Key Points:

- The reversed energy spectra of ring current protons were observed by RBSPICE to show the distinct flux minima ~50 - 100 keV and flux maxima ~200 - 400 keV.

- The reversed proton energy spectra mostly occur inside the plasmasphere during geomagnetically quiet periods.

- The global distributions of reversed proton energy spectra suggest the underlying contributions of various physical processes.

29

30 **Abstract**

31   Energy spectra of ring current protons are crucial to understanding the ring

32 current dynamics. Based on high-quality Van Allen Probes RBSPICE measurements,

33 we investigate the global distribution of the reversed proton energy spectra using the

34 2013-2016 RBSPICE datasets. The reversed proton energy spectra are characterized

35 by the distinct flux minima around 50 - 100 keV and flux maxima around 200 - 400

36 keV. Our results show that the reversed proton energy spectrum is prevalent inside the

37 plasmasphere, with the occurrence rates > 90% at L ~ 2 - 4 during geomagnetically

38 quiet periods. Its occurrence also manifests a significant decrease trend with

39 increasing L-shell and enhanced geomagnetic activity. It is indicated that the

40 substorm-associated processes are likely to lead to the disappearances of the reversed

41 spectra. These results provide important clues for exploring the underlying physical

42 mechanisms responsible for the formation and evolution of reversed proton energy

43 spectra.

44

45

46 **Plain language summary**

47   The energy spectra of ring current protons are significant for us to understand the

48 ring current dynamics. Several previous studies reported the reversed energy spectra

49 of ring current protons that represent flux minima at lower energies and flux maxima

50 at higher energies. In the literature, there is rather limited statistical investigation on

51 the global distribution features of such spectra. The availability of high quality Van

52 Allen Probes RBSPICE data enables a comprehensive study in this regard. Based on

53 RBSPICE measurements, we report the reversed energy spectra of ring current

54 protons particularly featured by the distinct flux minima around 50 - 100 keV and flux

55 maxima around 200 - 400 keV. We further adopt 4-year RBSPICE proton datasets

56 from 2013 to 2016 to investigate the occurrence rate, corresponding energies of flux

57 maximum and minimum, and the ratio of flux maximum to minimum as a function of

58 L shell, MLT and geomagnetic activity level. Our results demonstrate that these

59 reversed proton energy spectra are prevalent inside the plasmasphere, with the

60 occurrence rates > 90% at L ~ 2 – 4 during geomagnetically quiet periods. The strong

61 L and geomagnetic activity dependence imply the physical processes in association

62 with proton substorm injections.

63

64

65 **1. Introduction**

66   Energy spectrum distributions of energetic particles are an essential indicator for

67 understanding the underlying physics of magnetospheric particle dynamics. In

68 general, it is well recognized that both electron and proton energy spectra in space

69 plasmas follow a Kappa or Kappa-like profile having fluxes steeply falling with

70 increasing energy (e.g., Freden, 1965; Pizzella et al., 1962; Summers et al., 2009). In

71 contrast, a number of previous studies reported 'reversed' energy spectra of energetic

72 particles that do not follow monotonically decrease profiles of fluxes with increasing

73 energy but represent flux minima at lower energies and flux maxima at higher

74 energies. Based on the Molniya 1 measurements, Vakulov et al. (1975) observed a

75 flux maximum of the outer belt electron energy spectra at energy ~1- 2 MeV. West et

76 al. (1981), using 60 keV to 3 MeV electron data from Ogo5, showed a flux maximum

77 at ~1.5 MeV and a minimum at ~500 keV. By analyzing the ring current proton

78 spectra (1 - 300 keV) observed by the Explorer 45, Williams et al. (1973) reported the

79 flux minima of proton energy spectra at energies ~20 - 100 keV over L ~ 3.2 - 4.0,

80 which they attributed to the ion-cyclotron instability. Based on the AMPET CCE

81 measurements, Krimigis et al. (1985) observed the flux maxima at energies ~100 -

82 300 keV during both the main and recovery phases of a geomagnetic storm.

83   Along with the launch of the twin Van Allen Probes mission in August 2012

84 (Mauk et al., 2012), the long-term accumulation of unprecedented, high quality

85 particle datasets with fine energy resolutions has fueled a resurgence in

86 magnetospheric particle dynamics studies. By combining the MagEIS and REPT

87 measurements, Zhao et al. (2019a) reported a reversed energy spectrum of radiation

88 belt electrons, which is featured by the flux maximum ~1 – 2 MeV and flux minimum

89 ~ 100's keV and is reasonably accounted for energy-dependent electron losses

90 induced by hiss wave (e.g., Ni et al., 2019; Fu et al., 2020). A following statistical

91 analysis of Zhao et al. (2019b), on basis of the detailed analysis of reversed electron

92 energy spectra, found that reversed energy spectra dominate inside the plasmasphere

93 at L < 2.5.

94   Comparatively, there remains lacking the systematic information about the global

95 distribution of the reversed energy spectra of ring current protons. The availability of

96 Van Allen Probes RBSPICE data enables a comprehensive study in this regard.

97 Therefore, this letter is dedicated to investigate the global distribution of reversed

98 proton energy spectra based upon multi-year RBSPICE data from Van Allen Probes.

99 By establishing an automatic identification criterion for the reversed proton energy

100 spectra, we intend to perform a statistical analysis to explore the global distribution

101 features of the reversed proton energy spectrum, its occurrence pattern, its dependence

102 on geomagnetic activity, and its profile characteristics in terms of the energy range of

103 local flux minimum and the ratio of local flux maximum to minimum.

104

105 **2. Instrumentation and Datasets**

106   The Van Allen Probes, launched in August 2012, consist of two identical

107 satellites and operate in almost same orbits with perigees of ~600 km, inclination of

108 ~10°, apogees of ~5.8 Earth radii (R_E) and spin period of ~11s (Mauk et al., 2012).

109 The Radiation Belt Storm Probes Ion Composition Experiment (RBSPICE)

110 instrument onboard the Van Allen Probes, which are designed to obtain a

111 comprehensive physical understanding of ring current, provides measurements of

112 protons in the energy range of ~7 - 600 keV (Mitchell et al., 2013). The level 3-PAP

113 data with pitch angle information are adopted in this study. Due to the high-voltage

114 issues during the early phase of the emission of RBSPICE-A, we only adopted the

115 data from RBSPICE-B in the present study (Summers et al., 2017). The L shell used

116   in this study is McIlwain L calculated with IGRF and OP77Q (Olson and Pfitzer,

117   1982) magnetic field model.

118

119   **3. Observations and Statistical Results**

120   Figure 1 displays the observations of proton fluxes during 16 - 30 March, 2015.

121   The solar wind parameters and geomagnetic indices obtained from the OMNIweb are

122   plotted in Figures 1a-b. On 17 March 2015 when an intense geomagnetic storm

123   occurred, the solar wind speed jumped from ~400 to ~600 km/s and the interplanetary

124   magnetic field (IMF) B_z turned quickly from northward (~15 nT) to southward (~-15

125   nT). The Dst index dropped from ~30 to ~-220 nT with the AE index increasing

126   significantly from ~100 to 1500 nT. At the same time, the RBSPICE onboard the Van

127   Allen Probe B observed evident proton flux increases at energies of 44.7 and 81.6

128   keV (Figures 1c-d). However, the enhancements of 268.9 keV proton fluxes did not

129   occur until 18 March. The black solid lines in Figures 1c-e indicate the plasmapause

130   location calculated using Liu et al., (2015) model. In Figures 1c-d, the proton fluxes

131   outside the plasmasphere are higher than those inside the plasmasphere during quiet

132   times. During the recovery phase after 18 March, 44.7 and 81.6 keV proton fluxes at

133   lower L (~2 – 4) gradually decreased while the 268.9 keV proton fluxes increased and

134   then remained relatively stable. Figures 1f-h further show the proton energy spectra at

135   the indicated time intervals. As shown in Figure 1f, the proton fluxes generally

136   decreased monotonically with increasing energy over L ~3.0 – 5.6. However, several

137   days later (Figures 1g-h), the proton energy spectra at L < ~5.2 exhibited "reversed"

138   structures with fluxes decay more significantly at low energies < ~200 keV, leading to

139   flux minima at energies ~80 keV. These flux minima reduced with decreasing L

140   shells.

141   Figure 2 illustrates some key parameters of the reversed proton energy spectra.

142   This representative example occurred at 02:04:47 on 29 March 2015at L = 3.15. In

143   this example, proton energy spectrum has a clear flux minimum (f_{min}) at E_{min} ~82 keV

144   and a flux maximum (f_{max}) at E_{max} ~221 keV with the ratio of flux maximum to

145 minimum reaching ~60. To automatically identify the reversed proton energy spectra,

146 we adopted three criteria: (1) proton energy spectra show the existence of the

147 maximum and minimum, and the corresponding energy of flux maximum (E_{max}) is

148 greater than that of flux minimum (E_{min}), (2) $\frac{f_{max}}{f_{min}} > 3$, and (3) there must be at least one

149 energy channel between the E_{max} and E_{min} to avoid the misclassification.

150   To further investigate the relation between the geomagnetic activities and the

151 reversed proton spectra in a long period, we present the geomagnetic indices and

152 proton fluxes with three energy channels (44.7, 81.6 and 268.9 keV) during 2015 in

153 Figures 3a-d with the white solid lines representing plasmapause locations. When the

154 Dst index suddenly decreased and the AE index increased, the locations of

155 plasmapause were reduced to lower L (~2 − 3). For 44.7 and 81.6 keV protons, the

156 fluxes outside the plasmasphere are ~1 order of the magnitude higher than those

157 inside the plasmasphere in most cases, yet this is opposite to the fluxes of 268.9 keV

158 protons. While inside the plasmasphere, the proton fluxes at energies 44.7 and 268.9

159 keV are generally 1~2 orders higher than those at energies 81.6 keV. With increasing

160 energy, the proton energy spectra are going to show the decreasing and then

161 increasing trend which is the reversed feature depicted in Figure 2. Figures 3e-h

162 demonstrate the key parameters of automatically selected reversed proton energy

163 spectra. The occurrence rate of the reversed proton energy spectra is calculated with

164 the grids of 0.1 L and one day. The locations of plasmapauses match well with the

165 upper boundaries of the region with the occurrence rate > 90%. During quiet times,

166 the plasmapauses usually locate at L > 4.5 so that the reversed proton energy spectra

167 locate at L ~2 − 4. We find that the proton reversed energy spectra are likely to be

168 observed under active geomagnetic conditions (Dst > -50 nT and the AE > 1000 nT).

169 As shown in Figures 3f-h, the proton energies of flux maxima mostly lie in the range

170 of ~82-400 keV, decreasing with increasing L shells. Similarly, the proton energies of

171 flux minima for reversed energy spectra are tens of keV. Note that there still are a few

172 events which distribute outside the plasmasphere at L > ~4.5 with E_{max} > 328 keV and

173 E_{min} > 100 keV. Figure 3f reveals that the flux maxima are ~10 to 30 times greater

174 than the flux minima at L < 4, while the ratios decrease from ~10 to 3 with increasing

175 L shells at L > 4.

176   Figure 4 shows the global distributions of reversed proton energy spectra as a

177 function of L shell and MLT for three indicated geomagnetic conditions (Dst>-30 nT,

178 -50 nT<Dst<-30 nT and Dst<-50 nT) from January 2013 to December 2016. From top

179 to bottom, each row presents the number of total samples, occurrence rate, the

180 corresponding energies of flux maximum and minimum, and the ratio of flux

181 maximum to minimum. The region of our interest has been divided into smaller bins

182 with the resolution of 0.5 L × 1 MLT, and the blank bins means the observational

183 samples are less than 50. Both the E_{max}, E_{min}, and the ratio of flux maximum to

184 minimum in Figures 4g-o are valued by averaging the cases in one bin. Most samples

185 are observed during quiet times (Dst > -30 nT) at L ~2.5 - 4.5 (Figure 4a). The

186 reversed proton spectra almost persistently exist over L ~ 2 − 4 during quiet times,

187 with occurrence rates >90%. Besides, the occurrence rates decrease with increasing L

188 shells, which is consistent with the observations shown in Figure 1, and decreases

189 under more active geomagnetic activities. The upper boundary of higher occurrence

190 rate (>90%) regions shift from higher to lower L shells. Regarding to the MLT

191 dependence, we find that the occurrence rates on the dayside are slightly higher than

192 those of nightside, especially during the geomagnetically active periods (Dst < -50

193 nT). In Figures 4g-l, the statistical distributions of the E_{max} and E_{min} demonstrate that

194 the proton fluxes mostly reach the peaks at energies ~200 - 400 keV and drop to the

195 valleys at energies ~50 - 100 keV. Both E_{max} and E_{min} decrease first as the L shell

196 increases to ~5, while they suddenly increase on two MLT sectors (15-19, 22-05) at

197 L>5 with relatively small samples. In addition, the statistics of E_{max} and E_{min} show a

198 less geomagnetic activity dependence. The ratios decrease with the increasing L

199 shells, which are smaller under the more active geomagnetic conditions (Figures 4m-

200 o).

201

4. Discussions

Our results show that the reversed proton spectra are preferentially inside the plasmasphere and show significant losses of lower energy (~50 - 100 keV) protons after the geomagnetic storm (Figures 1f-h). It is significant for us to further understand the mechanisms that produce the reversed proton energy spectra. There are several possible explanations for the formation of the reversed proton energy spectra.

Firstly, charge exchange is found to be the main loss process of ring current protons by capturing electrons from neutral atoms (Ebihara & Ejiri, 2003; Dessler & Parker, 1959; Smith & Bewtra, 1976). The lifetime of proton due to charge exchange is shortest at energies around tens of keV with the value of 0.2 – 1 day (Fok et al., 1991). This energy range is consistent with our statistical distributions of E_{min} in reversed proton spectra. Furthermore, the densities of neutral hydrogen are higher at lower L shells (Østgaard et al., 2003). Thus, the loss effect due to charge exchange is stronger at lower L shells. We also find that the reversed proton energy spectra show a high occurrence at low L shells (L=2 - 4). These agreements in spatial distribution suggest that charge exchange plays an important role in the formation of reversed proton energy spectral.

Another candidate for the loss of protons is Coulomb collision (Fok et al., 1996; Jordanova et al., 1996, 1999). When particles travel through the plasma, they will loss energy or change pitch angles due to collisions with other particles. Similar to charge exchange, Coulomb collision also likes to occur in lower L shells (Fok et al., 1991). However, this process is dominant in decreasing the proton fluxes at low-energies (<10 keV) (Fok et al., 1996) and is not likely to produce the reversed proton energy spectra with local minima at energies ~50 - 100 keV.

There are also two collisionless scattering mechanisms for the ring current decay: wave-particle interactions and field line curvature (FLC) scattering. The electromagnetic ion cyclotron (EMIC) waves can effectively scatter several keV to hundreds of keV protons into the loss cone due to pitch angle diffusion with a time

230 scale of a few hours (Cao et al., 2019, 2020; Cornwall, 1977; Jordanova et al., 1997;

231 Xiao et al., 2011; Summers, 2005). The field line curvature scattering is of importance

232 for the ring current decay when the field line configuration is stretching (Chen et al.,

233 2019; Ebihara et al., 2011; Sergeev et al., 1993; Yu et al., 2020). Yu et al. (2020)

234 investigated the role of FLC scattering in ring current decay during the 17 March

235 2013 storm and found that the associated proton precipitation mainly occurs at L > 5

236 on the nightside. This finding is basically consistent with our observations that the

237 reversed proton energy spectra are distributed at L > 5 on two MLT sectors (15-19,

238 22-05). The formation mechanism of reversed energy spectra at L>5 may be different

239 from those at L<5.

240   Although several loss mechanisms have been proposed to explain the decay of

241 Earth's ring current. The relative contributions of difference mechanisms to the

242 formation of the reversed proton energy spectra still remain to be fully understood,

243 which however is outside the scope of this study and is left to a future study.

244

245 **5. Conclusions**

246   In this study, based on the high-resolution proton flux data from RBSPICE

247 onboard the Van Allen Probe B during 2013 − 2016, we have performed a detailed

248 statistical analysis of the global distribution of reversed energy spectra of ring current

249 protons. The major conclusions are summarized as follows:

250   (1) The reversed proton energy spectra are preferentially observed inside the

251 plasmasphere, with the occurrence rates > 90% at L ~ 2 - 4 during geomagnetically

252 quiet periods. As the geomagnetic activity intensifies, the preferential occurrence

253 region of the reversed proton energy spectra shrinks to lower L shells (~2.5 - 3.5).

254   (2) The proton energies corresponding to the flux maxima and minima of the

255 reversed energy spectra decrease with the increase of L shell in the region of L < 5.

256 The flux minima of the reversed proton spectra mainly occur at ~50 - 100 keV, while

257 the flux maxima are generally present at ~200 - 400 keV.

258   (3) Similar to the global distribution of the reversed spectrum occurrence rate,

the ratios between flux maxima and minima are strongly L shell and geomagnetic activity dependent, showing that the ratios during active times and at higher L shells are smaller than those during quiet times and at lower L shells.

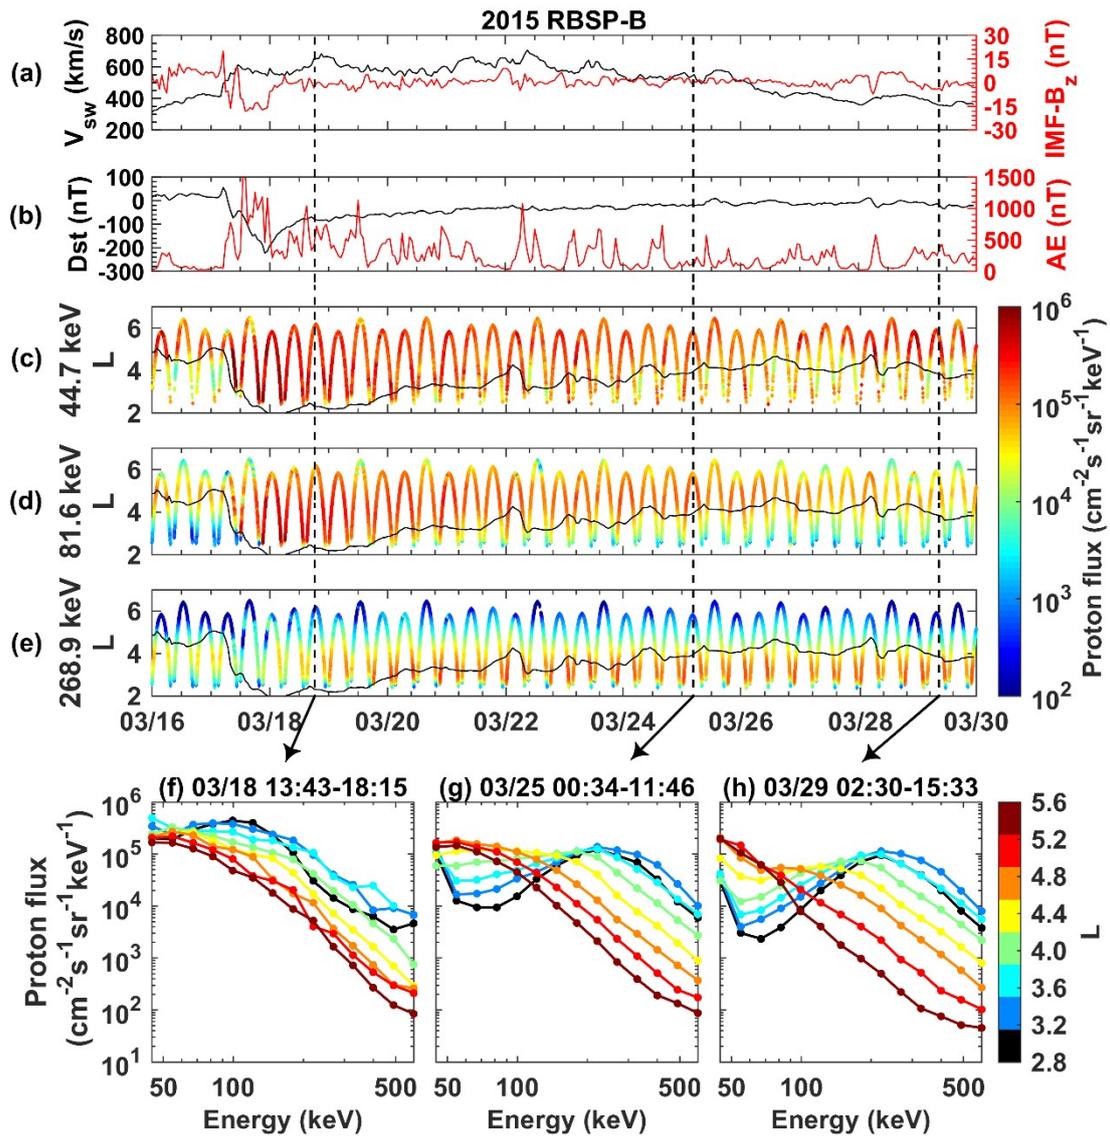

Figure 1. An overview of the 17 March 2015 strong geomagnetic storm. (a) solar wind speed (V_{sw}) and interplanetary magnetic field (IMF) B_z, (b) Dst and AE indices, (c-e) 90° pitch angle proton fluxes at energies of ~44.7 keV, ~81.6 keV, and ~268.9 keV, respectively, with the black solid lines indicating the plasmapause location. (f-h) The proton energy spectra at L ~ 2.8 - 5.6 during three indicated time intervals of the storm.
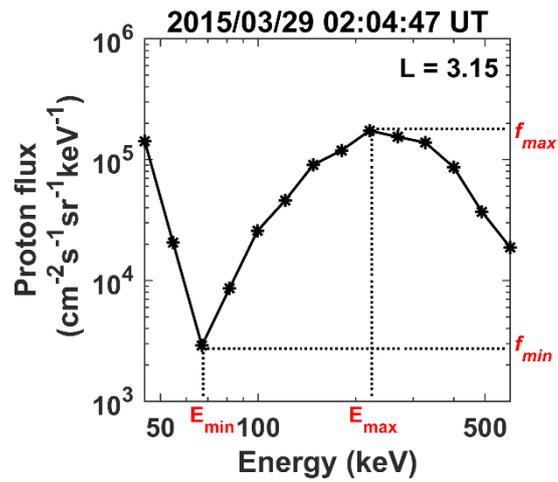

Figure 2. A representative example of the reversed proton energy spectrum at L = 3.15 based on the RBSPICE measurements at 02:04:47 UT on 29 March 2015. Four characteristic parameters of the reversed energy spectrum, i.e., flux maximum (f_{max}), flux minimum(f_{min}), the energy of flux maximum (E_{max}), and the energy of flux minimum (E_{min}), are defined on the plot.
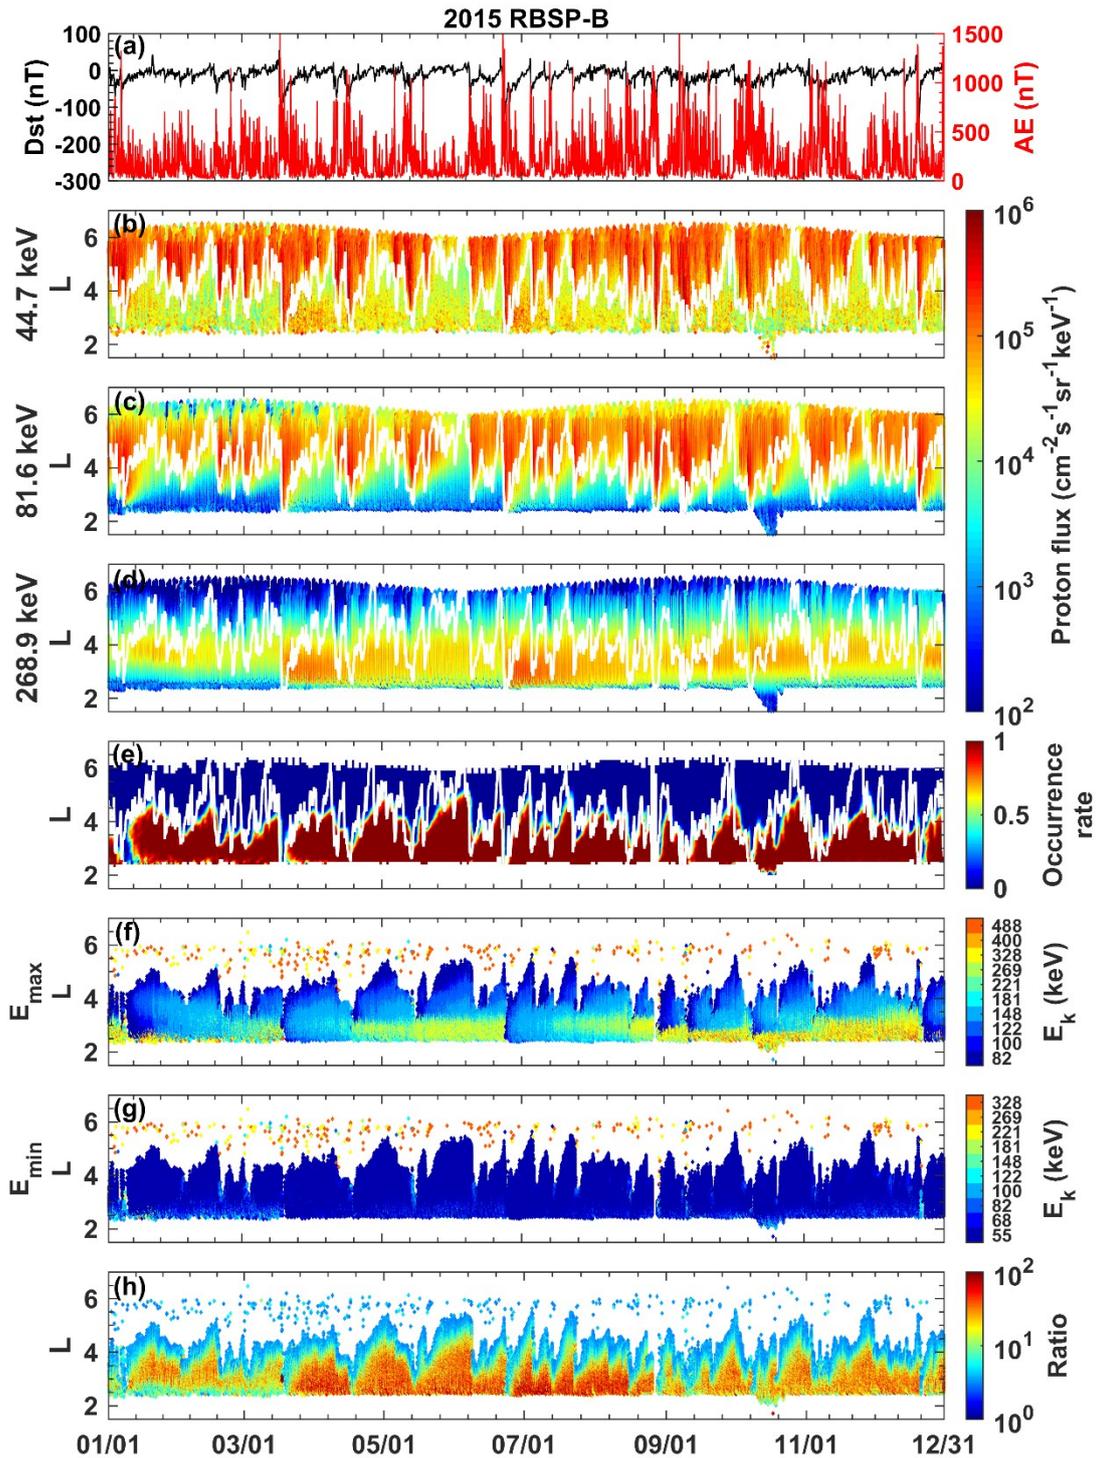

Figure 3. RBSPICE observations of proton fluxes during 2015 and the corresponding distributions of reversed proton energy spectra. (a) Dst and AE indices, (b-d) 90° pitch angle proton fluxes at energies of ~44.7 keV, ~81.6 keV, and ~268.9 keV, respectively, (e) occurrence rate of the reversed proton energy spectrum, (f) the proton energy of flux maximum, (g) the proton energy of flux minimum, and (h) the ratio of proton flux maximum to minimum. The white solid lines in (b-e) indicate the plasmapause location.
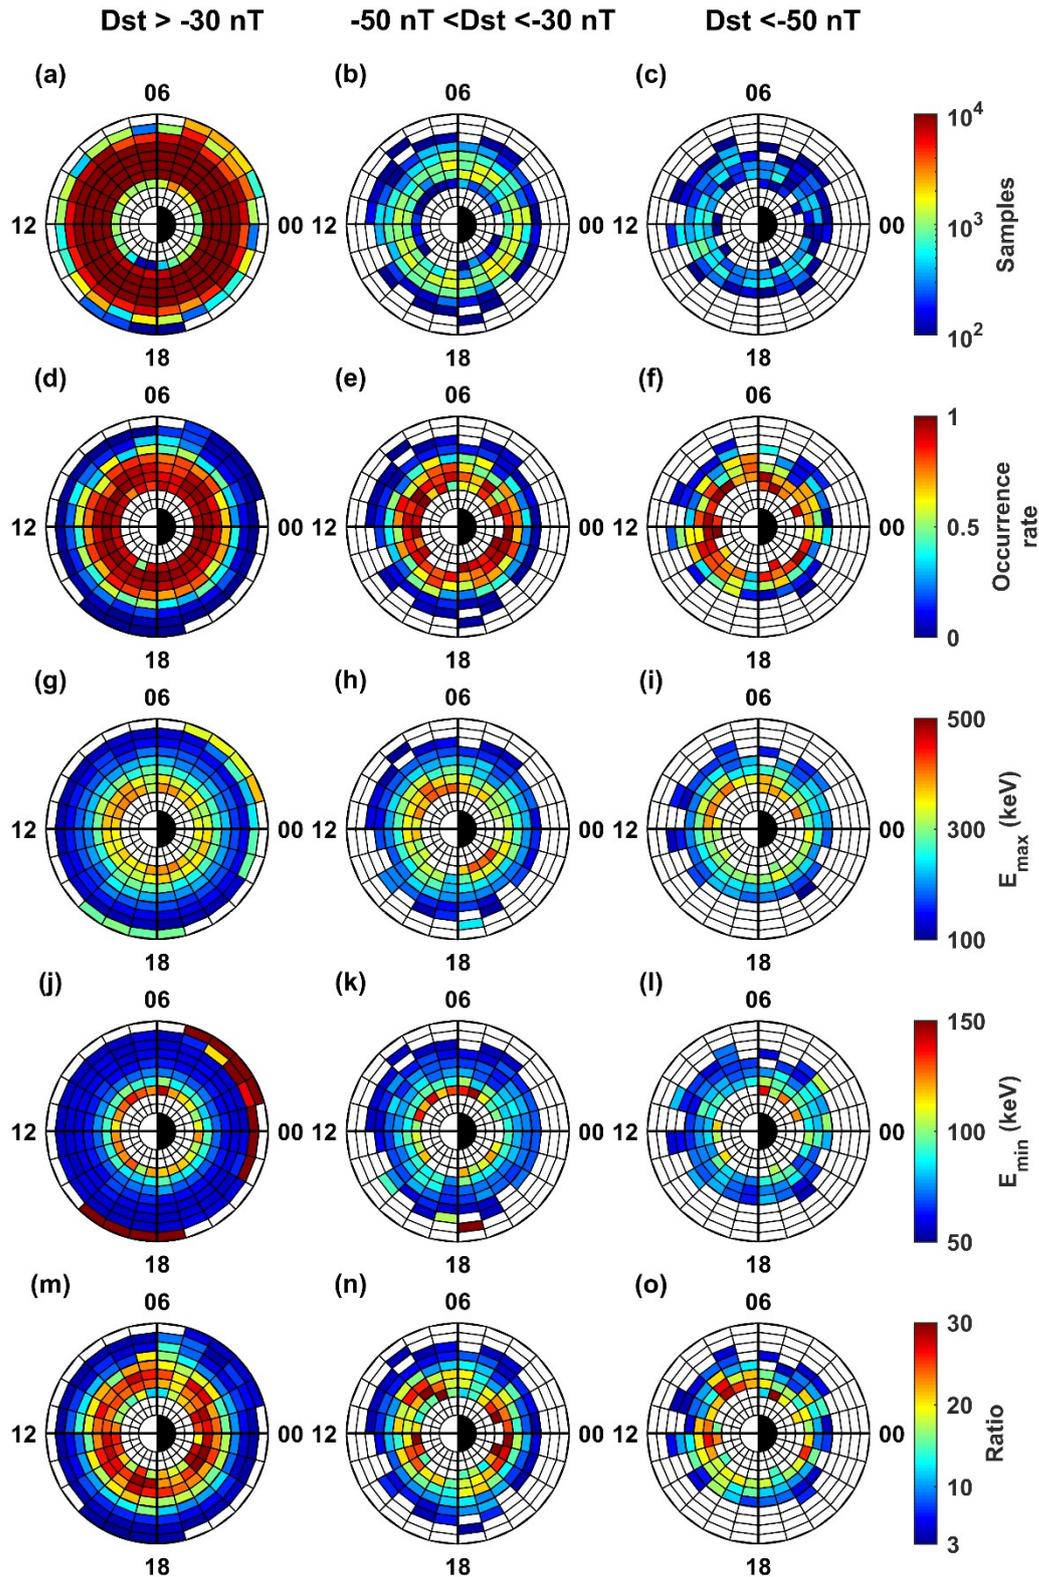

Figure 4. Statistical results of the global distribution of reversed proton energy spectrum during 2013-2016 under the indicated three geomagnetic conditions (from left to right: Dst > -30 nT, -50 nT < Dst < -30 nT, and Dst < -50 nT). (a-c) samples, (d-f) occurrence rate, (g-i) the proton energy of flux maximum, (j-l) the proton energy

392   of flux minimum, and (m-o) the ratio of the proton flux maximum to minimum.
