1 **Abstract**

2 Okmok volcano located on the northeastern part of the Umnak Island is one of the most active

3 volcanoes in the Aleutian Arc. It was initially built as a large shield volcano, but was strongly

4 destroyed by two caldera-forming eruptions 12,000 and 2,040 years ago. The post-caldera

5 eruptions occur mostly along the inner perimeter of the caldera from a series of distinct cones.

6 Here, we perform seismic tomography to explore the deep sources of magmatic activity beneath

7 Okmok. We use the local earthquake data of the Alaska Volcano Observatory (AVO) in the time

8 period from 2003 to 2017 to build a model with the 3D distributions of the *P* and *S* wave

9 velocities and *Vp/Vs* ratio. At depths of more than 10 km, we observe a vertically aligned

10 anomaly of high *Vp/Vs* ratio representing a steady conduit likely responsible for the volcano

11 evolution since its origin. Above this conduit, we reveal a large anomaly of high *Vp/Vs* ratio

12 representing the main magma reservoir providing the material for all recent eruptions in the

13 caldera. It appears to be connected with another large shallow reservoir located below the Cone

14 A that was the source of most of Okmok's historical eruptions. The most recent eruption in 2008

15 took place right above the deep conduit. To reach the surface, the magma for this eruption passed

16 through the shallow ductile zone, where it was saturated by silicic components. This

17 interpretation is consistent with the petrology studies and modeling of ground deformations.

18

19 **Plain Language Summary**

20 Okmok is one of the most active volcanoes of the Aleutian Arc. Initially it was formed as an

21 isometrical shield volcano, which was later destroyed by two caldera-forming eruptions. The

22 post-caldera activity mostly occurred at several cones distributed along the inner perimeter of the

23 caldera. The latest eruption with the explosivity index of VEI 4 took place in 2008. This

24 eruption, which produced a new large cone Ahmanilix in the northeastern part of the caldera,

25 was significantly different in composition and eruption style compared to other intra-caldera

26 eruptions. We present a new seismic tomography model, which was constructed based on the

27 arrival times of the *P* and *S* waves from local seismicity. Below 10 km depth, we observe an

28 anomaly of high *Vp/Vs* ratio, which may represent a steady magma conduit that is responsible for

29 the long-term formation of the entire Okmok volcanic complex. In the upper crust, the model

30 reveals a series of separate local magma sources beneath volcanic centers where historical

31 eruptions took place. The 2008 eruption was fed by a magma diapir that was initially formed in

32 the deep conduit and then slowly ascended through a ductile layer at depths from 6 to 2 km.

33

Key points:

- The new crustal model beneath the Okmok Caldera with the 3D distributions of Vp, Vs and Vp/Vs ratio reveals the geometry of magma sources
- Below 10 km depth, an anomaly of high Vp/Vs ratio indicates the location of the main magma conduit that fed the long-term formation of Okmok
- At shallow depths, seismic anomalies reveal several magma sources that fed eruptions along the inner perimeter of the caldera

Key words: Seismic tomography, Okmok caldera, Aleutian Arc, magma sources, volcanic eruption

Introduction

Okmok is one of the most active volcanoes of the Aleutian Arc. Initially, it was founded as a large circular shield volcano with a diameter of ~30 km that occupies the northeastern half of the dumbbell-shaped Umnak Island. According to the K-Ar dating, the formation of this volcano began approximately 1.7-2.1 Ma (Birgham and Stone, 1972), which indicates the existence of a long-term steady magma conduit existing for millions years. The central part of this volcano was destroyed by at least two ignimbrite-forming eruptions 12,000 and 2,050 years ago (Larsen et al., 2007) that created two overlapped well-exposed circular calderas with the total size of ~10 km (Figure 1). The amount of material in dense rock equivalent for these two eruptions was estimated as 30 km^3 and 15 km^3, respectively (Larsen et al., 2007). These eruptions had an important impact on the climate that was felt globally. There is evidence that the latter eruption affected people in Europe and caused serious historical perturbations (McConnel et al., 2020). Untypically for caldera-forming eruptions, the products of these two eruptions contained very little amount of rhyolite and dacite magmas, which were ejected at the initial stages, but then were replaced by a larger amount of andesite and basaltic andesite (Larsen et al. 2007).

The post-caldera eruption activity mostly occurred along the inner perimeter of the caldera through a series of vents some of which created well-expressed cinder and tuff cones indicated by letters from A to H (Figure 1). The compositions of these eruptions were mainly basaltic. The oldest flows were composed of pillow lavas, which indicated that the caldera was initially filled by a deep lake (Larsen et al. 2007). Nowadays, in the caldera, there are several

66   shallow lakes that are abruptly changing their configurations during eruptions. Besides the intra-
67   caldera eruptions, there were several flank eruptions forming a few outer cones of which the
68   largest are Tulik and Jag Peaks.

69   At least 17 historical explosive and effusive eruptions have been recorded on Okmok
70   since the beginning of the nineteen century (Larsen et al., 2015). The majority of these eruptions
71   occurred from the cone A in the southwestern part of the caldera. In the twentieth century, the
72   well-documented eruptions with basaltic-andesite lava flows and moderate ash falls occurred in
73   1945, 1958 and 1997 exclusively from the vent A (e.g., Miller et al., 1998, Larsen et al., 2015).

74   The latest eruption with the high explosivity index of VEI 4 took place in July-August
75   2008 and it appeared to be among the strongest historical eruptions of Okmok. It occurred in the
76   northeastern part of the caldera close to the Cone D and produced a new large cone called
77   Ahmanilix. This eruption was classified as explosive phreatomagmatic eruption with a large
78   amount of steam, ash and tephra ejected. According to the geochemical analyses by Larsen et al.
79   (2013), the eruption products in this part of caldera are distinctively different from those in the
80   southwestern part around the A cone; namely they have higher SiO_2 content. A specific feature
81   of the 2008 eruption is that it almost did not produce any lava flows (Larsen et al., 2015). Unlike
82   the previous instrumentally recorded events of volcanic activity of Okmok, the eruption of 2008
83   was not preceded by any significant seismic precursors. For ten days prior to the eruption, only
84   11 locatable earthquakes were recorded. An active seismogenic process started only five hours
85   before the eruption onset (Larsen et al., 2009).

86   Okmok's dynamic and near-continuous deformation during and in between eruptions
87   made it the subject of many studies using GPS, InSAR, or both to constrain its subsurface
88   magma system structure and its evolution. The 1997 and 2008 eruptions caused meter-scale
89   deflation of the caldera center (e.g., Mann et al, 2002; Freymueller and Kaufmann, 2010), while
90   inter-eruptive deformation is characterized by discrete inflation pulses modulated onto steady
91   background inflation of several centimeters per year (e.g., Qu et al., 2015; Xue et al, 2020) .
92   Inversions of InSAR data (e.g., Lu et al., 2000, Mann et al., 2002; Qu et al., 2015; Lu &
93   Dzurisin, 2014), GPS data (e.g., Fournier et al., 2009; Freymueller and Kaufmann, 2010) or joint
94   inversions of both (e.g., Biggs et al., 2010; Xue et al., 2020) generally yield a spherical magma
95   reservoir near the center of the caldera between 2-5 km depth, with most results placing the
96   source between 2-3.5 km. Xue et al. (2020) suggested that in addition to this spherical source a
97   shallow sill at about 0.9 km is necessary to explain the post-2008 geodetic observations. They
98   also count five inflation pulses since the 2008 eruption that emerge rapidly and slow down

following an exponential decay. Walwer et al. (2019) explained the origin of these short-term inflation pulses by hydraulic interaction between two shallow magma chambers.

Another group of studies examined structure and dynamics of magma sources beneath Okmok based on the analysis of seismic data, which were continuously recorded by a network of permanent telemetric seismic stations operated since 2003 (Dixon et al., 2017). The temporary and spatial distributions of volcano-tectonic events during the eruption in 2008 were investigated by Johnson et al. (2010), who also provided estimates for seismic anisotropy based on the shear wave splitting technique. Moment tensors of these events were determined by Pesicek et al. (2012). Haney et al. (2010) investigated the very long-period seismicity, which was the indicator of magma dynamics in the conduit and therefore was considered as one of the eruption precursors.

In the context of this research, it is important to mention the previous seismic tomography studies of the Okmok area. The ambient noise tomography method was used by Masterlark et al. (2010) to build the 3D distribution of the *S*-wave velocity down to 7 km depth. They identified a low-velocity anomaly right below the caldera, which was interpreted as deposits of non-consolidated rocks accumulated after the latest caldera-forming eruptions. Another anomaly was observed at depths of 3-5 km below the caldera and was associated with the presence of the shallow magma reservoir. Later this model was used together with data on ground deformations to validate the numerical model of magma source dynamics (Masterlark et al., 2012). However, it should be noted that this model was constructed on the basis of only 12 stations, of which 9 were equipped by single-component short period sensors (1 Hz). This network provided a limited number of inter-station paths and could not enable high lateral resolution of the resulting velocity distribution, especially at large depths.

Another tomography model by Ohlendorf et al. (2014) was constructed based on the local earthquake tomography using generally the same principle and data type as in our work. They reported both the models of the *P* and *S*-wave velocities, as well as the distribution of the *P*-wave attenuation; however, the authors admitted that their *S*-wave model was based on too sparse data coverage and therefore was not robust. Similarly as in the model by Masterlark et al. (2010), the body wave tomography revealed low *P*-wave velocity beneath the caldera; however, the *S*-wave velocity was unexpectedly high in the same locations. Note also, that in this model, the resolution suffered from too large grid spacing making the results strongly grid-dependent. Furthermore, the authors did not present the distribution of the *Vp/Vs* ratio, which appeared to be the key parameter to identify magma sources beneath active volcanoes.

132   In this study, we construct a new seismic velocity model based on a considerably

133   enlarged dataset and using another tomography code LOTOS (Koulakov, 2009), which

134   previously demonstrated its efficiency for studying different volcanic systems in the world

135   (Kasatkina et al., 2014, Koulakov et al., 2013, Bushenkova et al., 2019). Here, we will pay

136   special attention to showing the distributions of the *Vp/Vs* ratio, which is presumed the most

137   sensitive seismic attribute to the presence of partially molten and fluid saturated magma. In this

138   study, we will present several synthetic tests showing the resolution limitations of our model.

139   Therefore we claim that the results presented in this work give important new information on the

140   magma system structure beneath Okmok compared to the previous studies and therefore brings

141   an important contribution to understanding the processes leading to initiation of eruptions.

142   **Data and algorithms**

143   In this work, we use the catalog data from 2003 to 2017, which includes the arrival times

144   of the *P* and *S* waves from local seismicity recorded by 13 permanent telemetric stations located

145   around Okmok and operated by the Alaska Volcano Observatory (AVO) (Dixon et al., 2017). Of

146   these stations, four are equipped with the broadband seismometers Guralp CMG-6T; the

147   remaining nine are based on the short-period (1Hz) single-component sensors L-4 (Figure 2).

148   However, for determination of arrival times from the local seismicity, the frequency ranges of

149   the both types of seismometers are equally suitable. The initial catalog includes 4,174 events and

150   the corresponding arrival times of 19,249 *P* and 14,278 *S* waves (on average 8.03 picks per

151   event). To select data for the tomography inversion, we applied several criteria: (1) the number

152   of picks per event should be equal or larger 8; (2) the time residuals after the source location in

153   the starting 1D model should be smaller than 0.5 s; (3) the horizontal distance from an event to

154   the nearest station should be less than 20 km. After the selection, the final dataset used for

155   tomography included 2869 events with the corresponding 17,040 *P*- and 12,145 *S*-picks (on

156   average 10.17 picks per event). The distributions of the events and seismic stations are shown in

157   map view and in vertical projections in Figure 2. Further information on the event distributions

158   after locations in the final 3D velocity model will be presented in cross-sections with the main

159   tomography results.

160   These data were processed using the passive-source tomography algorithm LOTOS

161   (Koulakov, 2009). As the input, the algorithm uses the arrival times of the *P* and *S* waves and it

162   starts with the absolute locations of sources using the grid-search method and a simplified

163   algorithm for travel time calculations along straight lines. Then the relocation of the sources is

164   performed in an iteratively updated 3D velocity model with the use of a more sophisticated ray

165   tracing algorithm based on a bending technique (Um and Thurber 1987).

5

166   The velocity model is parameterized with a set of nodes distributed in the 3D space. In

167   map view, the nodes are installed regularly with a spacing of 1 km. In the vertical direction, the

168   spacing is inversely dependent on the ray coverage, but should not be smaller than 0.5 km. In

169   areas without rays, no nodes are installed. To reduce the effect of parameterization on the results,

170   we performed the inversions in four grids with different basic orientations along the azimuths of

171   0, 22, 45 and 66 degrees, and then averaged the results.

172   The inversion of the matrix was performed simultaneously for the 3D *P* and *S* wave

173   velocity anomalies (*dVp* and *dVs*) and source relocation parameters (coordinate shifts, *dx, dy, dz*,

174   and origin time correction, *dt*). The inversion was performed using the Least Square algorithm

175   with QR factorization (LSQR) (Page and Saunders, 1982; Nolet, 1987).To regularize the stability

176   of the resulting velocity models, we used the amplitude damping and flattening that controlled

177   the difference between all pairs of neighboring nodes. In our case, the values of the amplitude

178   damping for the *P* and *S*-wave models were 0.5 and 1, respectively; the corresponding flattening

179   coefficients were 0.7 and 1.5. These regularization parameters were identified based on the

180   results of synthetic modeling, which will be presented below.

181   The iterative cycle included the steps of source locations in the updated 3D velocity

182   model, matrix calculation, simultaneous inversions for four different grids and calculation of the

183   new averaged 3D model. In total, we performed five iteration cycles, which was an appropriate

184   compromise between the model stability and calculation speed. Note also that the tomography

185   inversion provides the 3D distributions of the *P* and *S* wave velocity anomalies. The distribution

186   of the *Vp/Vs* ratio is calculated by simple division of the resulting absolute *Vp* and *Vs*. The

187   adequacy of this approach was tested by a series of synthetic tests, which will be presented in the

188   next section.

189   **Synthetic tests**

190   Before presenting the main velocity models, we show the results of several synthetic tests

191   demonstrating resolution limitations of the tomography results. We perform synthetic modeling

192   to simulate the conditions of the experimental data processing as closely as possible. The

193   synthetic travel times are calculated for the same source-receiver pairs, as in the experimental

194   dataset, in the predefined 3D synthetic velocity model with the use of the bending ray tracing

195   algorithms. The travel times are then perturbed by random noise with average deviations in the

196   L1 norm equal to 0.03 s and 0.05 s for the *P* and *S* wave data, respectively. Then we "forget" any

197   information about source coordinates and origin times and start the recovery using the same

198   workflow as in the case of experimental data inversion, including the initial step of absolute

199   source locations. All the controlling parameters in the synthetic modeling remain the same as in

200   the case of computing the main model.

201   Here, we separately analyze the horizontal and vertical resolution based on the same

202   sections as used for presenting the main results. In the first test presented in Figure 3, we define

203   the horizontal checkerboard model with alternated positive and negative anomalies of ±8%

204   having the size of 5 km and separated by 1 km intervals. In the vertical direction, the anomalies

205   remain unchanged at all depths. In the resulting horizontal sections in Figure 3, we can see that

206   the anomalies are correctly recovered at all depths down to at least 7 km, although, in the deeper

207   sections, the amplitudes of anomalies become weaker, which is explained by considerably

208   smaller amounts of data.

209   In the next series of tests, we explore the vertical resolution of the models, which is

210   usually poorer than the horizontal resolution due to the trade-off between velocity and source

211   parameters (especially of focal depths). In Figure 4, we present three synthetic models separately

212   defined along three vertical sections used for presenting the main results. Along the sections, we

213   defined alternated anomalies with the amplitudes of ±8% having the sizes of 5 by 6 km. In the

214   horizontal direction, they are separated by a 1 km interval. In the vertical direction, the interval is

215   2 km. The change of the anomaly sign occurs at the depth internals of 2-4 km and 10-12 km. In

216   the resulting images, we can see that we can robustly resolve the upper two layers of anomalies,

217   whereas the third layer below 12 km depth appears not to be recovered.

218   To further assess the capacity of our algorithm to resolve the deep structures we

219   performed another series of tests presented in Figure 5, in which the anomalies are defined in a

220   single layer located below 8 km depth. We see that most of the anomalies are recovered in the

221   correct locations, which shows that such kinds of structures appear to be trustworthy.

222   To further assess the reliability of some structures inferred from the main results and used

223   for interpretation, we have produced a series of tests with realistic anomalies that are presented

224   in Figure 6. In this test, several patterns are defined along vertical section 1 by a series of closed

225   polygons, in which we set some values of the *P* and *S* wave velocity anomalies (the values in

226   percent are indicated in Figure 6 by numbers inside each pattern). Here, we consider two models

227   with and without the deep conduit beneath the location of the 2008 eruption. In the recovery

228   results (lower row in Figure 6), we can see that in Model 2 (without conduit), there is some

229   downward smearing of the shallower anomalies, which can be misinterpreted as downgoing

230   roots of this structure. However, this case is distinguishable from the result of the recovery of

231   Model 1, in which we defined the deep conduit. These tests demonstrate that we should be

232   prudent when interpreting the structures below 10 km depth. Another structure, which is

233   examined in this test is an anomaly located at the left end of the profile corresponding to the

234   high-seismicity zone beneath the isthmus connecting two parts of the island. This area is located

235   outside the network distribution, therefore, the reliability of the derived structures is

236   questionable. In these tests, we defined a large anomaly in a broad range of depths with highly

237   contrasted deviation of the Vp/Vs ratio. In the recovery result, we see that this anomaly is

238   restored with much lower amplitude and at smaller depths. This test shows that we should be

239   careful when considering numerical values of this structure and should only interpret it

240   qualitatively.

241   It is important that in all tests, we present the distributions of the *Vp/Vs* ratio calculated

242   by the division of the recovered absolute values of *Vp* and *Vs* and show fair recovery of the main

243   structures. These examples show the adequacy of this approach.

244   The synthetic tests allow also for accessing the accuracy of source parameter

245   determinations. In Figure 7, we present an example of mislocations of sources in the starting 1D

246   model and in the final 3D velocity distributions in the recovered velocity model. This example

247   corresponds to the case of the synthetic Model 1 with realistic anomalies presented in Figure 6.

248   The black points depict the current hypocenter solutions, whereas the red bars direct to the true

249   source locations. It can be seen that in the starting model, the mean error of source locations is

250   1.35 km, while in the final model, it is reduced to 1.05 km. The largest errors are observed in the

251   southwestern part of the study area located outside the station network, which remain

252   considerable after completing the iterative inversion procedure. At the same time, for areas

253   inside the network, we can visually observe a notable improvement of the source locations

254   during tomography inversions. The similar error range is expected in the case of the

255   experimental data inversion.

256

Seismic tomography results

258   The main resulting distributions of the anomalies of *Vp* and *Vs*, as well as the *Vp/Vs* ratio

259   are shown in a series of horizontal and vertical sections in Figures 8 and 9. All these results were

260   calculated after five inversion cycles. During the iterative inversion procedure, the *P*-wave

261   residual deviations in the L1 norm were reduced from 0.1455 s to 0.1084 s (25.51%), and those

262   of the *S*-wave reduced from 0.1968 s to 0.1381 s (29.79%). The detailed interpretation of the

263   resulting models will be presented in the next section. Here we only describe the most important

264   structures obtained from seismic tomography.

As we can see in the horizontal section at a 0 level in Figure 8, in the shallowest part of the model, we observe prominent negative anomalies inside the caldera, which likely indicate non-consolidated deposits of volcaniclastic rocks. The *P*-wave velocity anomalies appear to be stronger and in some places exceed 20%. The stronger *P*-wave anomaly may be indicative for the porous structure of the material, which behaves as a sponge and has low bulk elastic modulus (Takei, 2002). In this case, the *Vp/Vs* shows strongly negative anomaly, which is quite typical for caldera-filling rocks (see, for example, a similar feature in the Semisopochnoi Island in the tomography model by Yaroshenko et al., 2022). In the vertical section (Figure 9), we can see that this anomaly of low *Vp/Vs* ratio is rather thin and hardly reaches 1 km. In the shallowest section, the only place within the caldera, where we observe a local anomaly of high *Vp/Vs* ratio, coincides with the cone A in the southeastern part of the caldera, which can be explained by the presence of the magma conduit close to the surface. Another low-velocity anomaly in the uppermost layer is associated with Mt. Tulik, which is a large cinder cone located outside the caldera, having similar mechanical properties as deposits in caldera.

At the depth of 4 km, the distributions of *dVp, dVs* and *Vp/Vs* ratio inside the caldera look considerably different compared to the upper section. The low *S*-wave anomaly almost perfectly coincides with the caldera contour, whereas the distribution of the *P*-wave velocity anomalies is more heterogeneous. Below the cones A and D, we observe locally high *P*-wave velocity patterns (indicated by "1" and "2"), which give the inverse correlation of *dVp* and *dVs* and high values of *Vp/Vs* ratio. Such a relationship is a clear attribute of the presence of the magma with some content of partial melts and fluid saturation, which is normally observed in tomography models for most active volcanoes (Kasatkina et al., 2014, Bushenkova et al., 2019; Koulakov et al., 2013).

In the vertical sections 1 and 2 (Figure 9), we can see that the upper level of the high-*Vp/Vs* anomaly "1" beneath the cone A is located at a depth of less than 500 m, and the bottom side is at ~5 km b.s.l. The lateral size of this anomaly is approximately 3 km. Beneath the Ahmanilix vent, newly opened during the 2008 eruption, in Sections 1 and 3, we see that the upper limit of the high *Vp/Vs* anomaly "2" is located at the depth of 2 km below surface. The lower limit of this anomaly is not clearly determined in our model: it rather looks as a chain of several structures aligned vertically. The upper anomaly "2" is identified at depths of 2 - 5 km, and the second one indicated by "3" is located at 6 to 10 km depth. Below, we observe a vertically oriented anomaly "4", which may represent a deep magma conduit. Based on the two synthetic models with realistic structures presented in Figure 7, despite some obvious vertical

298 smearing in the lower part of our model, we can distinguish such a conduit-related anomaly;

299 though, we should be careful about its numerical parameters.

300   The results in deep sections at 7 and 10 km depth look generally similar. The most

301 prominent feature is an anomaly of high *Vp/Vs* ratio indicated by "3" and "4", which is located

302 beneath the caldera and slightly shifted to its northwestern part, where the 2008 occurred. This

303 anomaly, which likely represents the deeper magma reservoir, is also marked by clustered

304 seismicity.

305   There are two other interesting seismic structures located outside the caldera. As we can

306 see in both horizontal and vertical sections, in the southwest corner of our study area, at the

307 isthmus between two parts of the island, a zone of high seismicity appears to be associated with

308 high *Vp*, low *Vs* and high *Vp/Vs* ratio. In vertical section 1, this anomaly indicated by "6" is

309 observed down to ~10 km depth. However, as was shown in the synthetic test with realistic

310 anomalies in Figure 7, in this part of the area, the available data do not enable high-quality

311 recovery, and we can only interpret it qualitatively. In horizontal sections, we see that this zone

312 seems to be connected with the caldera-related anomaly by elongated low-velocity anomalies.

313   Another zone of elevated seismicity is located in the offshore area, at the southern border

314 of the study area (indicated by "7"). This zone is located outside the station network, therefore

315 we cannot enable sufficient resolution for velocity recovery in this area. However, in the

316 horizontal sections, we see some elongated low-velocity anomalies that connect this zone with

317 caldera.

318   We can compare our results with the previous seismic tomography studies of Okmok.

319 Some of the images in the study by Ohlendorf et al. (2014), which were based on the generally

320 the same technique and data sources as in this work, appear to be consistent with our results. A

321 prominent low-velocity anomaly of the *P*-velocity inside the caldera determined by them seems

322 to be similar to our results, especially to the anomalies of the *S*-wave velocity. Similar

323 correlation is observed between their distribution of the *P*-wave attenuation and our *S*-wave

324 velocity model. However, in the *S*-wave velocity model, Ohlendorf et al. (2014) revealed a

325 prominent high-velocity velocity anomaly beneath the caldera, which appeared to be inversely

326 correlated with our result. Furthermore, they did not resolve several important features, such as

327 local high *Vp* anomalies at 4 km depth beneath the eruption centers of 1997 and 2008, as

328 apparent in our model, probably because of insufficient resolution and too sparse grid spacing.

329 At the same time, our *S*-wave velocity distribution fairly well correlates with the model by

330 Masterlark et al. (2010) constructed with the use of ambient noise tomography. In that study, the

331   low-velocity anomaly of *Vs* is observed beneath the caldera down to 7 km depth; for the deeper

332   sections, they did not have a sufficient resolution.

333

334   **Discussions**

335   Seismic tomography is especially beneficial for identifying the properties of the magma

336   plumbing system beneath active volcanoes, when several seismic attributes, such as *Vp*, *Vs* and

337   *Vp/Vs* ratio can be determined. Based on the experience of previous seismic tomography studies

338   (Koulakov et al., 2013, 2020, 2021; Koulakov, 2022) and the existing experimental results

339   (Takei, 2002), we can single-out several regularities that can be useful to interpret the model

340   obtained in this work. The *P*-wave velocity is primarily sensitive to the composition, whereas the

341   variation of the *S*-wave velocity is mostly controlled by the presence of a liquid phase. The

342   coexistence of higher *P*- and lower *S*-wave velocity, and the corresponding very high values of

343   *Vp/Vs* ratio is a rather typical feature observed beneath many active volcanoes and interpreted as

344   magma reservoirs or conduits (Bushenkova et al., 2019, Koulakov et al., 2013, 2020, 2021).

345   Indeed, the intruded magma has a different composition compared to the host crustal rocks,

346   which determines the higher *Vp*. On the other hand, the active magma sources contain some

347   partial melts and dissolved volatiles that reduce the *S*-wave velocity. This feature provides a very

348   high and contrasted *Vp/Vs* ratio, which is used to determine the geometry of the magma

349   reservoirs and conduits.

350   It should also be noted that the *P* and *S* wave velocities, when considered separately, in

351   many cases cannot provide unambiguous interpretation. For example, the high *Vp* can be

352   associated with both highly solidified rigid bodies and fresh magma intrusions. The low *S*-wave

353   anomalies can appear to be similar in cases of soft sediments and partially molten magma

354   reservoirs. Thus, when only one of these parameters is available, misinterpretations are possible.

355   The interpretation becomes less ambiguous, when the *Vp* and *Vs* are jointly considered. In

356   particular, the *Vp/Vs* ratio gives clearer images of magma-associated structures, than *Vp* and *Vs*

357   alone and it allows distinguishing the cases mentioned above. For example, considering only *Vs*

358   in Masterlark et al. (2010) does not allow distinguishing between the low-velocity soft rock

359   deposits and underlying magma sources. However, we see that the *Vp/Vs* ratio presented in our

360   study successfully solves this problem and clearly differentiates between the low-*Vp/Vs* in

361   sediments and the very high *Vp/Vs* ratio in the magma reservoir. Similar differentiation was

362   observed in the area between Avacha and Koryaksky volcanoes (Bushenkova et al., 2019),

363   Akutan (Koulakov et al., 2021) and in many other places. For Okmok, the *Vp/Vs* ratio

364   demonstrates a very shallow location of the magma source beneath the cone A.

365   Based on the distribution of the *Vp/Vs* ratio in Figures 8 and 9, we can single out several

366   prominent anomalies that might be associated with magma sources. Our schematic interpretation

367   of these structures is presented in Figure 10. Below the cone A, at the intersection of sections 1

368   and 2 (Figure 9), we observe a contrasted anomaly "1" with the *Vp/Vs* exceeding 2. According to

369   our model, the upper limit of this anomaly is located at a depth of a few hundred meters and it

370   extends down to ~6 km. We interpret this anomaly as a magma reservoir that fed the multiple

371   eruptions of crater A that occurred in the historical times.

372   Below the cone D and the Ahmanilix vent formed during the 2008 eruption at

373   intersection of sections 1 and 3 (Figures 9 and 10), we observe a chain of the vertically oriented

374   anomalies of high *Vp/Vs* ratio. The deep part indicated by "4" represents a steady magma conduit

375   that is likely responsible for forming the Okmok volcano during the entire history of its

376   evolution. Its location roughly corresponds to the summit of the ancestral shield volcano that was

377   being formed here for more than a million of years, and the conduit is thought to have been

378   active for the same time span.

379   It appears to be paradoxical that the major recent activity in Okmok occured along the

380   perimeter of the caldera and not in the center, just above the conduit, where the strongest seismic

381   velocity anomalies are observed. Indeed, most of the historical eruptions, including one in 1997,

382   took place in cone A, which is laterally shifted to ~5-7 km from the conduit center. Similar shift

383   is observed for the 1817 eruption that occurred in the cone B in the northern part of the caldera.

384   The cones F, E, G, H are also located away from the conduit's projection to the surface. The

385   cones D and Ahmanilix were the only eruption centers, which appeared to be directly connected

386   with the conduit, but they were the result of monogenic episodes and had not a regular eruption

387   activity, like in the A cone. Similar offsets between magma reservoir and eruptive site exist at

388   other calderas. A notable example is Grimsvotn in Iceland, with a stable magma reservoir at the

389   northern caldera edge, yet the recent eruptions occurred at the southern caldera rim (e.g.,

390   Hreinsdottir et al., 2014).

391   We explain this paradox by the existence of a mechanical barrier under the central part of

392   the caldera that prevents magma ascending upward and coerces it to find other paths to the

393   periphery of the caldera. The long-term thermal effect from the conduit led to forming a ductile

394   layer with some content of partial melts. Based on the obtained distribution of the *Vp/Vs* ratio,

395   we propose that this layer corresponds to the anomaly "2" located at depths from 2 to 5 km,

perhaps to shallower depths as suggested by the recently proposed very shallow sill-like sources (Xue et al., 2020).

This ductile zone is underlain and likely well connected (Figure 9) to another anomaly of high Vp/Vs ratio indicated by "3". Together this shallow system may represent the major magma reservoir feeding the ongoing eruptions at Okmok. This is consistent with the magma source depth estimates obtained from ground deformation modeling, placing magma source regions in the 2-6 km range. This depth range may indicate that this part of the system is over time active at different depths, or the geodetic data cannot resolve simultaneous activity of both sources unless they are sufficiently separated. This is perhaps due to the limited aperture afforded to geodetic observations by the small radius of the main land mass.

The ductile medium in zone "2" may serve as a barrier for the magma to ascend directly to the surface. Soft rheology does not allow magma to create fractures, and it can only ascend in the form of diapirs due to buoyancy, which enables much slower movement than migration through a brittle medium (e.g., Sigmundsson et al., 2021). That is why, to escape from reservoir "3", for magma, it is easier to form some lateral conduits in colder brittle areas where migration can be conducted by hydraulic fracturing. In Figure 10, based on the distribution of the *Vp/Vs* ratio, we identify that such a conduit takes place between the anomalies "3" and "1" that delivers the magmatic material to the reservoir below the cone A. Such a transportation of magma between the reservoirs "3" and "1" likely occurred continuously during the recent epoch, when the regular historical eruptions occurred in the cone A. This has directly provided mafic material to the reservoir "1" from the deep conduit without significant changes at intermediate levels, which is consistent with available information on dominantly basaltic compositions of the eruption products from the Cone A (Larsen et al., 2013).

There might be a similar lateral magma conduit toward the anomaly "5" below the northern border of the caldera, which likely represented another magma reservoir that was responsible for the eruption of in 1817. Its upper limit is observed at ~4 km depth. As there is no activity in this part of the caldera for more than 200 years, any traces of shallow conduits bringing magma from the reservoir "5" to the surface were healed, and nowadays they are not visible in the tomography model.

The vertical ascents of magma that caused the formations of cones D and Ahmanilix are rather exceptional cases, which occurred only two times during the recent activity of Okmok. In these cases, the magma was able to pass through the ductile zone "2" and to reach the surface. This way of magma ascending is supported by the fact that no increase of seismicity was

429   observed before the 2008 eruption (Larsen et al., 2009; 2015). The seismic activity started only

430   five hours prior to the eruption onset, and it likely represented the moment when magma came

431   out from the ductile layer and reached the uppermost brittle cover. In this scenario, the magmas

432   of the 2008 eruption should be contaminated by the rock components existing in zone "2". This

433   is generally consistent with the concept of Larsen et al. (2013) who hypothesized that the 2008

434   eruption in the northeastern part of the caldera was fed by basaltic magma that initially arrived

435   from a deep reservoir and then was intersected with a more evolved basalt-andesitic magma in

436   shallower layers. This provided a broader range of compositions in different vents of the 2008

437   eruption compared to those of the 1997 eruption in the cone A.

438   In the southwestern corner of our study area near the isthmus separating two parts of the

439   Umnak Island, there is an area of high geothermal activity called the Hot Springs Cove.

440   Although it is located outside the seismic station network, a large number of seismic events was

441   recorded in this zone. For seismic tomography, we cannot guarantee high resolution for the

442   structures sitting there. As shown by the synthetic test with realistic anomalies, in this zone, we

443   can only recover general background velocities. Here, we obtain higher P and lower S wave

444   velocities. In the context of known geothermal activity, it is natural to propose that the low dVs

445   are associated with high fluid saturation, which can reach significant depths. Based on the

446   existing data, we can speculate that the observed seismicity at depths down to 8-10 km might be

447   caused by upward migration of deep fluids, as the meteoric fluids cannot reach such depths.

448   However, this hypothesis should be verified or disproved by geochemical examination of the

449   hydrothermal sources. The adjacent area of high geothermal activity Geyser Bight was

450   investigated by Nye et al. (1990) with the aim to explore the geothermal activity. In their report,

451   they claimed that hydrothermal activity in this area was mostly driven by circulation of meteoric

452   waters. However the ratio of 3He/4He=7.4 in emanating gas may provide evidence for a

453   magmatic influence on the hydrothermal system. A similar effect of the deep processes on the

454   hydrothermal processes may take place in the area of Hot Spring Cove.

455   It is interesting that in maps of the P and S wave velocity anomalies at 4 and 7 km, the

456   area of the Hot Springs Cove is connected with the caldera by an elongated low velocity

457   anomaly. It can be proposed that this structure represents a hidden tectonic fault that serves as a

458   weakened zone facilitating migration of magma and fluids. Associations of such fault-related

459   linear seismic velocity anomalies with volcanic and geothermal centers is a rather typical feature

460   observed in several volcanic areas, such as Tolbachik in Kamchatka (Koulakov et al., 2017) and

461   Toba Caldera in Sumatra (Koulakov et al., 2016). If there is a tectonic fault, the seismicity

462 beneath this zone can be of tectonic nature. However, the ruptures might be facilitated by the

463 presence of deeply migrating fluids.

464

465 **Conclusions**

466 Here, we revisit the local earthquake data for the Okmok volcano provided by the Alaska

467 Volcano Observatory to build a new seismic tomography model. Owing to implementing the

468 LOTOS tomography algorithm with adapting parameterization and using a larger dataset

469 compared to the previous study by Ohlendorf et al. (2014), we have obtained higher resolution

470 for the resulting distributions of the *P* and *S* wave velocities and the *Vp/Vs* ratio. In the derived

471 models we can identify some important features that were not seen before and that provide

472 important insight on the geometry of magma sources beneath Okmok. A number of synthetic

473 tests have demonstrated the resolution limitations for the recovered models and proven the

474 reliability of the main structures used for the interpretation. To reveal the geometry of the

475 magma sources, we mostly use the distribution of the *Vp/Vs* ratio, which appears to be a sensitive

476 attribute for the presence of magma having different composition and containing partial melts

477 and dissolved fluids.

478 Based on the retrieved seismic model, we conclude that the steady magma conduit, which

479 is responsible for forming the entire Okmok volcanic complex, is located beneath the

480 northeastern part of the caldera. At depths of 6-10 km, this conduit is headed by the main

481 reservoir, which is thought to be the main magma source for all volcanic vents along the inner

482 perimeter of the Okmok caldera.

483 We speculate that for the magma from the deep conduit, it is difficult to ascend vertically

484 because of the presence of a ductile layer at the depth of 2-5 km that serves as a natural barrier

485 for ascending magma. In the post-caldera time, only in two cases, magma could pass this layer

486 and reach the surface. In the first case, it caused forming the monogenic cone D. The second

487 eruption occurred in 2008 and resulted in forming the new cone Ahmanilix. In this sense, the

488 vertical transport of magma directly from the deep conduit appears to be exceptional for Okmok.

489 In most cases, magma escapes from the central reservoirs toward the periphery of the

490 caldera and creates local reservoirs beneath active vents. In historical times, the most active vent,

491 where the majority of the recorded eruptions of Okmok occurred, corresponds to the cone A in

492 the southwestern part of caldera. Below this location, we observe a large anomaly with the upper

493 boundary located at the depth of a few hundred meters and the bottom at ~5 km depth, which

15

represents the magma reservoir that feeds all these eruptions. In our tomography model, we see that this anomaly is connected with the central magma reservoir, which provides for continuous infill of the storage below the crater A by fresh magma with mafic composition. Another periphery reservoir and a conduit can be detected below the vent of the 1817 eruption; however, it appears to be less clear, as it might have been dissipated during more than 200 years of quiescence.

Our result shows that the magma reservoir beneath the cone A is located very close to the surface, possibly at a few hundred meters depth. This finding should be further verified using alternative geophysical methods, such as active seismics or electromagnetic methods. In case it is approved, this would give a unique possibility to reach the magma storage by a relatively small borehole and investigate it for the purposes of using the heat of active magma to produce geothermal energy.

Figure captions:

Figure 1. Shaded-relief map of the Okmok volcano (Umnak Island, Alaska) and its location within the Aleutian volcanic arc. Main eruptive features in the caldera shown sketchily after Larsen et al. (2015) and represent the recent 2008 eruption formations – new tephra cone with additional vents, area of collapsing pits and two renewed Cone D lakes. Post-caldera cones marked by letters after Byers, 1959. Base map topography and bathymetry data was loaded from www.marine-geo.org (GRMT data, Ryan et al., 2009); central part of the map (including caldera) have been constructed with detailed DEM data from Schaefer et al, 2012. See features descriptions in the legend.

524 **Figure 2.** Seismic network on the Okmok volcano and spatial seismicity distribution used for
525 tomographic inversion in this study. Seismic events (2003 – 2017) are shown by dots colored by
526 focal depth. Purple and lilac triangles depict two types of seismic instruments with its ID's. Gray
527 star indicate Ranch house at Fort Glenn Cape field.

528 **Figure 3.** Results of the checkerboard test for determining horizontal resolution. Results of
529 recovery are presented for P -, S - and Vp/Vs models at 4 and 7 km depth levels. Initial
530 configuration of synthetic 5-km-side anomalies with 1 km intervals is highlighted with the dotted
531 lines. The thin black lines shows topography contours with 200 m intervals.

532 **Figure 4.** Results of three checkerboard tests for checking the vertical resolution in which the
533 synthetic models were defined along three vertical sections, same as indicated in Figure 8. The
534 recovery results are presented for the Vp and Vs anomalies and Vp/Vs ratio. The shapes of the
535 synthetic anomalies are highlighted with the dotted lines.

536 **Figure 5.** Synthetic tests for checking the resolution in the deeper part of the model. The
537 synthetic models were defined along three vertical sections, same as indicated in Figure 8. The
538 recovery results are presented for the Vp and Vs anomalies and Vp/Vs ratio. The shapes of the
539 synthetic anomalies are highlighted with the dotted lines.

540 **Figure 6.** Results of recovery of two synthetic models with realistic shapes of anomalies defined
541 along Section 1 (same as used for presenting the main results in Figure 8). The initial synthetic
542 patterns are shown in the upper row; the values of the P and S wave velocity anomalies are
543 indicated by two numbers inside each pattern. The results of the recovery are shown for the
544 Vp/Vs ratio in the lower row. The shapes of the initial anomalies are highlighted with the dotted
545 lines. The comparison of the results of these two tests gives a possibility to assess the reliability
546 of the deep conduit resolving.

547 **Figure 7.** Mislocations of the sources during the synthetic modeling (for the model indicated in
548 the right column in Figure 6) shown in the map view and vertical section. Upper row is the
549 location results with the use of the starting 1D model, and the lower row is the location results in
550 the final 3D velocity model. Black dots indicate the current locations of events, and the red bars
551 direct to the true locations. The mean errors of source locations are indicated in figure captions.

552 **Figure 8.** The distributions of the resulting anomalies of Vp, Vs and Vp/Vs ratio in four
553 horizontal sections. The red dots indicate the locations of seismic events at the vicinity of the

554 corresponding depth levels. The thin black lines shows topography contours with 200 m

555 intervals.

556 **Figure 9.** The distributions of the resulting anomalies of Vp, Vs and Vp/Vs ratio in three vertical

557 sections with the locations shown in Figure 7. The black dots indicate the projections of seismic

558 events located at distances of less than 2 km from the profile. The numbered dotted lines indicate

559 the intersections with other sections.

560 **Figure 10.** Schematic interpretation of the resulting distributions of the Vp/Vs ratio in sections 1

561 and 3 in terms of conduits (filled red zones) and magma reservoirs (empty red contours). The

562 yellow dots indicate the seismicity along the sections. On the surface, the detailed topography

563 with the locations of the 1817, 1997 and 2008 eruptions is shown. More details with the

564 description of this figure are in the Discussion section.

Figure 1. Shaded-relief map of the Okmok volcano (Umnak Island, Alaska) and its location within the Aleutian volcanic arc. Main eruptive features in the caldera shown sketchily after Larsen et al. (2015) and represent the recent 2008 eruption formations – new tephra cone with additional vents, area of collapsing pits and two renewed Cone D lakes. Post-caldera cones marked by letters after Byers, 1959. Base map topography and bathymetry data was loaded from www.marine-geo.org (GRMT data, Ryan et al., 2009); central part of the map (including caldera) have been constructed with detailed DEM data from Schaefer et al, 2012. See features descriptions in the legend.

Figure 2. Seismic network on the Okmok volcano and spatial seismicity distribution used for tomographic inversion in this study. Seismic events (2003 – 2017) are shown by dots colored by focal depth. Purple and lilac triangles depict two types of seismic instruments with its ID's. Gray star indicate Ranch house at Fort Glenn Cape field.
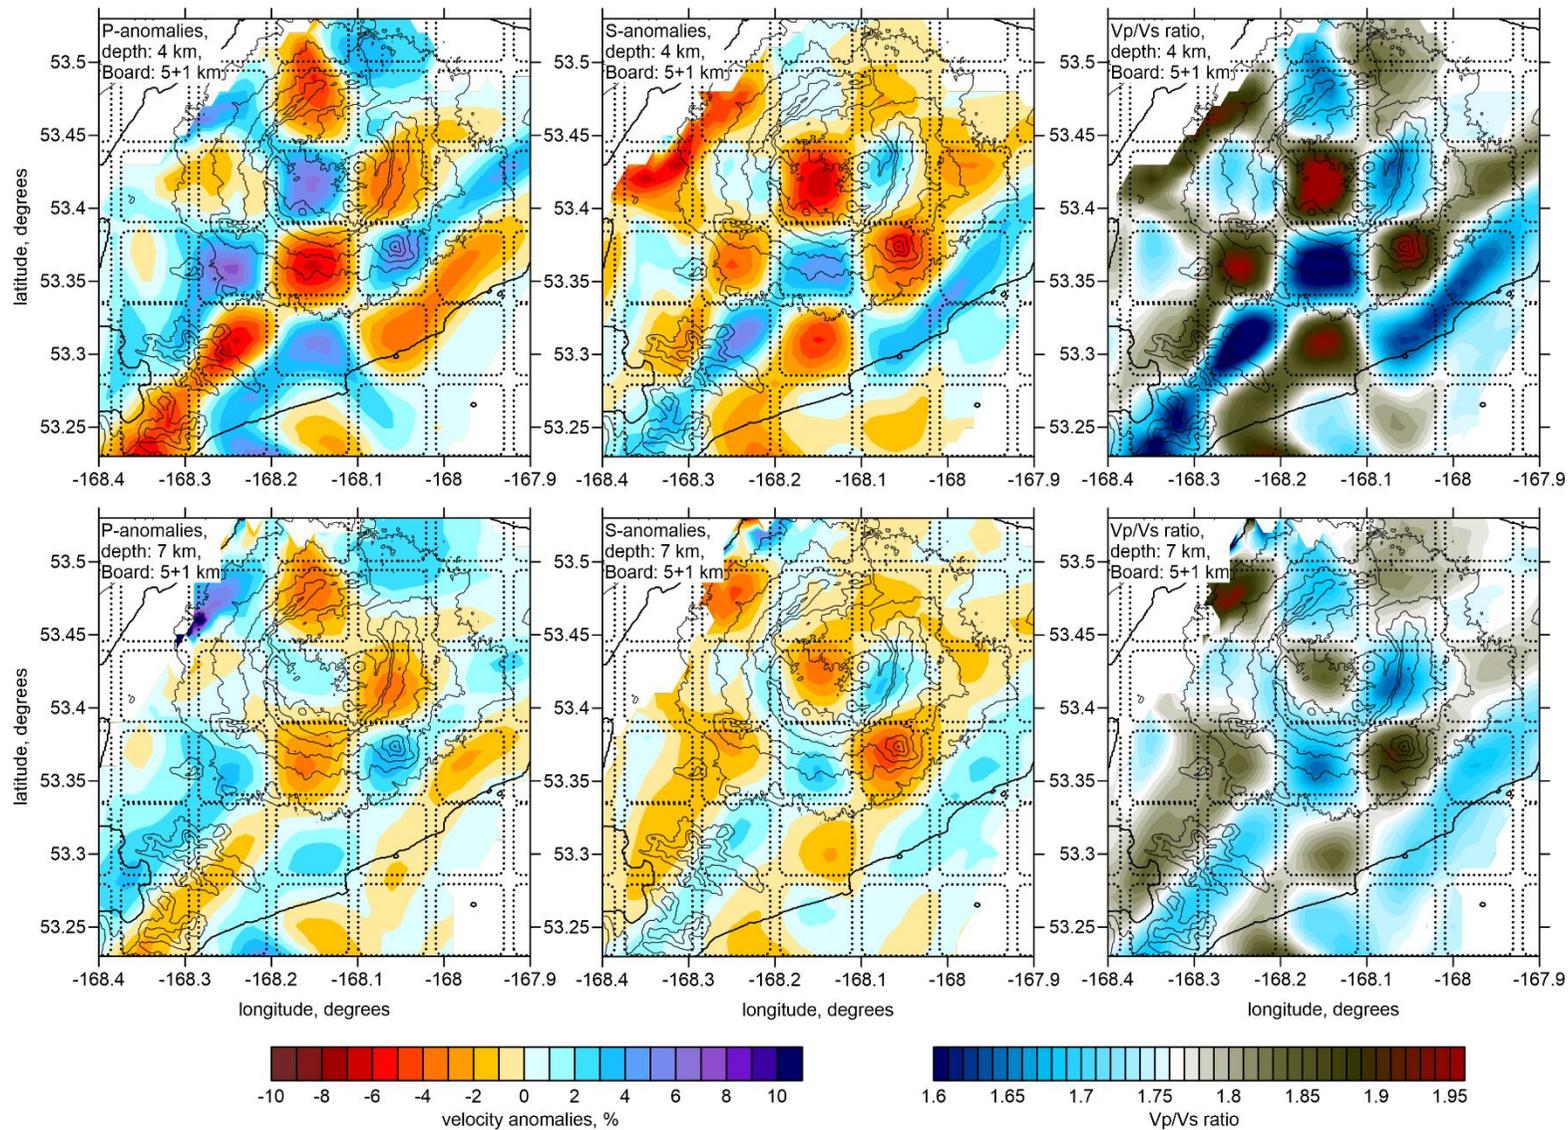

Figure 3. Results of the checkerboard test for determining horizontal resolution. Results of recovery are presented for P -, S - and Vp/Vs models at 4 and 7 km depth levels. Initial configuration of synthetic 5-km-side anomalies with 1 km intervals is highlighted with the dotted lines. The thin black lines shows topography contours with 200 m intervals.
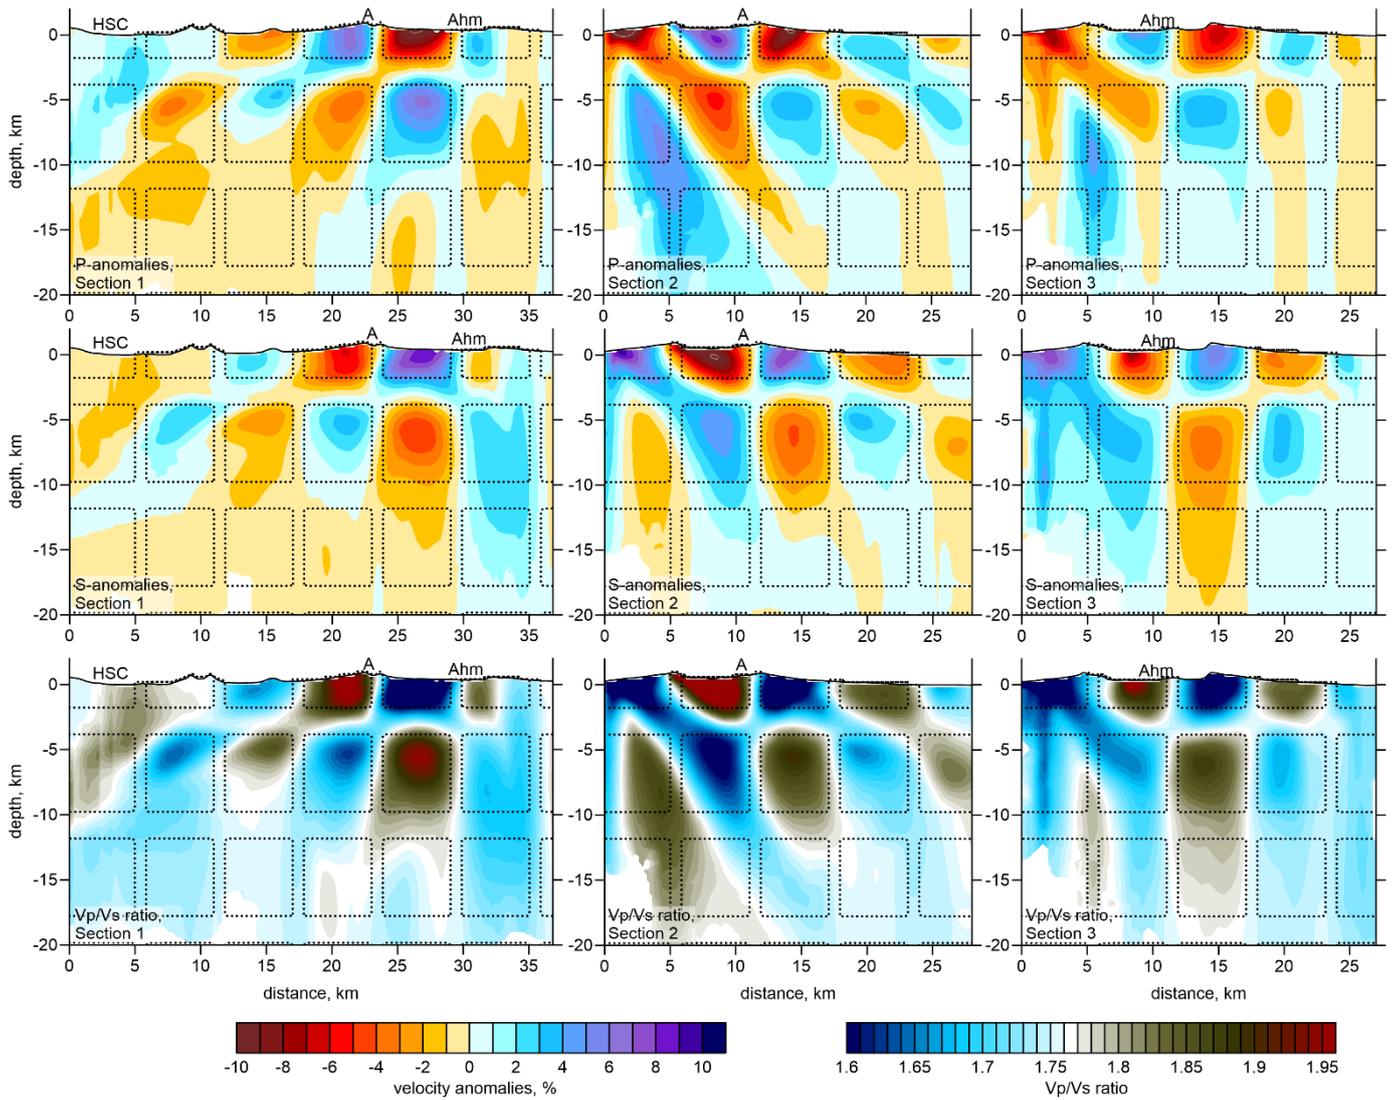

Figure 4. Results of three checkerboard tests for checking the vertical resolution in which the synthetic models were defined along three vertical sections, same as indicated in Figure 8. The recovery results are presented for the Vp and Vs anomalies and Vp/Vs ratio. The shapes of the synthetic anomalies are highlighted with the dotted lines.
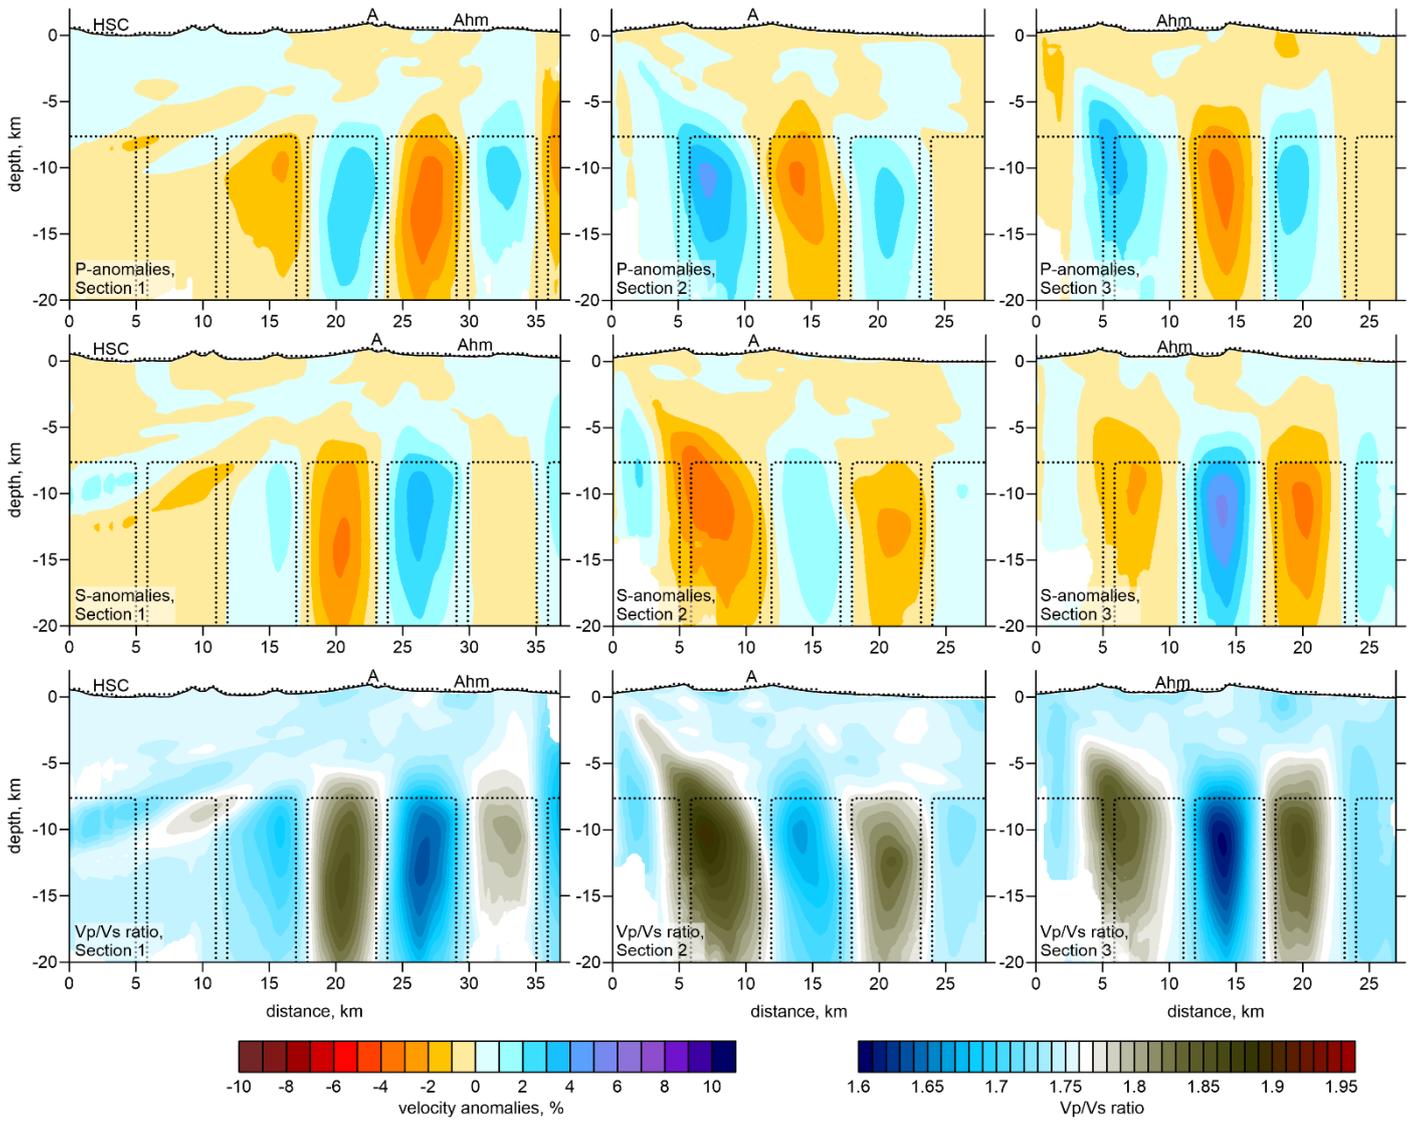

Figure 5. Synthetic tests for checking the resolution in the deeper part of the model. The synthetic models were defined along three vertical sections, same as indicated in Figure 8. The recovery results are presented for the Vp and Vs anomalies and Vp/Vs ratio. The shapes of the synthetic anomalies are highlighted with the dotted lines.
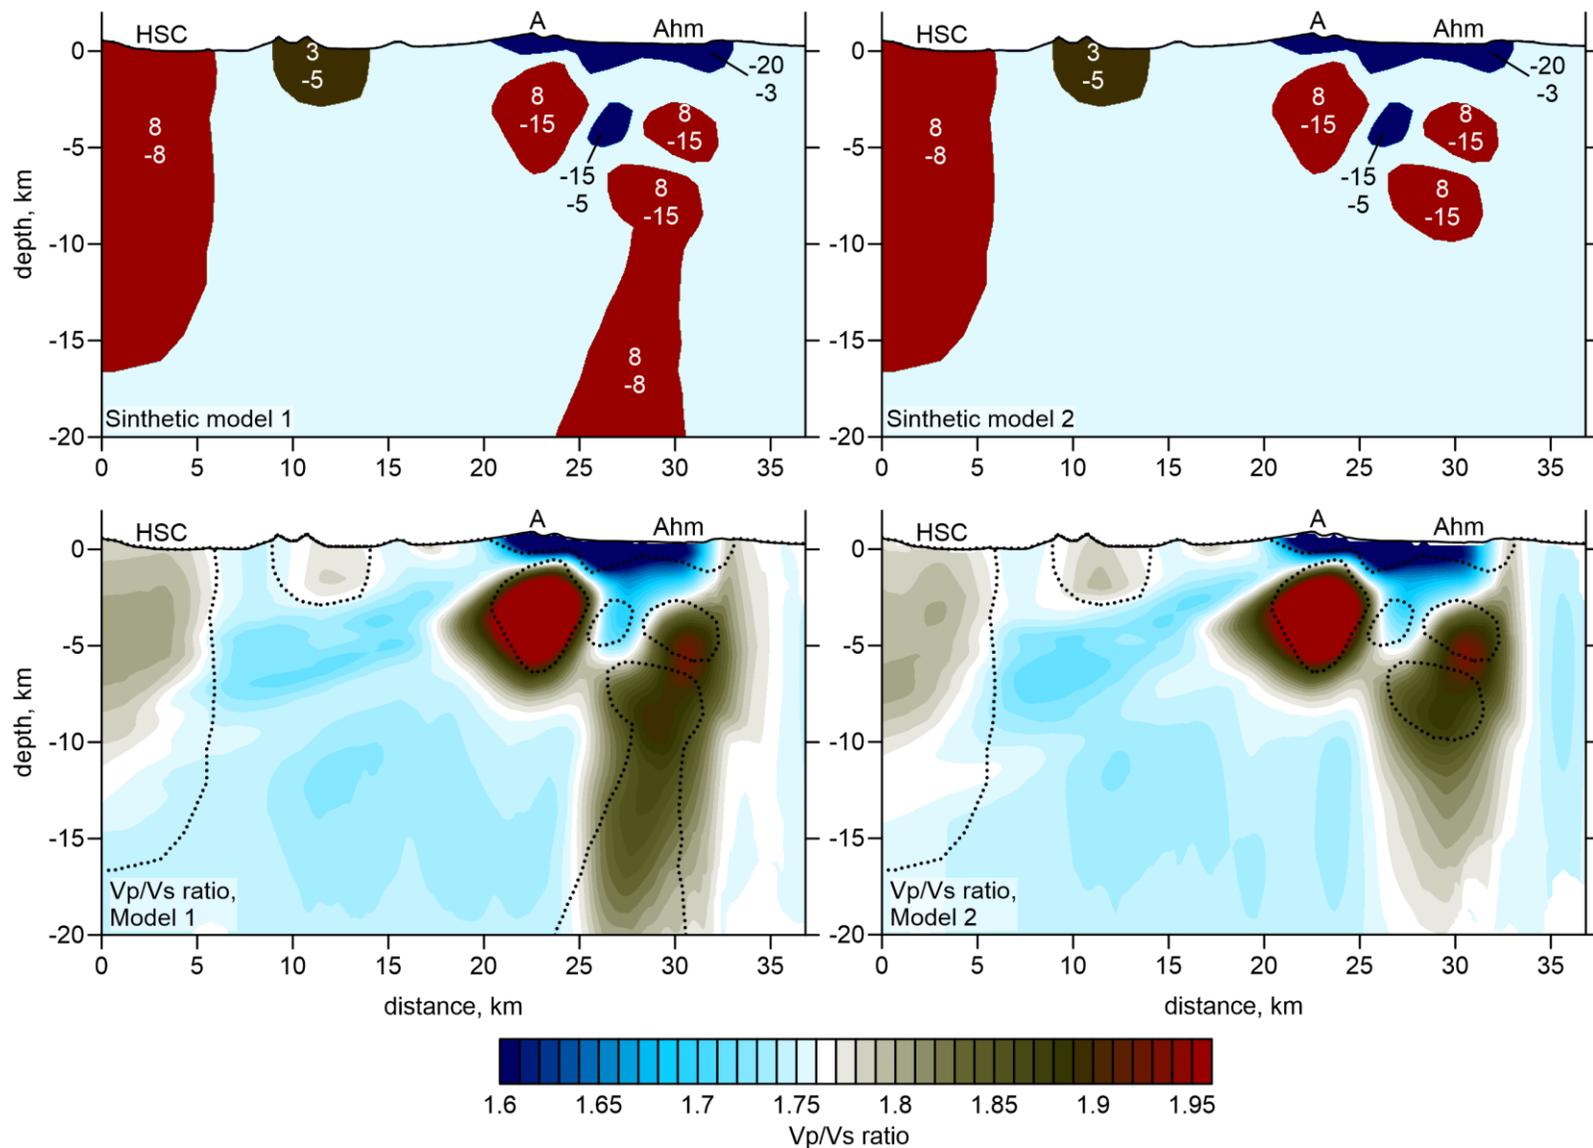

Figure 6. Results of recovery of two synthetic models with realistic shapes of anomalies defined along Section 1 (same as used for presenting the main results in Figure 8). The initial synthetic patterns are shown in the upper row; the values of the P and S wave velocity anomalies are indicated by two numbers inside each pattern. The results of the recovery are shown for the Vp/Vs ratio in the lower row. The shapes of the initial anomalies are highlighted with the dotted lines. The comparison of the results of these two tests gives a possibility to assess the reliability of the deep conduit resolving.
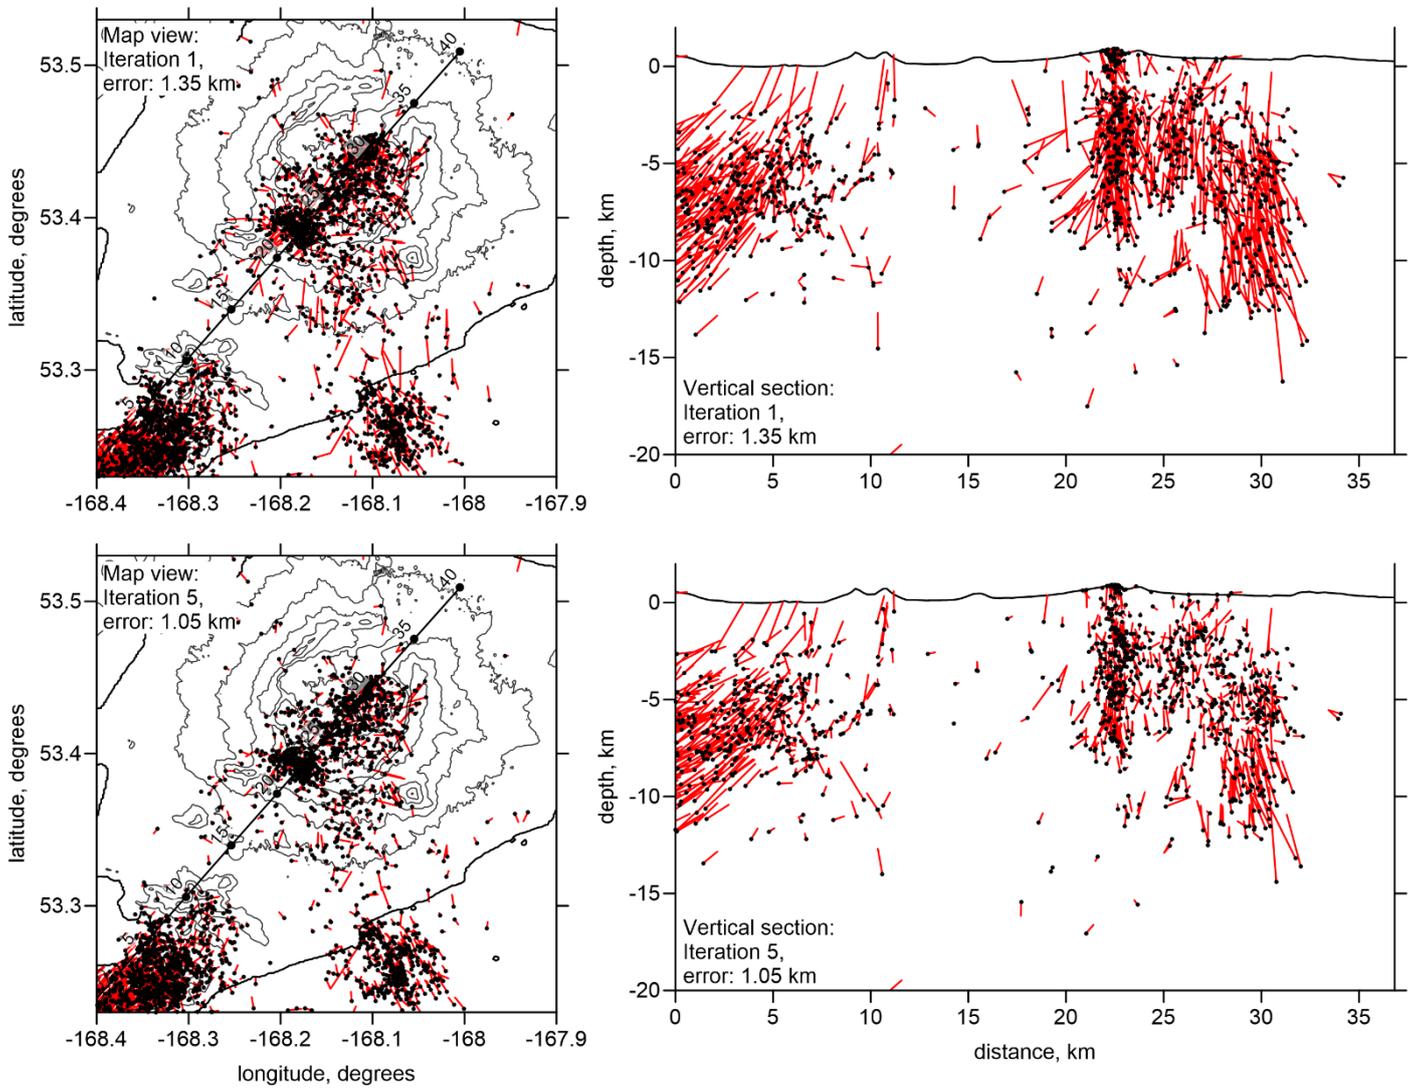

Figure 7. Mislocations of the sources during the synthetic modeling (for the model indicated in the right column in Figure 6) shown in the map view and vertical section. Upper row is the location results with the use of the starting 1D model, and the lower row is the location results in the final 3D velocity model. Black dots indicate the current locations of events, and the red bars direct to the true locations. The mean errors of source locations are indicated in figure captions.
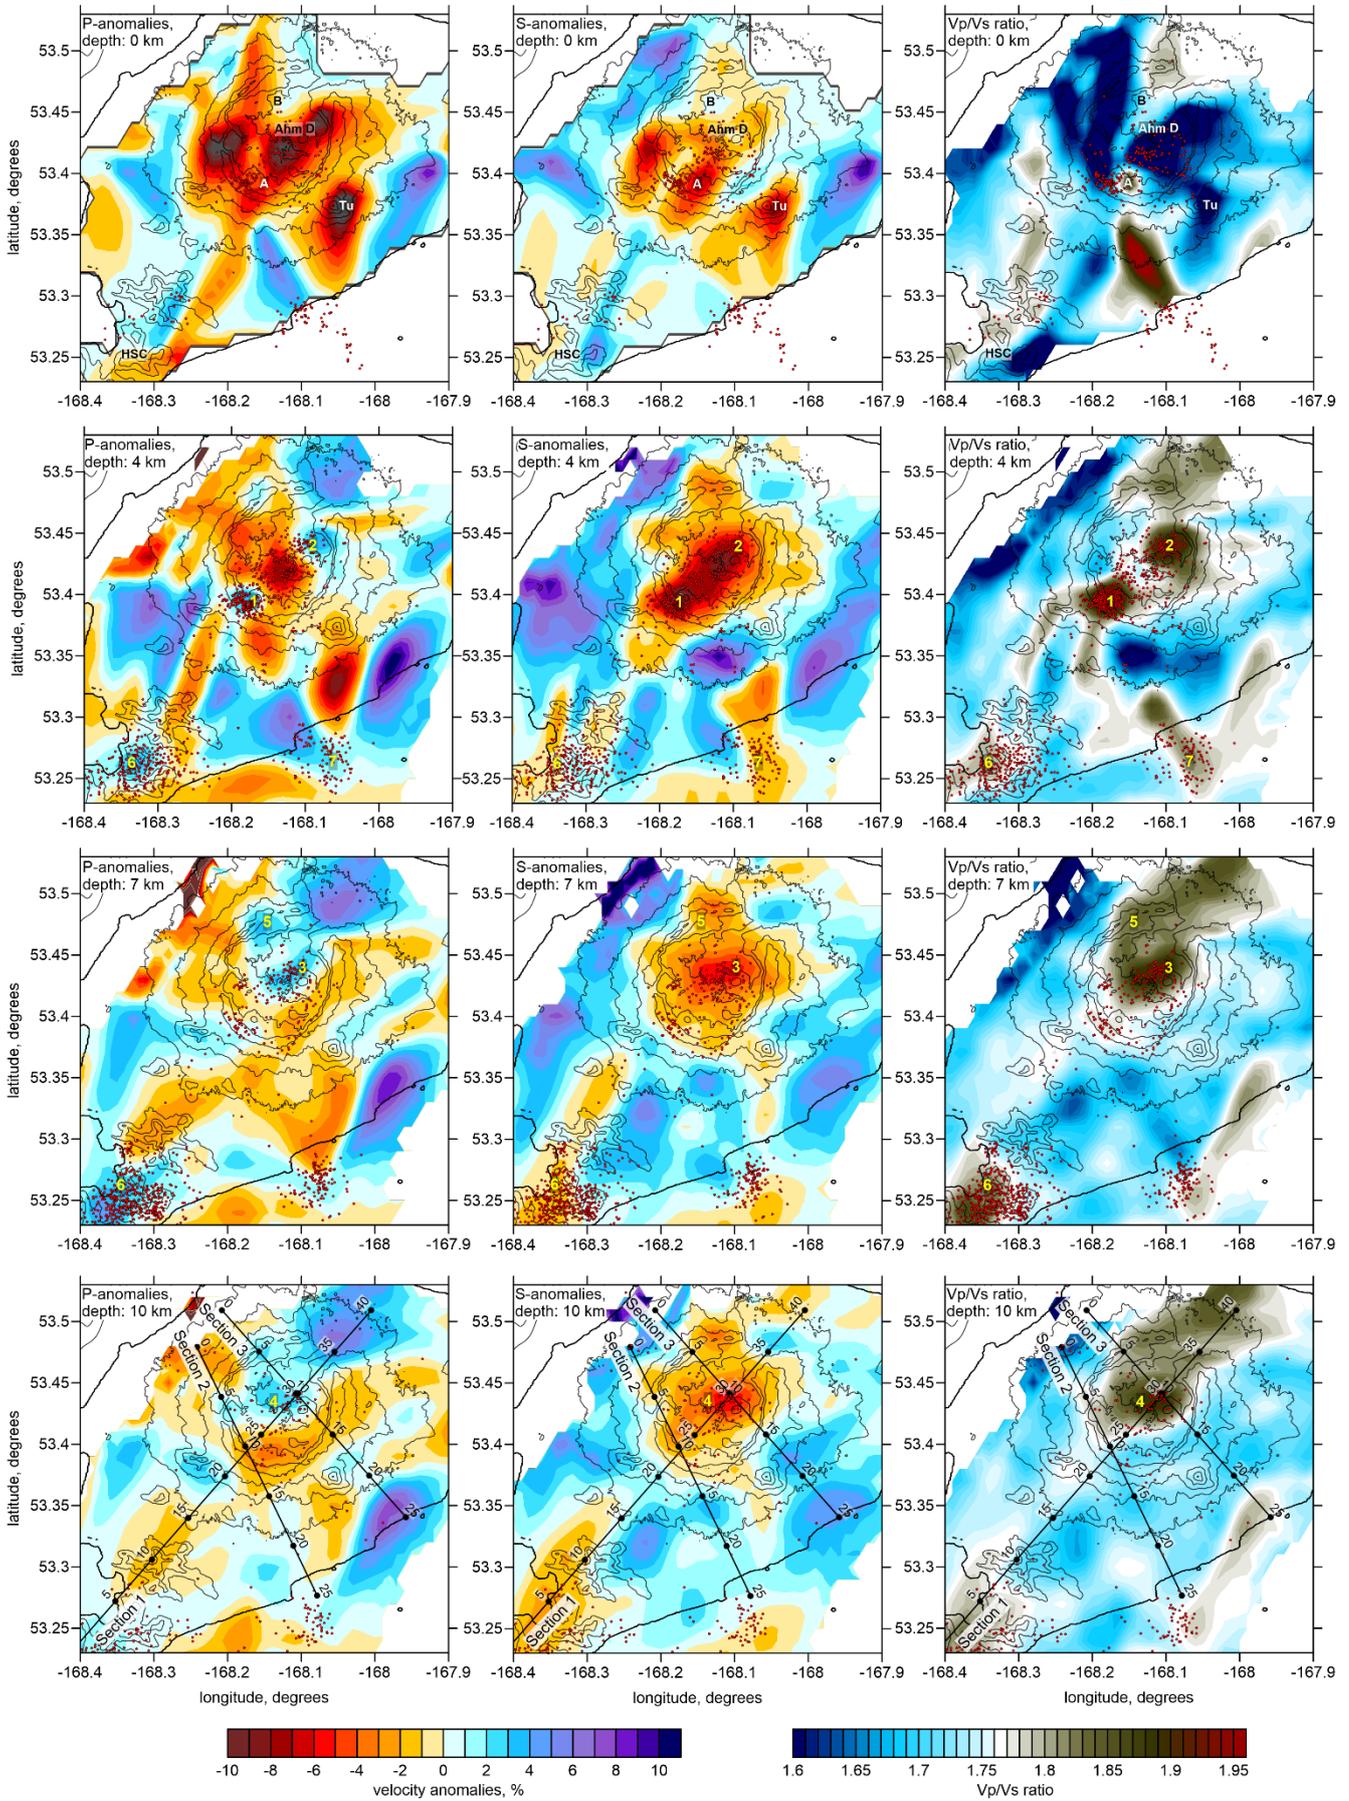

Figure 8. The distributions of the resulting anomalies of Vp, Vs and Vp/Vs ratio in four horizontal sections. The red dots indicate the locations of seismic events at the vicinity of the corresponding depth levels. The thin black lines shows topography contours with 200 m intervals.
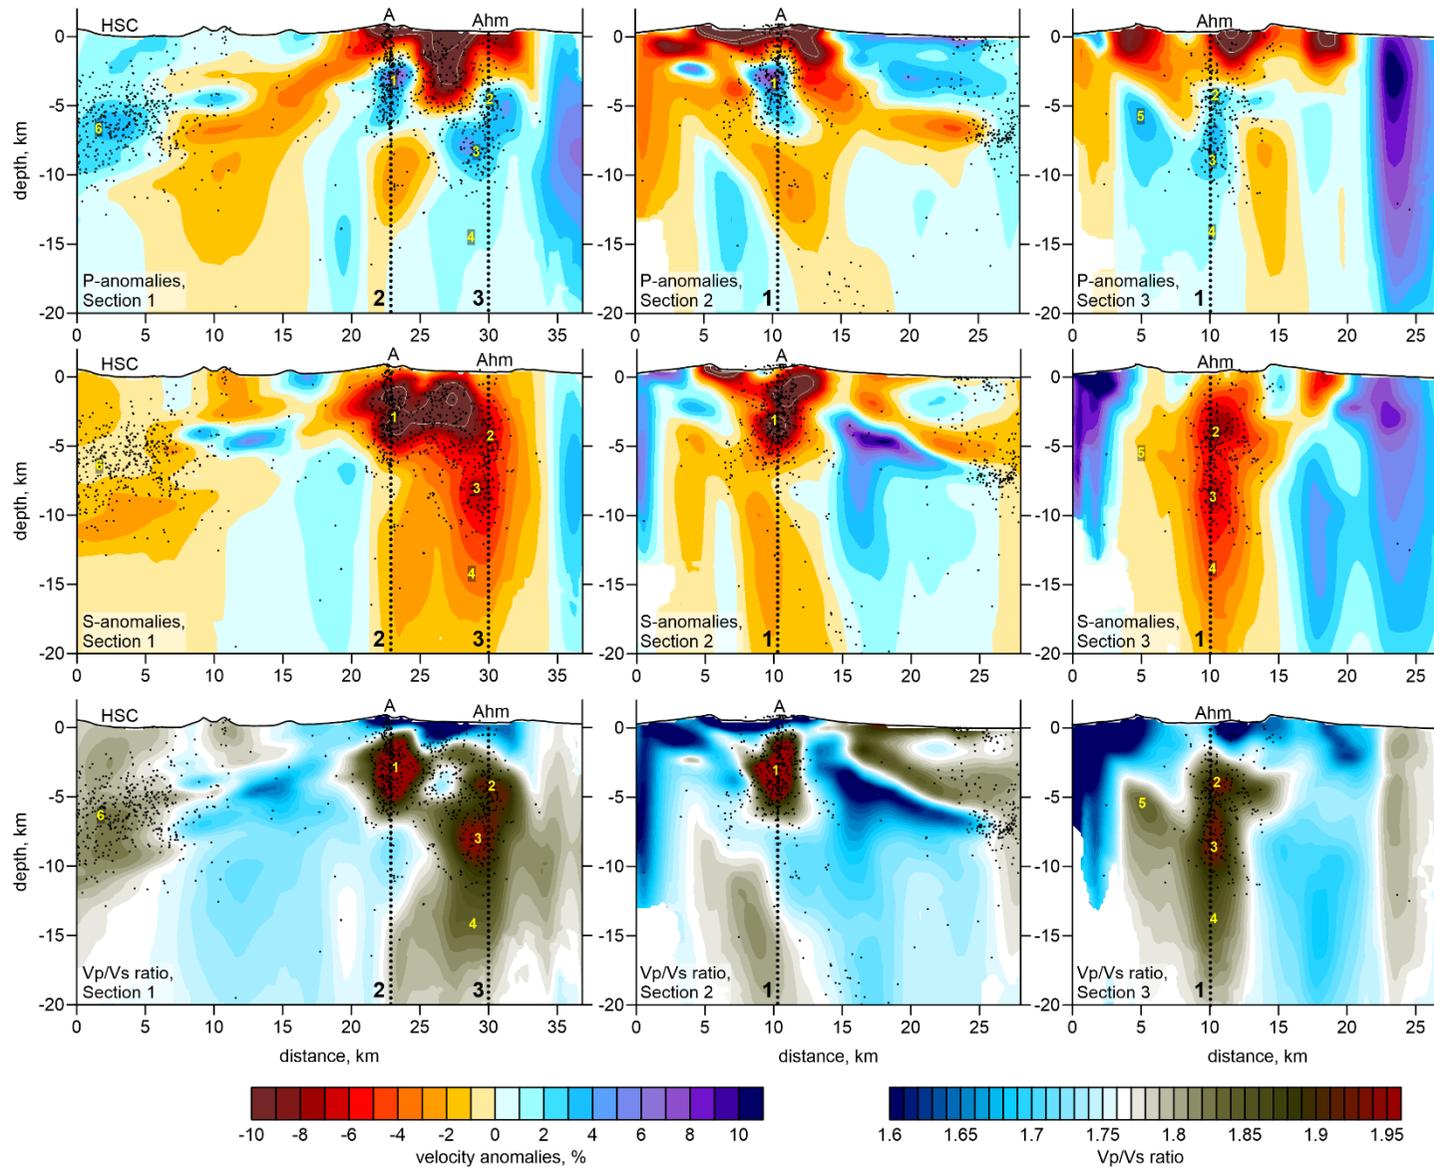

Figure 9. The distributions of the resulting anomalies of Vp, Vs and Vp/Vs ratio in three vertical sections with the locations shown in Figure 7. The black dots indicate the projections of seismic events located at distances of less than 2 km from the profile. The numbered dotted lines indicate the intersections with other sections.
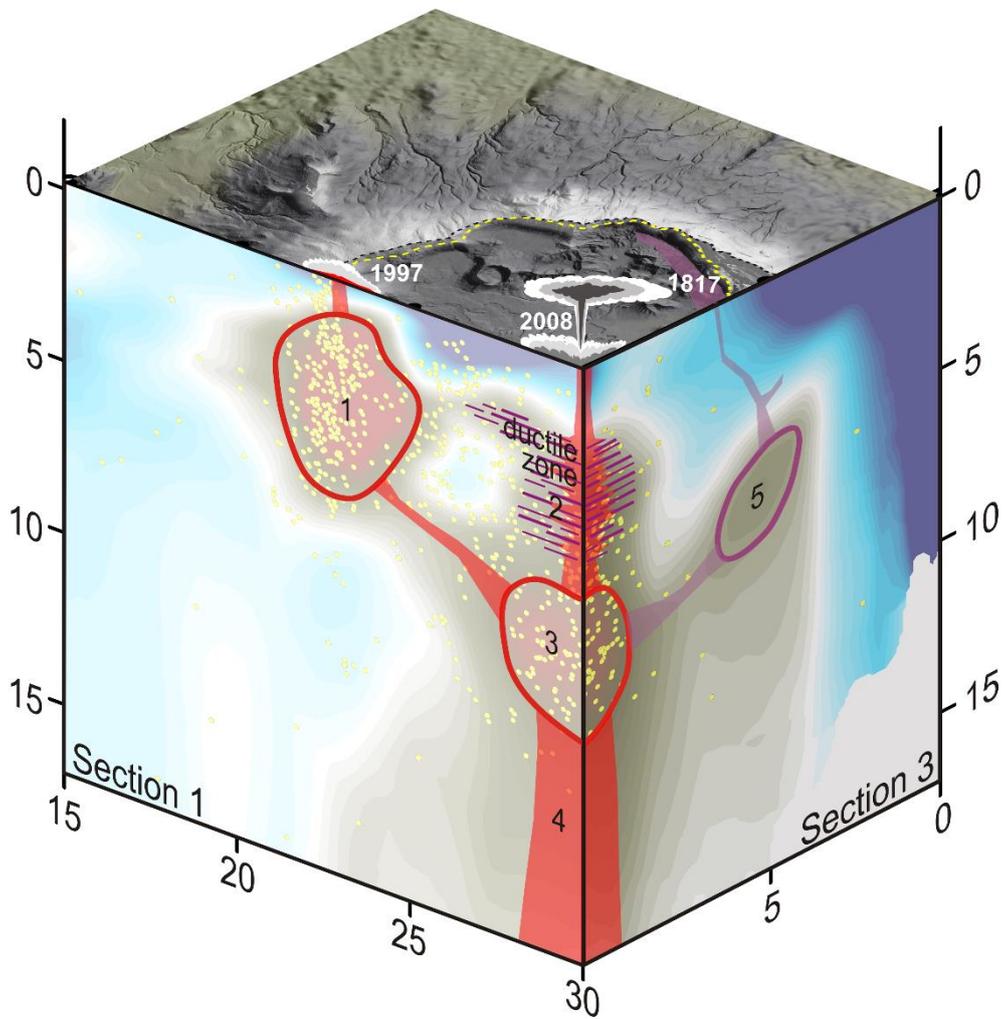

Figure 10. Schematic interpretation of the resulting distributions of the Vp/Vs ratio in sections 1 and 3 in terms of conduits (filled red zones) and magma reservoirs (empty red contours). The yellow dots indicate the seismicity along the sections. On the surface, the detailed topography with the locations of the 1817, 1997 and 2008 eruptions is shown. More details with the description of this figure are in the Discussion section.
