**Key Points:**

- Maximum poleward shift (~11°) of EIA crests was observed between ~15°W-5°W Glon

- Reversed C-shape Equatorial Plasma Bubbles (EPBs) extended to ~$\pm$36° Mlat (~40°N and ~30°S Glat) with apex altitudes reaching ~4000 km

- Shear in EPBs zonal drifts is formulated as a function of magnetic apex heights based on their tilts.

**Key Words:** NASA GOLD mission, Geomagnetic storm, Equatorial Ionization Anomaly, Equatorial Plasma Bubble, Nighttime ionosphere, Extreme EPB, Super Plasma Bubbles

## Abstract

A coronal mass ejection erupted from the Sun on 21 April 2023 and created a G4 geomagnetic storm on 23 April. NASA's Global-scale Observations of the Limb and Disk imager observed bright Equatorial Ionization Anomaly crests at ~25° Mlat, ~11° poleward from their average

27    locations, computed by averaging the EIA crests during the previous geomagnetic quiet days (18

28    to 22 April) between ~15°W-5°W Glon. Reversed C-shape Equatorial Plasma Bubbles were

29    observed reaching ~$\pm$36° Mlat (~40°N and ~30°S Glat) with apex altitudes ~4000 km and large

30    westward tilts of ~52°. Using GOLD's observations EPBs zonal motions are derived. It is observed

31    that the EPBs zonal velocities are eastward near the equator and westward at mid-latitudes. Model-

32    predicted prompt penetration electric fields indicate that they may have affected the postsunset

33    pre-reversal enhancement at equatorial latitudes. Zonal ion drifts from a defense meteorological

34    satellite program satellite suggest that westward neutral winds and perturbed westward ion drifts

35    over mid-latitudes contributed to the observed latitudinal shear in zonal drifts.

36

37    **Plain Language Summary**

38    A severe geomagnetic storm occurred on 23 April 2023. The effects of the storm on the nighttime

39    equatorial and mid-latitude ionosphere are investigated using NASA's Global-scale Observations

40    of the Limb and Disk measurements. GOLD observed bright, widely separated Equatorial

41    Ionization Anomaly crests between ~15°W-5°W Glon. Extreme Equatorial Plasma Bubbles

42    reaching mid latitudes at ~40°N and ~30°S Glat with apex altitudes of ~4000 km at the magnetic

43    equator were observed over these longitudes. The EPBs velocities were eastward at low latitudes,

44    between the EIA crests, and reversed to westward near mid-latitudes. At mid-latitudes EPBs

45    showed westward tilts that were larger than previous observations during similar geomagnetic

46    conditions.

47

48    **1 Introduction**

49        The Equatorial Ionization Anomaly (EIA), also referred to as the Appleton Anomaly, is a

50    consistent ionospheric feature at equatorial and low latitudes (Appleton, 1946). It's caused by

51    interactions between equatorial F region eastward electric fields and horizontal northward

52    magnetic fields, resulting in an upward drift over the magnetic equator. This vertical drift causes

53    the ionospheric plasma to ascend to higher altitudes and diffuse along magnetic field lines towards

54    lower latitudes, a phenomenon known as the fountain effect (Hanson and Moffet, 1966).

55    Consequently, the plasma density exhibits a double-peaked structure in the latitudinal distribution

56    of the F region, with two maxima around 15°-20° north and south of the magnetic equator and a

57    minimum at the equator. This distinctive pattern, characterized by crests on each side and a trough

over the magnetic equator, defines the EIA. In the same ionospheric region, Equatorial Plasma Bubbles (EPBs) are also observed. Following sunset, the lower side of the ionosphere undergoes faster recombination due to increased ion-neutral collision frequencies compared to the upper side. Additionally, the equatorial vertical drift increases shortly after sunset, known as the Pre-Reversal Enhancement (PRE), causing an upward movement of the ionosphere. This results in a sharp gradient in electron density, leading to the Rayleigh-Taylor Instability (RTI). Perturbations in depleted or enhanced density at the bottom side of the ionosphere move upward or downward, respectively (Kelley, 2009). These depleted plasma density regions, or depletions, alter vertical electron density distributions, giving rise to plasma irregularities known as equatorial plasma bubbles (EPBs) in airglow ionospheric images.

The characteristics and variations of the EIA depend on several factors, including neutral winds, tides, electric fields, magnetic declination, PRE, ion production and loss rates, and the subsolar point location (Eastes et al., 2023 and references therein). EPBs are linked to factors like neutral winds, electric fields, conductivities, and plasma density, as noted in Karan et al., (2020, 2023b). Geomagnetic disturbances alter the above factors affecting the EIA and EPBs, causing changes in their characteristics.

Geomagnetic storms alter winds and electric fields through prompt penetration electric field (PPEF) (Kelley et al., 2003) and disturbance dynamo electric fields (DDEF) (Blanc and Richmond, 1980; Fejer et al., 1979), thereby changing the EIA morphology (Abdu et al., 1991, 1995; Balan et al., 2018). Sometimes during nights, the electron density in the EIA crests latitudes increases due to the penetration of an eastward disturbance electric field (Takahashi et al., 1987; Balan et al., 2018). Furthermore, storm-generated equatorward winds can move up ionospheric layers to higher altitudes, where recombination occurs more slowly, resulting in larger EIA peak densities that decay more slowly (Lin et al., 2005). During storms, the EIA may expand polewards, displacing the crests to mid-latitudes. Karan et al., (2023a) observed an 8º-10º poleward shift of post-sunset EIA crests during a storm, attributed to an enhanced PRE driven by an increase in eastward PPEF, corroborated by ionosonde measurements that showed an increase in the height of the peak electron density, hmF2.

Like the changes in the EIA's behavior during geomagnetic storm time, EPB's occurrence and morphology are also impacted. Geomagnetic storms can either promote or hinder the formation of EPBs (Aarons et al., 1991; Abdu et al., 1995; Cherniak & Zakharenkova, 2022; Martinis et al., 2005; Kil et al., 2016; Patra et al., 2016). During some storms, the PRE is intensified, causing EPBs to ascend to higher apex altitudes with field lines reaching latitudes around ~30-40$^\circ$ Mlat (Aa et al., 2018, 2019; Martinis et al., 2015; Rajesh et al., 2022; Huba et al., 2023; Sousasantos et al., 2023). In the equatorial F region during geomagnetically quiet conditions, the nighttime zonal plasma motion is eastward, but it is slower at higher and lower altitudes. This causes the EPBs to move slower at higher and lower apex altitudes. Thereby, the EPB appears to be a reversed C-shaped (Karan et al., 2020; 2023a; Kil et al., 2009; Martinis et al., 2003; Zalesak et al., 1982). Using data form an all-sky imager at Ascension Island (~14$^\circ$W Glon, ~8$^\circ$S Glat, ~18$^\circ$S Mlat), Mendillo and Tyler (1983) formulated a relationship between the EPBs westward tilt and the local time, showing that the tilt increased as the night progressed. During geomagnetic storms the wind pattern changes, causing changes in the shape of EPBs. Zonal drifts of the plasma at low and mid latitudes can become westward due to the westward neutral winds (Sutton et al., 2005), equatorward expansion of subauroral ion drifts (Ferdousi et al., 2019), or the influence of traveling ionospheric disturbances (TIDs) (Aa et al., 2019). These westward drifts of plasma can increase the EPBs' westward tilt, but this has not been quantified under perturbed geomagnetic conditions.

In this work, we investigated the poleward expansion of EIA and reversed C-shape EPBs extending to mid-latitudes between ~15$^\circ$W-5$^\circ$W Glon during the 23 April 2023 geomagnetic storm, using NASA's Global-scale Observations of the Limb and Disk (GOLD) images. Relationships between the EPB's zonal drifts with apex altitudes are established.

**2 Data**

This study utilizes nighttime partial disk images from the GOLD imager, situated in a geostationary orbit at 47.5$^\circ$W, featuring two identical and independent channels (A and B, CHA and CHB hereafter), capturing FUV wavelengths (~132-162 nm). Nominal operations and observations commenced on 9 October 2018. The primary objectives of GOLD are twofold: (i) to investigate the response of Earth's ionosphere-thermosphere system to geomagnetic storms, solar

120 activity, and atmospheric waves, and (ii) to explore the formation and development of ionospheric

121 plasma irregularities. GOLD measures the emission rate integrated along the line of sight. One of

122 GOLD's strengths is its ability to observe the longitudinal regions of the South America, the

123 Atlantic, and Western Africa, offering a unique opportunity to observe the spatial-temporal

124 evolution of various features of the ionosphere and thermosphere that are visible to GOLD. It

125 conducts entire disk observations, limb scans, and occultations which have resulted several

126 interesting findings about the ionospheric and thermospheric behavior during different geophysical

127 conditions (Aa et al., 2022; 2023; Aryal et al., 2023; Cai et al., 2023; Gan et al., 2023; Laskar et

128 al., 2024; ). The instrument and its observations are detailed in Eastes et al., (2017, 2019, 2020)

129 and McClintock et al., (2020). The nighttime OI 135.6 nm emission is produced by recombination

130 of atomic oxygen ions and electrons in the Earth's ionosphere. Since the emission rate varies

131 approximately as the square of the electron density, it maximizes at the peak F layer which is

132 assumed to be 300 km. GOLD takes images across the American, Atlantic, and West African

133 longitudinal sectors between 19 and 22 LT.

134

135 Solar wind parameters, geomagnetic indices, and modeled equatorial ionospheric eastward

136 electric field (EEF) (Manoj and Maus, 2012) are used to provide context for the GOLD

137 observations. The EEF is continuously forecasted in real-time by leveraging solar wind data from

138 the Deep Space Climate Observatory (DSCOVR) and NASA/ACE spacecraft, sourced through

139 NOAA's Space Weather Prediction Center. Employing a transfer function model, the application

140 predicts EEF fluctuations based on solar wind data, while incorporating a climatological model to

141 accommodate variations in EEF during quiet days. Zonal ion drifts from a Defense Meteorological

142 Satellite Program (DMSP) satellite are compared with GOLD-inferred EPB zonal drifts.

143

144 **3 Results**

145 Figure 1 presents GOLD observations of the EIA and EPBs on the storm night, 23-24 April

146 2023. Images are selected to cover all the longitudes and to avoid repetition at similar longitudes.

147 All the images during 23 April 20:10 UT to 24 April 00:25 UT are available as Movie-M1 in the

148 supporting information. The images in the top row (panels A-D) illustrate that the EIA crests are

149 brighter, and EPBs, represented by dark bands extending through the EIA crests, are observed at

longitudes to the east of ~ 30° W, while no EPBs are seen to the west of ~30° W (panels E-H). All the EPBs exhibit significant westward tilts on both hemispheres.

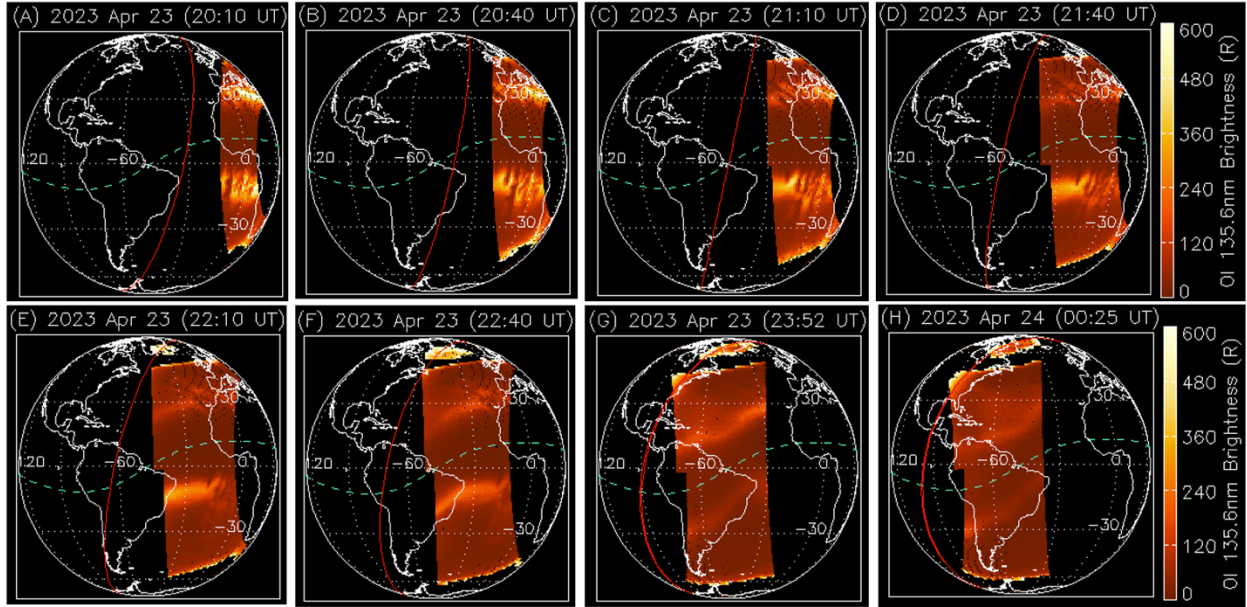

Figure 1. Nighttime 135.6 nm images captured by the GOLD imager on April 23-24, 2023. Highlighted are selective images covering all longitudes monitored by GOLD. The dashed green line and solid red line represent the geomagnetic equator and the sunset terminator, respectively.

The geomagnetic conditions on 22-23 April 2023 are shown in Figure 2. Solar wind parameters are in panels A (magnetic field IMF Bz and electric field IEF Ey) and B (solar wind proton density and speed). Panel C displays the equatorial geomagnetic index (SYM-H). The thick red line at the bottom of panel C indicates the times of GOLD's observations. The main phase of the storm commenced around 09:00 UT on 23 April and persisted until ~05:00 UT, when SYM-H reached a minimum value of ~ -220 nT. About 11 hrs after the initiation of the main phase, GOLD nighttime observations started as the SYM-H reached a minimum value of ~175 nT. At about 18 UT, Bz changed suddenly (density and speed also changed), reaching ~22 nT and maintaining this level for ~2 hrs. The 18-20 UT time range corresponds to post-sunset times in the longitudes ~15°W-5°E. These conditions led to the penetration of an E-field into equatorial latitudes.
Figure 2. Solar wind parameters and geomagnetic indices on 23-24 April 2023. (A) IMF Bz and IEF Ey; (B) proton density and plasma flow speed, and (C) Sym-H. The thick horizontal red line indicates the timing of GOLD observations.

167

168     To investigate the geomagnetic storm's effect on the EIA crests latitude values, we

169     obtained the crests latitudes on the storm night (23-24 April). GOLD's captured images are

170     transformed into quasi-dipole geomagnetic coordinates, using the International Geomagnetic

171     Reference Field scalar potentials. These remapped images allow us to analyze variations in

172     brightness at 135.6 nm concerning magnetic latitudes, spaced at 2° magnetic longitude intervals.

173     Peaks in brightness along latitudinal variations indicate the positions of EIA crests. By applying

174     this approach to all images, we derive the latitudes of the EIA crests. Subsequently, we calculate

175     the average and standard deviation of the latitudes for both the North (N) and South (S) crests

176     which is shown in Figure 3 panel A. This methodology is detailed in the work by Eastes et al.

177     (2023). Larger standard deviations, particularly near ~15°W, are a result of increased uncertainties

178     during the calculation of EIA crests locations in the presence of EPBs. The red and blue solid lines

179     indicate the average EIA crests latitudes during the previous geomagnetic quiet days (18 to 22

180     April). On the storm night, the EIA crests extended furthest between ~15°W-5°W Glon, with the

181     N and S crests at ~27° and ~25° Mlat, respectively. Panel B illustrates the differences between the

7

182    storm night EIA crest latitudes and the quiet time average values. Maximum poleward shifts of

183    ~11° and 9° in the N and S EIA crests were observed between ~15°W-5°W Glon.

184

Figure 3. (A) EIA crests latitudes, North (red) and South (blue). 23 April shown as dashed lines and quiet time average as solid lines; (B) Relative shifts in EIA crests latitudes on 23 April 2023 compared to quiet time average with uncertainties.
185

186

Figure 4. (A), (B), (C) combined CHA (N-hemisphere) and CHB (S-hemisphere) images at 20:10, 21:10, and 22:10 UT, respectively.

187

188    Panels A, B, and C in Figure 4 show the combined CHA and CHB images in quasi-dipole

189    (QD) coordinates (Laundal and Richmond, 2017) at 20:10, 21:10, and 22:10 UT, respectively,

190    encompassing seven EPBs (marked as B1 to B7) observed during this night. These EPBs exhibit

191    a westward tilt relative to the magnetic meridian and extend poleward through and beyond the EIA

192    crests. The foot points of B3 and B4 (indicated by white and cyan '+' symbols, respectively)

193    extended beyond $\sim\pm36^\circ$ Mlat ($\sim40^\circ$N and $\sim30^\circ$S Glat) (panels 4B and 4C), implying structures

194    with apex altitudes exceeding $\sim4000$ km. Magnetic field lines were traced using the IGRF-13

195    model (Alken et al., 2021). EPB B2 appeared to merge with B3 at latitudes beyond the EIA crest

196    (panel 4C). The time sequence of the behavior of EPBs is shown as a movie Movie-M2 in the

197    supporting information. All seven EPBs were situated within $\sim15^\circ$W-$0^\circ$ Glon ($\sim60^\circ$ to $75^\circ$ Mlon).

198    For a clear view of EPB locations near the magnetic equator, where the brightnesses were lower

199    compared to the EIA crests, panels 4A-C were replotted with a lower brightness scale in Figure

200    S1 in the supporting information. The bubbles separation at the equator was $\sim5^\circ$, which increased

201    to $\sim8^\circ$ at the EIA crests latitudes.

Figure 5. (A), (B), (C) longitudinal variations of normalized brightness obtained at different times as keograms for $30^\circ$-$20^\circ$S, $7^\circ$S to $7^\circ$N and $20^\circ$-$30^\circ$N latitude ranges, respectively.

202

203         The westward tilt angles of B2 and B3 at 22:10 UT are $\sim42^\circ$ at $\sim16^\circ$ Mlat, and $\sim52^\circ$ at $\sim30^\circ$

204    Mlat. These tilts can be related to altitudinal/latitudinal shears in the zonal plasma drifts. Thus, we

205    tracked the EPBs drifts at several latitudes. The method for deriving EPBs' drift velocity is detailed

206    in Karan et al., (2020). EPBs were moving eastward near equatorial and low latitude regions and

207    westward at latitudes higher than $\sim\pm20^\circ$ Mlat. Keograms in Figure 5 illustrate this behavior. Three

208    magnetic latitude ranges, $30^\circ$-$20^\circ$S, $7^\circ$S-$7^\circ$N, and $20^\circ$-$30^\circ$N were selected. In an image (at a fixed

209    UT), within $30^\circ$-$20^\circ$S latitude range, the brightness at each longitude is averaged to obtain the

210    longitudinal variations of the brightnesses at that UT. To enhance visibility of the EPBs against

211    the varying background brightness, the brightness array was normalized to a maximum of 1. This

212 process was repeated for all the images, and the results were coplotted as a keogram in panel 5A.

213 Same method is followed to obtain keograms for 7°S-7°N and 20°-30°N, shown in panels 5B and

214 5C, respectively. Different time gaps between the longitudinal stamps in the keograms are due to

215 varying latitudinal coverage of the images. EPBs longitudinal shifts are shown by red arrows

216 (drawn by hand to aid viewer's eyes). The average zonal drifts of all EPBs during the observation

217 periods is $120\pm15$ m/s eastward within the 7°S-7°N latitudes (panel 5B), whereas within the

218 latitude range of 20°-30°N and 30°-20°S, they reversed and are $70\pm3$ and $85\pm4$ m/s westward,

219 respectively.

220

221 **4 Discussion**

222 On 23 April 2023, we observed maximum poleward shifts of ~11° in the northern and ~9°

223 in the southern hemisphere EIA crests in between ~15°-5°W Glon. In the same longitude sector,

224 reversed C-shape EPBs extending poleward beyond ±36° Mlat (~40°N and ~30°S Glat) were

225 detected. The poleward shifts of the EIA crests are similar to the ones reported by Karan et al.,

226 (2023a) at a larger longitude range of ~65°-35°W Glon, during a co-rotating interaction region

227 geomagnetic storm weaker than the coronal mass ejection one on 23 April 2023. The ionospheric

228 response in that study showed that the peak altitude of the ionospheric hmF2 layer increasing over

229 those longitudes. The number of EPBs also increased, as on 23 April 2023, but now the

230 morphology shows extreme characteristics.

231

Figure 6. (A) Sym-H index in black and d(Sym-H)/dt in green during 12 to 24 UT on 23 April; (B) modeled total zonal electric field (black), PPEF (red), and quiet time electric field (blue) at 15°W Glon on 23 April.

232

233      The maximum poleward shifts of the EIA crests latitudes in between ~15°-5°W Glon

234    (Figure 3) is likely due to an enhanced PRE (Abdu et al., 1991; Balan et al., 2018), This

235    enhancement could be due to a penetration electric field. Sym-H and its rate of change, d(Sym-

236    H)/dt, are shown in panel A of Figure 6. The rate of change of Sym-H showed a large negative

237    excursion at ~18:30 UT with a maximum value of ~ -12 nT/5 min (~ -144 nT/hr). The sudden

238    increase of IEF Ey at ~18UT (panel 2A) and the sharp decrease in Sym-H at ~18-19 UT suggest a

239    prompt penetration of an eastward electric field into the equatorial and low latitudes at this dusk

240    sector (~15°W Glon) due to under-shielding conditions (Fejer et al., 1979; Kelley, 2003; Martinis

241    et al., 2005). In the absence of electric field measurements over this longitude sector, the electric

242    field model developed at Geomagnetism, CIRES (Cooperative Institute for Research in

243    Environmental Sciences) (Manoj and Maus, 2012) was used. This model has been applied in other

244    studies (Aa et al., 2019; Karan et al., 2023a; Spogli et al., 2021). Panel B shows the quiet time,

245    prompt penetration (PPEF), and total electric fields in blue, red, and black lines, respectively. PPEF

246    between ~18:15-20:15 UT contributed to ~2 hr extended PRE (peak value ~0.7 mV/m at ~20 UT).

247    The maximum poleward shift in the EIA crests latitudes observed an hour after the peak PRE could

248    be due to the transport time of plasma from equator to EIA crests (Karan et al., 2016, Karan and

249    Pallamraju, 2020). A zonal electric field of ~0.7 mV/m produces an upward drift of ~32 m/s at this

250    longitude. The PRE duration was ~1hr in the previous quiet days. For the mid latitude EPBs

251    reported by Aa et al. (2019), the model total electric field was 0.9 mV/m with a duration of ~1hr.

252    The longer duration PRE in the present case (~2 hrs) could have enhanced plasma drift shifting

253    the EIA crests further poleward.

254

255      The long-duration PRE is also an important factor for the generation and maximum altitude

256    of the EPBs. At 20:10UT, just one hour after the sunset, GOLD detected a well-developed EPB

257    B3 already reaching an apex altitude of ~2000 km (Panel A in Figure 4). This implies that the

258    EPBs had upward drifts of ~500 m/s, an unusually large value that, has rarely been reported in the

259    past. For example, upward drifts ~1200 m/s were measured by Abdu et al. (2008), between 100-

260    1000 m/s by Aggson et al., (1992), and ~1200 m/s by Hysell (1994). While we have no means to

261    effectively measure the upward drift, some inferences can be made from the poleward motion of

262    EPBs as observed by GOLD. By measuring the poleward motion of B1, B2, B3, and B4 between

263    18°-24° Mlat an average speed of ~130 m/s is obtained, which is similar to ~110 m/s reported in

264 Martinis et al., (2015) who investigated EPBs reaching midlatitudes. This poleward drift can be
265 interpreted as a vertical drift near the magnetic equator with an eastward electric field of ~3.3
266 mV/m. In the present case, the long-duration PRE could have moved the F layer to high altitudes
267 and caused the generation of EPBs with deep density depletion.

Figure 7. Same as Figure 5 (Panels A-C but at 5° latitude ranges. The transition in the EPBs eastward motion at equatorial and low latitudes to westward at mid latitudes can be seen close to ±20° Mlat, between panels B-C and H-I.

268

269 Along with the expansion of the EPBs to higher altitudes/latitudes, their drift directions
270 changed from eastward (near the magnetic equator) to westward (at latitudes higher than ~±20°
271 Mlat) (Figure 5). The latitude where the EPB drifts reversed can be investigated by plotting the
272 keograms in 5° latitude ranges, shown in Figure 7. Panels 7A (10°-15°N) and 7G (10°-15°S) show
273 that, at ~ 22 UT EPB's longitude shift with time becomes flat when compared to the variation
274 within 7°S to 7°N latitude range (panel 5B). This indicates that the EPBs drifts slowed down from
275 equatorial to low latitude regions. The reverse in EPBs' longitude shift direction with time around
276 ±20° Mlat indicates that EPBs motion changed from eastward to westward close or below this
277 latitude.

278

279 The reduction and reversal of eastward drifts from low to midlatitudes has usually been
280 related to ionospheric disturbance dynamo (Blanc and Richmond, 1980; Fejer et al., 1979; Sutton
281 et al., 2005). Recently, Huang et al., (2021) show subauroral polarization streams (SAPS) effects
282 reaching low latitudes. Figure 8 displays the net change (or difference) in zonal ion drifts between
283 the storm and a quiet day (22 April), used as reference, as measured by DMSP F17. Panel 8a shows
Figure 8. (a) Difference zonal ion drifts measured by the DMSP F17 satellite at ~18:30 LT considering April 22 as a reference and (b) Latitudinal profile of the difference zonal ion drifts at 18 and 19 UT.

the difference in zonal ion drifts between 23 and 22 April. DMSP F17 observations at 18:30 LT at certain longitudes is interpolated for other UTs. Panel 8b shows the values at 18 and 19UT, which correspond to longitudes ~7.5°E and ~7.5°W on Apr 23, where westward tilted EPBs were observed. On the storm day, reductions of the zonal ion drifts ~30 m/s, ~60 m/s, and ~100 m/s at ~0°, ~15°, and ~30° Mlat, respectively, were observed. The westward drifts of ~800 m/s and ~500 m/s at subauroral latitudes of ~55° N and ~55° S indicate SAPS effects, potentially penetrating to middle and low latitudes, contributing to the westward drifts measured. Utilizing GOLD observations, we calculated the difference in EPBs' zonal drifts between 23 and 22 April. A reduction of ~90 m/s in EPBs' zonal drifts was identified at ~15° Mlat and ~7°W Glon (location of B3) around 19 UT, result that is similar with the DMSP reduction observed at ~15° Mlat (60 m/s). Thus, the reversal of EPBs' zonal drifts, transitioning from eastward at low latitudes to westward at middle latitudes, as observed by GOLD, agrees with the latitude profile of the difference in zonal plasma drifts measured by DMSP.

299  As mentioned earlier, the EPBs appeared as reversed C-shape structures, related to their

300  westward tilts. GOLD measures EPBs in a latitude and longitude plane, off the magnetic equator,

301  at a fixed height of 300 km. Focusing on bubble B3 the tilt seems to change with latitude. At 22:10

302  UT around 35°N Glat (~30° Mlat) and 25°N Glat (~16° Mlat) the tilts are ~52° and ~42° westward.

303  Considering that the magnetic declination at these locations are ~5° and 1.5°, then B3 is tilted ~47°

304  and ~40.5° with respect to (w.r.t.) the magnetic meridian. Bubble B2 shows a tilt of 40°, or ~37°

305  w.r.t. the magnetic meridian.  In comparison, the westward tilt w.r.t. magnetic meridian from Aa

306  et al., (2019) were ~25° and ~11° at similar magnetic latitudes and from Martinis et al., (2015), it

307  was ~22° at ~30° Mlat. Geomagnetic conditions were similar, with Sym-H reaching ~ -110 nT in

308  these studies. Because EPBs exhibit a plasma flux-tube nature along the magnetic field lines, an

309  alternative method for measuring tilt involves mapping them into the magnetic equatorial plane.

310  This representation depicts an EPB in an altitude-magnetic longitude plane, where altitude

311  corresponds to the field line's apex height, and is linked to the magnetic latitude at the field line's

312  footpoint. In this plane, B3 reaches ~36° Mlat with a break or kink in the shape of the bubble

313  between ~24-25 ° Mlat. The westward tilt for the upper portion of B3 is ~25 ° and for the lower

314  part ~32 °. B2 reaches ~25° Mlat with a westward tilt of ~34°.

315

316  Mendillo and Tyler (1983) (M&T) used this approach to quantify the EPBs westward tilt

317  (W) as a function of local time as observed from Ascension Island using ground-based imaging.

318  The apex altitudes they observed ranged from 400-1200 km.  For the relatively geomagnetic quiet

319  conditions prevalent during their observations, they found:

320           $W = 0.15 (LT-18.3)$                                    (1)

321  W is the westward shift in degrees of magnetic longitude per 100 km in apex altitude. Applying

322  this formula to EPBs B2 and B3 of Figure 4, we obtain W = 0.43. Expressed as the angle between

323  the orientation of the EPB and the magnetic meridian, this becomes 23°.

324

325  We next compare this result with the measured tilt values of B2 and B3. At 20° Mlat B3

326  has $W_{B3l} = 0.63$ (corresponding to a tilt angle of 32°), while at 30° Mlat B3 has $W_{B3u} = 0.47$

327  (corresponding to 25°). For B2, which does not extend much past 25° Mlat, $W_{B2} = 0.67$

328  (corresponding to 34°). Since the GOLD observations occurred during a geomagnetic storm, it is

329  not surprising that the westward tilts exceed those observed by M&T. Both studies found EPBs

with westward tilts. Under storm conditions, however, we observe nighttime zonal drifts at low and mid latitudes that display a reduction or even a reversal of the typical eastward motion to westward. Consequently, EPBs observed during storm conditions may exhibit a more 'compressed' reversed C-shape, which is precisely what GOLD is measuring.

If the westward tilt increases linearly following equation (1), M&T obtained an expression for the altitude dependence for an effective westward drift, or reduction in the overall eastward drift, V'(h) as

$$V'(h) = 0.0464(1+h/R_E) \qquad (2)$$

Where 0.0464, in (m/s)/km units, is the product of the slope, 0.15 (measured in degrees of magnetic longitude per 100 km vertical height) from (1), and a constant 0.31 (result of geometric factors used in the calculation). At 300 km V'(300) = 0.049 m/s/km. This value represents the shear in altitude of the zonal drifts from a height of 300 km. An eastward drift at 700 km apex height (12.5$^o$ Mlat) would lag the drift at 300 km by 0.049*(700-300) ~ 20 m/s. Using an imager with a field of view of ~ 47$^o$ located in Maui, Hawaii, Makela and Kelley (2002) applied the M&T approach to EPBs and obtained an average shear value of 0.05 m/s/km. But when they calculated the shear by computing the velocities obtained at each height, a value of 0.1 m/s/km was obtained. This discrepancy was not explained.

Figure 9 shows the calculated EPBs' average zonal drift velocities for each of the latitude ranges (as shown in Figure 7) as a function of apex altitudes (or magnetic latitudes). Figure 7c shows that the reverse in EPBs longitude shift direction with time occurred around ±20$^o$ Mlat. about 22 UT. So, EPBs westward drifts after 22 UT is considered for this latitude range. Below ~1500 km apex height the larger slope (compared to heights above 1500 km) indicating a faster decrease (with latitudes) in the drift speeds. The average zonal drifts of the EPBs at apex altitudes close to 300 km (magnetic equator), 700 km, and 1000 km, are 120 m/s, 62 m/s, and 25 m/s, respectively. The transition from eastward to westward drift occurs around 1000 km (17.5$^o$ Mlat). According to (2) the transition height (where the lag is equal to ~120 m/s) should occur at ~2750 km, much higher than the height observed. Like the underestimation in the westward tilt W from (1), V' is also showing a weak altitude variation.
Figure 9. EPBs' average zonal drifts (m/s) for each latitude ranges (shown in Figure 7) with corresponding apex altitudes are shown. The transition from east to west occurred at ~1200 km (~20º Mlat).

362　　　　The shear V'(300 km) for the GOLD data can be obtained from the slope of the fitted line

363　　to the data between 300 to 1500 km, shown in Figure 9. This slope is V'$_{GOLDl}$ = 0.179 m/s/km.

364　　This shear can also be obtained by considering the average westward tilt of the EPBs measured in

365　　GOLD images. The westward tilt W$_{GOLD}$ at 20º Mlat can be calculated as the shift in magnetic

366　　longitude (5º) divided by the extent of the bubble (920 km), equal to – 0.63. When this value is

367　　multiplied by 0.31, a shear of 0.195 m/s/km is obtained, close to the slope of the fitted curve in

368　　Figure 9. This result indicates a good agreement between the shears obtained by the two methods,

369　　something that was not observed in the Makela and Kelley (2003) study.

370

371　　　　With these new shear values (0.179 and 0.195), drifts at 1000 and 1500 km will lag the

372　　drift at 300 km by 112 (136) m/s and 192 m/s (234), respectively. The drifts at these heights will

373　　be 8 (-12) m/s and -70 (-114) m/s. The transition from eastward to westward occur at the observed

374　　height range of ~1000-1100 km. The upper part of B3 shows a different shear V'$_{GOLDu}$ = 0.026

375　　m/s/km, so the height variation of the drifts is weaker, as seen in Figure 8. We can summarize the

376　　results that relate westward tilts and height variation of zonal drifts of B3 as:

377　　W$_{GOLDl}$ = 0.63

$$\text{Vel}_l = 185 \text{ m/s} - 0.179 \text{*h} \quad \text{for } h < 1500 \text{ km} \quad (3)$$

and

$$W_{\text{GOLDu}} = 0.47$$
$$\text{Vel}_u = -57 - 0.026 \text{*h} \quad \text{for } h > 1500 \text{ km} \quad (4)$$

Therefore, we obtained average expressions for the westward tilt and zonal drifts as a function of apex height. At lower altitudes, below ~1500 km, the height variation of zonal drifts is large, but above ~1500 km it proceeds at a smaller rate, but large westward drifts are measured. This indicates a different response of the ionosphere at low latitudes when compared to mid latitudes. One important point about the calculated drifts to note is that while geolocating the pixels if the height is 600 km rather than 300 km, then the derived velocity changes by < 5% which is not large enough to invalidate our conclusions.

## 5 Summary

This paper investigated the EIA and EPB characteristics as observed by the NASA GOLD imager during the 23 April 2023 geomagnetic storm. The perturbed geomagnetic conditions prevailing on that night were responsible for the emergence of EPBs characterized by significant westward tilts and substantial latitudinal shears in the zonal drift velocities. The key findings are:

(i) Maximum (~11º) poleward shifts of both EIA crests latitudes and reversed C-shape EPBs were observed at ~15º-5ºW Glon. A modeled eastward PPEF lasted for ~2hrs and extended the PRE, moving plasma to higher latitudes.

(ii) EPBs reached beyond ±36º Mlat (~40º N and ~30ºS Glat), implying structures with apex altitudes exceeding ~4000 km. EPBs showed westward tilts of ~52º at ~30º Mlat and ~42º at ~16º Mlat, higher than previously reported cases under similar geomagnetic conditions.

(iii) EPBs zonal drifts showed a strong latitudinal shear, with eastward drifts of 120±15 m/s over equatorial latitudes and westward drifts of 70±3 m/s at N and 85±4 m/s at S EIA crests.

(iv) Inferred poleward drifts obtained by GOLD images were used to estimate an effective eastward electric field of ~3.3 mV/m near the magnetic equator.

410    (v)    The reversal of EPBs' zonal drifts as observed by GOLD, agrees with the latitude
411           profile of the difference in zonal plasma drifts measured by DMSP.

412    (vi)   We obtained expressions for the westward tilt of EPBs and the apex height (or magnetic
413           latitude) dependence of their zonal drifts. Results show a linear variation up to ~1500
414           km (~22.5° Mlat), with smaller shears observed at higher latitudes.
