). However, the glacier is thickening at Site 38, which is in

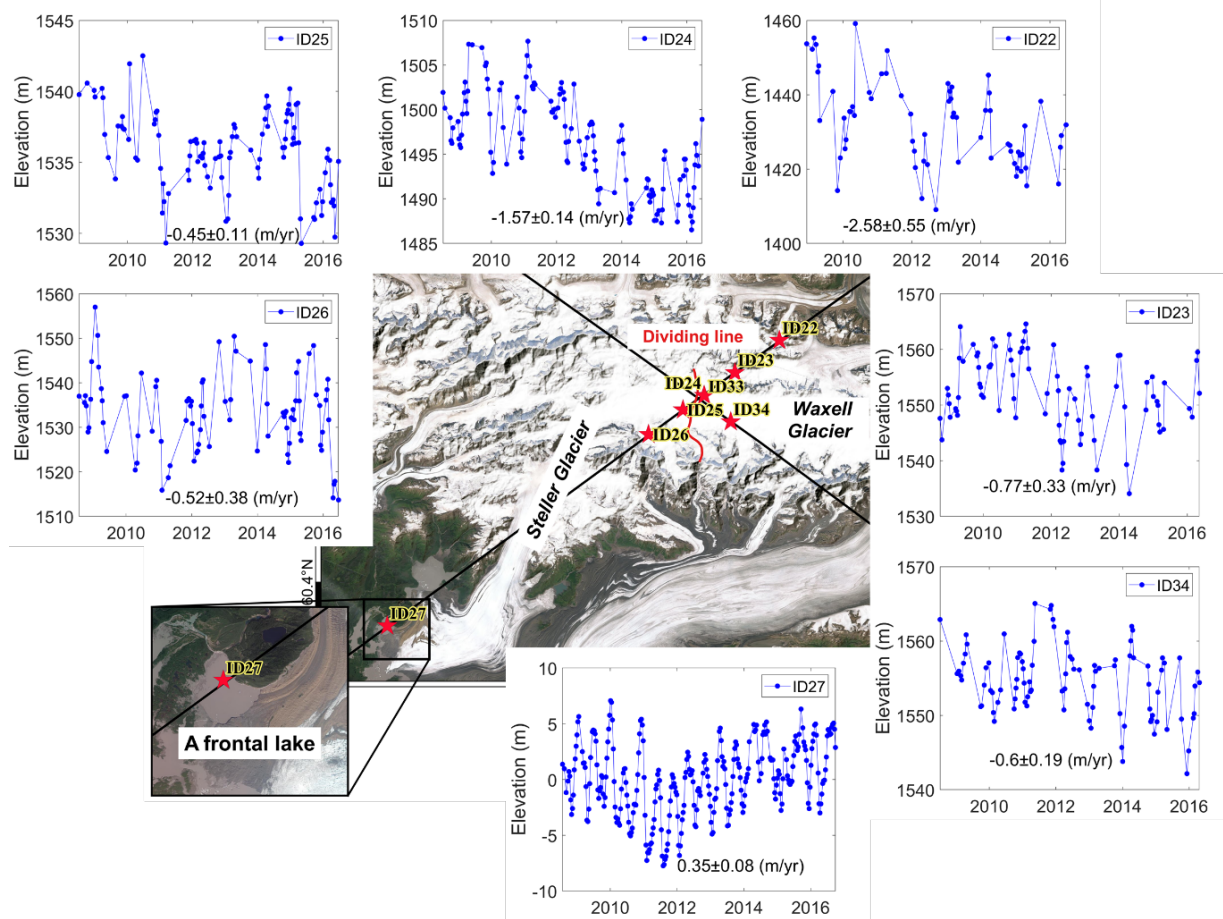

the upper reaches of the Logan Glacier. These asynchronous glacier elevation changes are consistent with the measurements of *Larsen et al. (2015)*. The measurements from T/P and J2 provide more details about the seasonal variations of the glacier fronts which are useful to the hydrological change research in the lower reaches of these glaciers. Due to the growth of glaciers at Logan Glacier's upstream (at Site 38), these three glaciers can sustain the water supply to the downstream river, despite the retreats of the terminuses of these three glaciers.

**Figure 13.** Glacier elevation changes at Sites 3, 4, 5 and 38 near Logan Glacier, Walsh Glacier, and Chitina Glacier

Steller Glacier and Waxell Glacier are located in the west of St. Elias Mountains. Figure 14 shows the glacier elevation changes at Sites 22, 23, 24, 33 and 34 over the west of Waxell Glacier and at Sites 25 and 26 near the upper reaches of Steller Glacier. The elevation changes suggest that the glaciers near Steller Glacier and Waxell Glacier were thinning with varying rates and their elevations experienced asynchronous interannual variations. A watershed divide between Waxell Glacier and

500 Steller Glacier results in two different drainage systems for the two glaciers (*Beedle et al.*, 2008).  
 501 Waxell Glacier contributes to the surging Bering Glacier system, while Steller Glacier advances to the  
 502 downstream Steller lobes along the main trunk to the south (*Bruhn et al.*, 2010). Compared with the  
 503 rapid ice loss of Waxell Glacier, the interannual variation of Steller Glacier is relatively stable. This is  
 504 consistent with the conclusion of (*Herzfeld and Mayer*, 1997). Site 27 is over an unknown frontal lake  
 505 in the downstream of Steller Glacier. The elevations at Site 27 underwent distinct seasonal fluctuations  
 506 and a trend reversal from a negative rate to a positive rate in late 2012. The seasonal fluctuations at  
 507 Site 27 are reflected the variations in the stream flows originating from Steller Glacier.

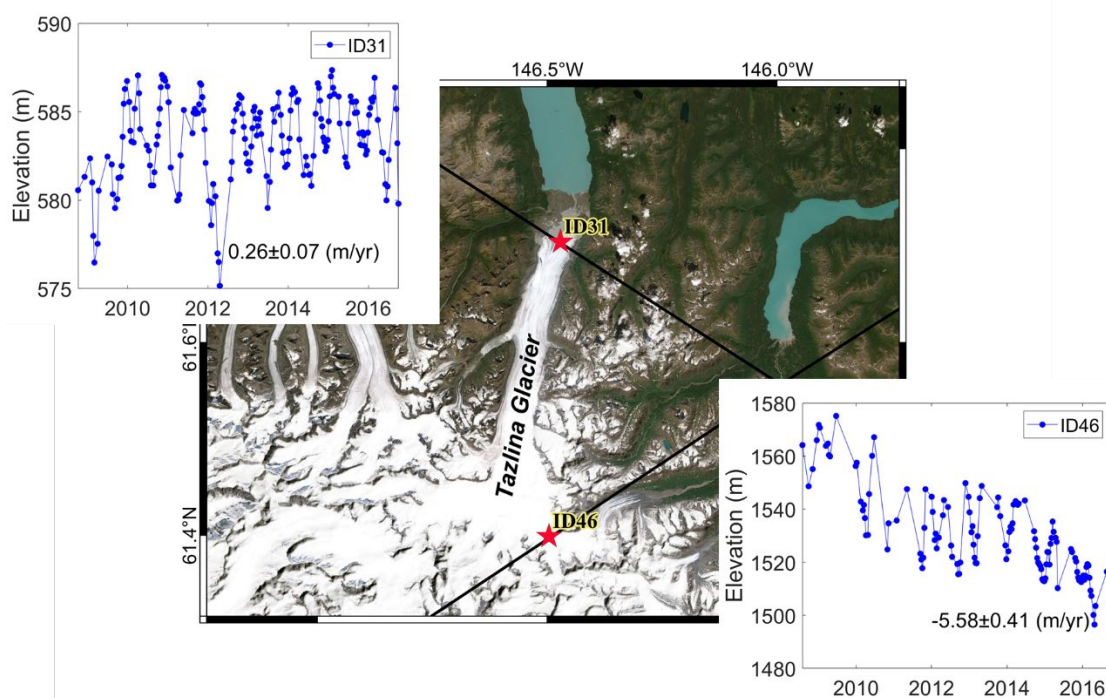

508  
 509 **Figure 14.** Glacier elevation changes at Sites 22, 23, 24, 25, 26, 27 and 34 near Steller  
 510 Glacier and Waxell Glacier

511 The thickness of the accumulation zone of Tazlina Glacier can reach 1030 m, which is the thickest  
 512 in Alaska glaciers (*Rignot et al.*, 2013). Figure 15 (Site 46) shows the elevation changes near an upper

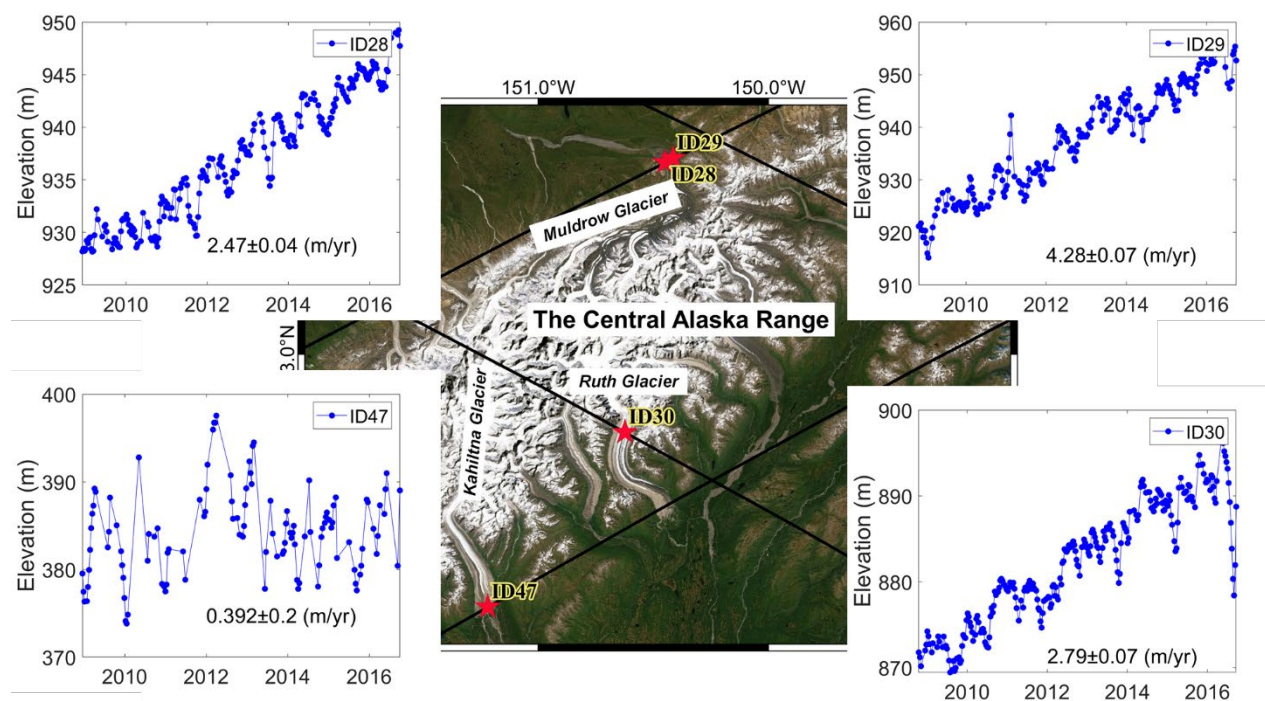

513 reach of Tazlina Glacier and its terminus (Site 31). Glaciers at Tazlina Glacier's upper reach thinned  
 514 at a rate of -5.58 m/yr, but Tazlina's terminus gained mass at a rate of 0.26 m/yr (Site 31). The airborne  
 515 Lidar measurements in the mid-1990s showed an average thinning rate of about -0.69 m/yr over  
 516 Tazlina Glacier (*Molnia*, 2006), which is smaller compared to the rate at Site 46. Although J2 can only  
 517 detect elevation changes at a single site (Site 31) over Tazlina Glacier's upper reaches, the large rate  
 518 (-5.58 m/yr) suggests that the ongoing global warming may have accelerated glacier melt at Tazlina  
 519 Glacier.

520  
 521 **Figure 15.** Glacier elevation changes at Sites 31 and 46 near Tazlina Glacier

522 Last, we discuss the J2-derived elevation changes over glaciers in the Central Alaska Range.  
 523 Glaciers here have experienced rapid thinning and retreating in the early 2000s (*Adema et al.*, 2007).  
 524 Figure 16 shows the glacier elevation changes from J2 at Sites 28, 29, 30 and 47 near Kahiltna Glacier,  
 525 Ruth Glacier, and Muldrow Glacier around the Central Alaska Range. Instead of thinning, the glaciers  
 526 at these sites were growing at rates ranging from 0.39 to 4.28 m/year. These rising glacier elevations  
 527 indicate mass gains around the four sites. One explanation of the increased elevations at the lower  
 528 reaches of the three glaciers is that the rapid melting of glaciers in the Central Alaska Range discharged

529 more ice into the lower reaches. The excessive ice discharges accumulated and expanded the glaciers  
 530 at the lower reaches due to basal roughness, bed topography and change in basin dimension (*Adema*  
 531 *et al.*, 2007; *Molnia*, 2007; *Campbell et al.*, 2012; *Turrin et al.*, 2014).

532  
 533 **Figure 16.** Glacier elevation changes at Sites 28, 29, 30 and 47 over the central Alaska  
 534 Range

#### 535 4.4 The response of glaciers to environmental changes

536 The types of glaciers at the 47 sites with the T/P and J2 elevation measurements include mountain  
 537 glaciers, valley glaciers, tidewater glaciers, rock glaciers, among others. In the previous sections, we  
 538 show the distinctive patterns of elevation changes associated with regional climates, orographic  
 539 conditions, surface and substrate characteristics that might control the presences and evolutions of the  
 540 studied glaciers. The altimeter result shows that neighboring glaciers can have asynchronous elevation  
 541 change patterns. Below we examine various environmental factors that can cause such spatial and  
 542 temporal changes in the glacier elevations.

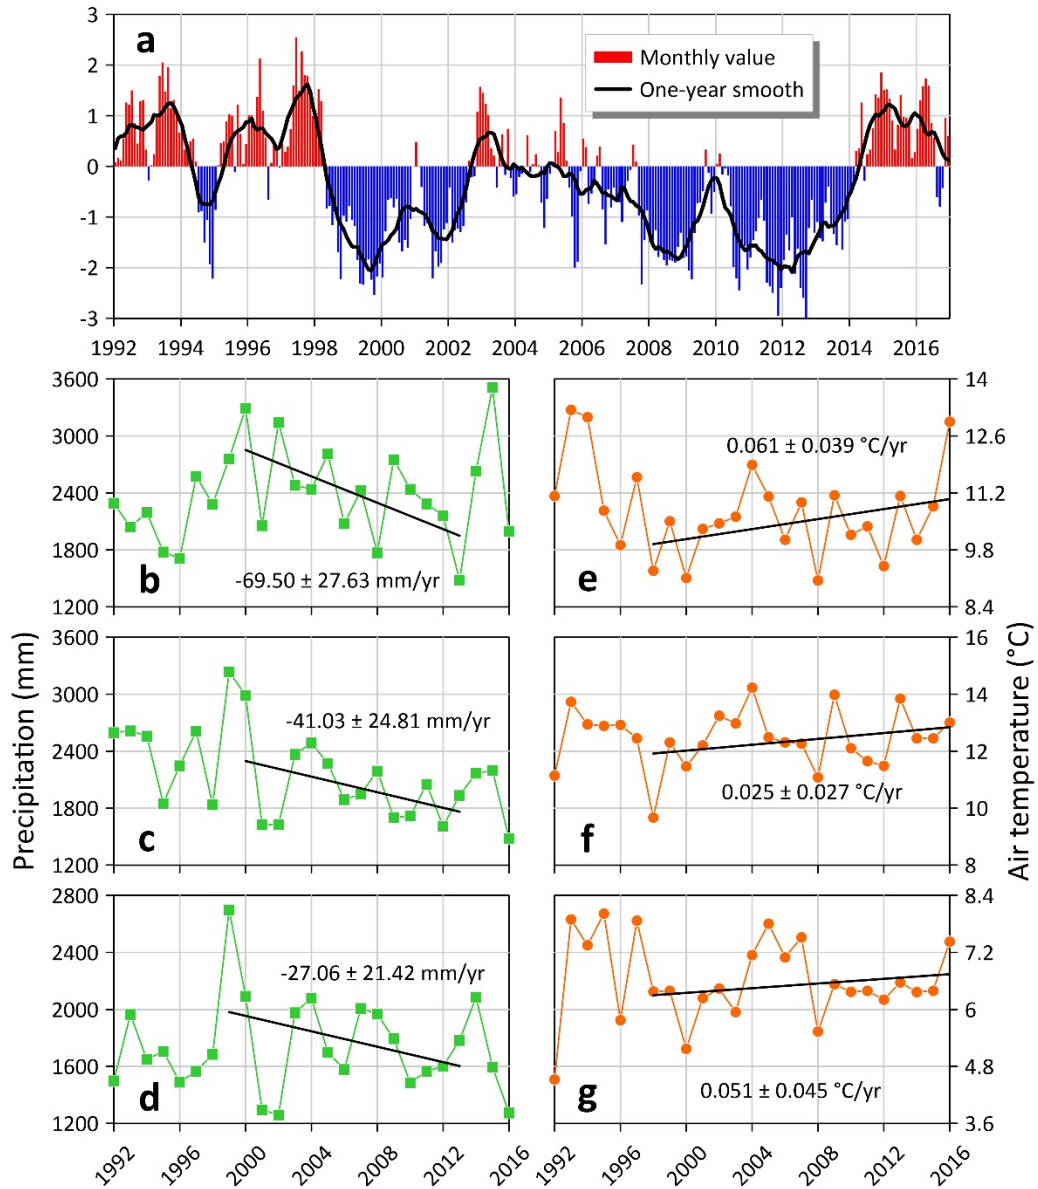

543 First, we discuss the potential impact of the Pacific Decadal Oscillation (PDO) on Alaska glaciers.  
 544 The PDO is a pattern of ocean-atmosphere climate variability, defined as the leading empirical

orthogonal function of sea surface temperature (SST) anomalies over the North Pacific north of 20°N. In general, a positive phase of the PDO is associated with high precipitation and warming along the coast of Alaska and a negative phase leads to decreases in temperature and precipitation (*Arendt et al.*, 2009). During the study period (1992–2016), the phases of PDO underwent two notable shifts in 1998 and 2014 (Figure 17 a), respectively. The meteorological station records at the National Oceanic and Atmospheric Administration (NOAA, <https://gis.ncdc.noaa.gov/maps/ncei>) show that the impact of the PDO on annual winter precipitation and summer temperature in Alaska are spatially heterogeneous. Specifically, the mountainous areas along the coast of Alaska experienced a significant decline in winter precipitation since 1999–2000 at the stations shown in Figure 17 b, c and d. As the PDO shifts from a negative phase to a positive in the summer 2014, the precipitation began to increase. However, the precipitation pattern on the northeast side of the Gulf of Alaska only shows stable, and small interannual fluctuation (Figure B1, a and b). At the stations near the Central Alaska Range (Figure 17 e, f and g), the summer temperature rose by a rate up to 0.061°C/year, compared to the negligible temperature change near Alaskan coastal areas (Figure B1, c and d).

The anticlockwise Alaska coastal current and the Alaska current (Figure 1) are responsible for the marine climate of the coast of Alaska (*Maraldo*, 2020). The ocean currents driven by strong wind, resulting in a large amount of precipitation on the windward side of the coastal mountains, especially in winter (2–6 m/yr) (*Weingartner et al.*, 2005). Due to the rain shadow effect, the heavy moisture stays on the windward side of the mountain, while the precipitation is rare on the leeward side. Since 1998, with the PDO phase changing from positive to negative, the precipitation along the coast of Alaska has experienced a distinct decline (Figure 17 b, c and d). The J2 result shows that the elevations of most glaciers in coastal mountainous area were rapidly declining (Table A2 and Table A3, Sites 13, 22, 24, 44, 45 and 46), or the glacier growth rates were slowing down significantly (Table A2 and Table A3, Sites 27 and 31). These changes in glacier elevations coincided with the significant decline of winter precipitation during this period (Figure 17 b, c and d). At the same time, the glacier elevations in the accumulation zone of Hubbard Glacier and Logan Glacier (Table A2 and Table A3, Sites 37 and 38)

571 were increasing at a steady rate during the mission periods of T/P and J2. These glacier growths agree  
 572 well with the estimates from surface mass balance (*Larsen et al.*, 2015) in the spatio-temporal pattern.  
 573 For the thickening glaciers like Hubbard Glacier and Logan Glacier, the supply of new firn and  
 574 refreezing processes play more dominant roles than climate change (*Trabant et al.*, 2003b).

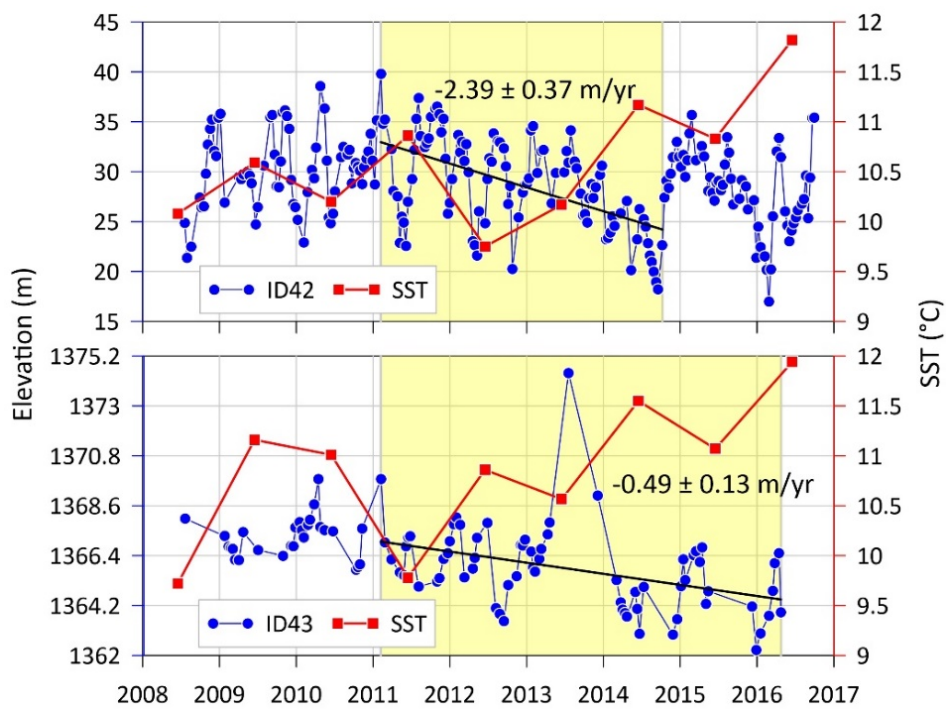

575  
 576 **Figure 17.** (a) The time series of Pacific Decadal Oscillation (PDO) from NOAA, and  
 577 annual winter (October–April) precipitation changes in (b) Port San Juan, (c) Yakutat, and (d)  
 578 Elfin Cove, and annual summer (May–September) temperature changes in (e) Chulitna River,  
 579 (f) Puntilla, and (g) McKinley Park. The locations of meteorological stations are shown in  
 580 Figure 1.

581 In the past half century, the temperature in the Central Alaska Range has increased by 3 °C, second  
582 only to that in northern Alaska (3.3 °C) (*Wendler et al.*, 2017). These above-average rises in  
583 temperature in Alaska are the result of the polar amplification of global warming (*Stone et al.*, 2002).  
584 Due to the large altitudinal range of Alaska, the glaciers here span a wide range of climate regimes,  
585 resulting in different responses of glaciers to different regional climate changes (*Young et al.*, 2018).  
586 For example, the cumulative mass balance recorded by the field sites indicate that Traleika Glacier, a  
587 major ice supply tributary at the upstream of Muldrow Glacier, experienced rapid ice loss, while the  
588 adjacent Kahiltna Glacier was growing slightly (*Adema*, 2006). Later, Kahiltna Glacier experienced  
589 ice loss, and by 2000 its mass balance was similar to that of Traleika Glacier (*Adema*, 2016). During  
590 our study period, a larger shift in rates of glacier elevation changes occurred in the Central Alaska  
591 Range (Site 28 and 47). In the T/P era (1993–2002), the terminuses of Muldrow Glacier and Kahiltna  
592 Glacier were thinning at rates of  $-6.43 \pm 0.36$  m/yr and  $-2.34 \pm 0.35$  m/yr, respectively, but the rates  
593 became positive in the J2 era (Muldrow Glacier:  $2.47 \pm 0.04$  m/yr, Kahiltna Glacier:  $0.39 \pm 0.20$  m/yr).  
594 The significant warming in the ablation season since 2000 (Figure 17 e, f, and g) may contribute to  
595 this sudden shift in the rates.

596 Unlike land-terminating glaciers, tidewater glaciers are very sensitive to SST variations (*Motyka*  
597 *et al.*, 2003; *Maraldo*, 2020). In this study, Sites 42 and 43 are near Guyot Glacier and Aialik Glacier,  
598 which are typical tidewater glaciers around the Gulf of Alaska. At the outlets of these two glaciers,  
599 SST rose by  $\sim 2$  °C from 2008 to 2016, according to data from JPL at <https://podaac.jpl.nasa.gov>.  
600 Figure 18 compares the J2-derived glacier elevation changes and temperature changes (from) at Sites  
601 42 and 43. From 2008 to 2016, the glacier elevations at Site 42 (near Guyot Glacier) dropped at a rate  
602  $-0.53$  m/year, and at Site 43 (near Aialik Glacier) the rate is  $-0.70$  m/year. The elevations at the two  
603 glaciers are negatively correlated with summer SST changes with a 2-year lag. A significant rise of  
604 water temperature may be a driving factor for the recent collapse and retreat of these tidewater glaciers  
605 (Site 42: from early 2011 to late 2014, Site 43: from early 2011 to mid-2016). At present, we do not  
606 have enough evidence to explain this time lag. A hypothesis is that the native cycles and morphometric

607 characteristics of tidewater glaciers, the depth and geometry of the fjords may have affected patterns  
 608 of glacier elevation changes (*McNabb et al.*, 2015; *Brinkerhoff et al.*, 2017; *Maraldo*, 2020). Previous  
 609 studies have shown that ocean forcing can lead to a stable retreat of calving glaciers (*Holland et al.*,  
 610 2008; *Motyka et al.*, 2011) and to a smaller retreat rate of nonclimatic-control tidewater glaciers than  
 611 that of terrestrial glaciers (*Larsen et al.*, 2015; *Maraldo*, 2020). The altimeter result in this study shows  
 612 large interannual variabilities of tidal glaciers and fast shifts in elevation patterns (e.g., glaciers at Sites  
 613 42 rose before 2011, then fell and rose again in 2014). These short to long-term glacier variabilities  
 614 are observed from the 10-day repeat, usable T/P and J2 data, which may overcome the problems of  
 615 underestimation or overestimation of the long-term trend of a tidewater glacier mass budget based on  
 616 observations with a low temporal resolution (such as those from airborne Lidar or stereo imagery  
 617 measurements).

618  
 619 **Figure 18.** Glacier elevation changes at Site 42 and 43 (blue), and the annual summer  
 620 (May–September) sea surface temperature (SST, red) near Sites 42 and 43.

## 621 5 Conclusion

622 In the extreme terrain conditions of mountain glaciers, it is a challenge for satellite radar altimeters

623 to monitor glacier elevation changes. In this study, we develop the GTM to extract glacier elevation  
624 changes based on the repeated and usable altimeter measurements. The GTM is an integrated  
625 processing system that includes the selection of the optimal waveform retracking algorithm, glacier  
626 footprint extraction, terrain correction and crossover analysis. An internal and external assessment  
627 confirm that the GIM can retrieve robust and precise glacier elevation changes over Alaska. The usable  
628 rates of the 10-day repeat altimeter observations range from 16% to 92%.

629 The T/P and J2 observations show that most glaciers in Alaska near the 47 sites in this study  
630 (1993–2016) are thinning. The maximum thinning rate reached -11.06 m/yr near Klutlan Glacier,  
631 followed by Chitina Glacier at  $-8.82 \pm 0.12$  m/year. Fan glacier has the largest rising rate of  $5.99 \pm$   
632  $0.92$  m/year, followed by Logan Glacier, which was rising at 4.30 m/year over 1993–2016. In addition,  
633 alternating rates in glacier elevation changes were also detected. Our result shows that that the thinning  
634 and thickening status of glaciers in St. Elias mountains are relatively stable in the two T/P–J2 periods,  
635 while larger rate shifts occurred over Muldrow Glacier, Kahiltna Glacier, Frank Mackie Glacier,  
636 Tazlina Glacier, and Kennicott Glacier.

637 With a phase change in the PDO in 1998 from positive to negative, a drop in winter precipitation  
638 for more than a decade occurred along the coast of Alaska. The precipitation drops in this area resulted  
639 in increasing glacier melts and slowed down the glacier growth rates in the accumulation zones. In the  
640 Central Alaska Range, the sharp increase in summer temperatures in 1998 intensified the long-term  
641 warming to accelerate glacier melts here. As a result, ice discharges from the mountains increased and  
642 then raised the elevations at the glacier terminuses, as evidenced by the altimeter observations. At two  
643 tidewater glaciers (Guyot Glacier and Aialik Glacier) in the Gulf of Alaska, we find that their  
644 interannual responses to summer SST anomalies are more significant than previously known. Warming  
645 waters may have increased their frontal ablations.

646 Despite the low spatial coverage of the T/P and J2 altimeters over Alaska mountain glaciers, the  
647 two missions' continuous 10-day repeat and usable observations can provide information to better  
648 understand the short- and long-term complex dynamics of a mountain glacier if the glacier is

649 sufficiently flat, wide and along a pass of the missions. The raw data from the T/P-series altimeter  
650 missions cannot be automatically used for detecting glacier elevation changes without a sophisticated  
651 processing system like the GTM. A capable altimeter processing system and repeat altimeter missions  
652 can facilitate the study of the physics of a small-scale glacier and provide data for verifying glacier  
653 measurements from other remote sensing technologies.

## 654 **Acknowledgements**

655 This study is supported by MOST/Taiwan under Grant Grants 109-2221-E-009-015-MY3 and  
656 109-2611-M-009-001, and the National Natural Science Foundation of China (Grants 41974093 and  
657 41774088). We are grateful to AVISO for the altimeter data used in this paper. All background images  
658 in Section 4.3 are from ESRI imagery.

## Appendix B: Precipitations and temperatures

**Figure B1:** Annual winter (October–April) precipitation changes in **(a)** Beaver Creek, **(b)** Burwash, and annual summer (May–September) temperature changes in **(c)** Little Port Walter, and **(d)** Port San Juan. The locations of meteorological stations are shown in Figure 1. Note: when there are missing daily records (< 7 days), the values in this figure are linearly interpolated from neighboring values. If the time gap is more than 7 days, the missing values are from the monthly averages.
