8 Corresponding author: Giacomo Nodjoumi (g.nodjoumi@jacobs-university.de)

9 **Key Points:**

10 • Instance Segmentation methodology is used to map landforms obtaining vectorial data in geopackage file
11 format.

12 • A newly developed composite toolset to perform the image pre-processing, data labeling, model training
13 and inference tasks, is presented.

14 • The results of a prime case of mapping pit and skylights on Mars surface are showed.

15 **Abstract**

16 Thematic map creation is a process that implies several steps to be accomplished regardless of the type of the map to

17 be produced, starting from data collection, through data exploitation and ending with maps publication as print, image,

18 and GIS format. An example are geological, lithological, and geomorphological maps, in which most of the highest

19 time-consuming tasks are those related to the discretization of single objects by identifying a set of unique

20 characteristics that describe uniquely those objects. Commonly these tasks introduce interpretative biases due to the

21 different experience of the mappers who's performing it. In this setting, Deep Learning Computer Vision techniques

22 could play a key-role but lack the availability of a complete set of tools specific for planetary mapping. The aim of

23 this work is to develop a comprehensive set of ready-to-use tools for landforms mapping, in which users have full

24 access to the workflow and over all the processes involved, granting complete control and customization capabilities.

25 In this work are presented both the developed tools and the approach that has been used and that is based on

26 consolidated Deep Learning methodologies and open-source libraries commonly applied in other fields of Computer

27 Vision. The toolset and the approach presented have been tested in the science case of mapping sinkhole-like

28 landforms on Mars and results are presented.

29 **Plain Language Summary**

30 The creation of maps is a complex set of several tasks that, regardless of the type of the map, are often very time-

31 consuming. For instance, all the occurrences of a specific object, natural or man-made in a defined area, needs to be

32 identified, drawn and classified manually; a work that can be easily accomplished for large object in small areas but

33 may be unmanageable in cases such the mapping of small landforms on the entire surface of a planet or moon.

34 Nowadays, especially on Earth, several of the above tasks takes adavantages of highly specialized computer codes

35 based on Deep Learning systems. Such codes are almost never ready-to-use, and require higher knowledge in

36 computer programming languages. In this work we present the first release of a novel open-source computer software,

37 almost ready-to-use, that provides all the instruments for creating or directly using custom Deep Learning models for

38 automatic landforms mapping. We present also the results obtained by trying this software using data of Mars's surface

39 with the aim of mapping sinkhole-like landforms.

40 **1. Introduction**

41 The exploration of terrestrial planets in the Solar System was and still is performed mainly on data that cover almost

42 all the electromagnetic spectrum, acquired over the last century by several types of orbiters, rovers, and landers.

43 Planetary data volumes are constantly increasing both in quality and quantity, with the contribution of both public and

44 private entities.

45 Imagery has always been the primary resource for researchers in planetary sciences, especially for geologists and

46 geomorphologists. In the last two decades the progress in the development of very high-resolution image sensors gave

47 access to the community to images with a spatial resolution in the order of centimeters. Data collected by High

48 Resolution Imaging Science Experiment (HiRISE) instrument, on board of the Mars Reconnaissance Orbiter (MRO)

49 (McEwen et al., 2007) or by the Narrow Angle Camera (NAC) experiment, on board of Lunar Reconnaissance Orbiter

50 (LRO) (Robinson et al., 2010), have been used in several works related on their planetary body.

51 These include not only publications related to specific surface's features such as the impact of megabreccia (Grant et
52 al., 2008), crater counting and morphometry (Benedix et al., 2020; Chen et al., 2017; Robbins & Hynek, 2014; Servis
53 et al., 2020; Watters et al., 2015), boulder counting (Le Mouélic et al., 2020; Sargeant et al., 2020; Watkins et al.,
54 2017) characterization of polar layered deposits (Milkovich et al., 2009), identification of the source of ice blocks in
55 the north polar cap (Su et al., 2021) but also comparative analyses and numerical modeling (Guimpier et al., 2021),
56 analyses of Mars's surface processes (Guallini et al., 2018; Luzzi et al., 2020) including skylight, pits (Barlow et al.,
57 2017; Cushing et al., 2015; Michikami et al., 2014; Xiao et al., 2014), pit chains (Wyrick, 2004) , and more advanced
58 application such as Structure-from-Motion (SfM), (Le Mouélic et al., 2020; Micheletti et al., 2015; Muller et al., 2021;
59 Y. Wang et al., 2021), Shapes-from-Shading (SfS) (Alexandrov & Beyer, 2018; Lohse et al., 2006), Machine Learning
60 for object detection and classification (Barrett et al., 2022; Dundar et al., 2019; Hipperson et al., 2020, 2020; Hu et
61 al., 2021; Lee, 2019; Nodjoumi et al., 2021; Palafox et al., 2017; Rashno et al., 2017; Silburt et al., 2019; Wilhelm et
62 al., 2020).

63 This leap in image quality and quantity has introduced new challenges for researcher since the higher resolutions
64 brought the great advantage of being able to analyze the surface of those planets with unprecedented details, retrieving
65 useful information of various field such the characterization of Martian and lunar pits (Cushing et al., 2015; Haruyama
66 et al., 2009; Kaku et al., 2017; Sharma & Srivastava, 2021; Wyrick, 2004; Xiao et al., 2014) or the Recurring Slope
67 Linae (RSL) (McEwen et al., 2021), but with several downsides, for instance, larger image size ad numbers of
68 acquisitions available may create problems for large scale processing due to the computational power requirements.

69 Map production is a complex set of tasks performed by teams and groups of researchers specialized in single to
70 multiple fields that combine their knowledge in order to describe and characterize the surface of a planet
71 ('Geomorphological Mapping', 2013; Napieralski et al., 2013; Nass et al., 2021). Depending on the type of the map
72 in production, these tasks may vary a lot but at least four major focal tasks are shared across all map types: a) data
73 collection, b) data exploitation , c) map creation, d) map dissemination (Naß et al., 2017, 2021). Among those major
74 tasks, the most time-consuming sub-tasks are the definition of the standards for the map production and dissemination
75 (Hare et al., 2018) and the proper digital creation of the map elements by manual drawing all the features of the area
76 of interest using GIS software. For instance, in geomorphological mapping, the main target is the identification of
77 landforms. With the term landform, is intended a topographic expression of the surface of a planetary body that can
78 be described by at least seven parameters, shape, size, height, texture, pattern, tone/hue, location/association (Tempfli
79 et al., 2009) that combined generate a unique object while Multiple landforms in an area describe a terrain (Bridge &
80 Demicco, 2008; DiPietro, 2013). See Table S1 in supporting information.

81 Genetic mechanisms are a complex combination of interconnected processes and forces, some of which are more wide
82 and planetary-scale dependent. For instance gravity usually drives the size of different morphologies such as lava
83 tubes and rilles on the Moon, Mars and Earth (Bardabelias et al., 2020; Chappaz et al., 2017; Cruikshank & Wood,
84 1972; Greeley, 1971; Haruyama et al., 2009; Horvath et al., 2020; Kaku et al., 2017; Léveillé & Datta, 2010; F. Sauro
85 et al., 2020; Whitten & Martin, 2019). Other mechanisms are more related to the presence of specific environmental
86 and atmospheric characteristics and may drive different subtypes of a common landform type.

87   Among the many examples, landforms such as landslides (Hungr et al., 2014) and sinkholes (Parise, 2019) found on

88   Mars (Bardabelias et al., 2020; Cushing et al., 2007; De Blasio, 2011; Guimpier et al., 2021; Hooper & Smart, 2013;

89   Sharma & Srivastava, 2021), may have some formation and driving mechanisms in common to their respective

90   landforms found on Earth (Acharya et al., 2006; Díaz Michelena et al., 2020; Gutiérrez et al., 2008; Hungr et al.,

91   2014; Jiang, 2020; Parise, 2019; U. Sauro, 2016; Van Den Eeckhaut et al., 2007; Youssef et al., 2012). Those

92   mechanisms and settings may be related to similar surface and subsurface characteristics and properties such as the

93   geological settings, type of substratum, the average slope, and the solar exposure of the area.

94   Conversely, the presence of liquid-water seasonal precipitation and groundwater circulation, on landslides and

95   sinkholes found on Earth is not only a driving mechanism but may also act as a trigger for the process (Allemand et

96   al., 2011; Alonso et al., 2010; Cahalan & Milewski, 2018; Díaz Michelena et al., 2020; Duhart et al., 2019; Gutiérrez

97   et al., 2008; Jiang, 2020; Lacerda et al., 2004; Lin et al., 2004; Van Den Eeckhaut et al., 2007; Youssef et al., 2012),

98   while it is still under debate on those found on Mars (De Blasio, 2011; Guimpier et al., 2021; Hooper & Smart, 2013;

99   Salese et al., 2019; Smith et al., 2006).

100   Several types of terrains and thus landforms exist, natural and artificial, some are peculiar to specific areas or even

101   planets or moons, others can be found in almost all planetary bodies of the Solar System (Hargitai & Kereszturi,

102   2015a).

103   In general terms, the occurrence of specific landforms are deeply connected to the geology of the area, the past and

104   present atmospheric processes and, at least on Earth, by anthropological activities (this applies to a certain extent also

105   to robotic or human landing sites) (Brierley et al., 2021; James et al., 2013; Slaymaker et al., 2021). Studying those

106   features is essential to better know the relations between those three main major processes and characteristics and the

107   evolution of the area.

108   Identification, classification and description of landforms is done by mappers using multiple data types and sources

109   such as images in various spectra, previous maps, digital elevation models and so on (Luzzi et al., 2020; Parente et

110   al., 2019; Sivakumar et al., 2017). The time necessary to accomplish this specific sub-task is strictly dependent on the

111   scale of the area of interest and scale of the features in it since wider areas and smaller features may lead to extremely

112   high workloads. The final map product is a fundamental element to consider while estimating the complexity of the

113   map production work. This is due to the wide diversity of map products available, and thus to the parameters to be

114   defined and the data to be collected and processed

115   Indeed, geological maps takes into account spatial-temporal relations between surface and subsurface's features, their

116   compositions and the past and present geological processes involved (Martinot et al., 2018; Naß & van Gasselt, 2021;

117   Pondrelli et al., 2020; Sun & Stack, 2020; Tsibulskaya et al., 2020), while geomorphological maps takes the same

118   parameters at a higher level, more related to the visual properties derived by the acquired images like colors, texture,

119   patterns and so on (Kumar et al., 2019; Tirsch et al., 2021; Tsibulskaya et al., 2020; B. Wu et al., 2020).

120   In addition, regardless of the type of map, the data collection steps can be very time-consuming tasks, beyond being

121   also complex, since most of the available data needs to be pre-processed prior to the proper analysis. For example,

122   there are more than 1.8 million products of HiRISE acquisitions that are roughly more than 49 Terabyte for a single

123   imager that is still acquiring data at the time of writing.

124   In this framework, Deep Learning computer vision methodologies, are robust and widely accepted and applied both

125   on Earth for crops monitoring and management (Grace et al., 2021), land use (Rousset et al., 2021; Talukdar et al.,

126   2020), risk management and assessment (Ghorbanzadeh et al., 2019; Liu et al., 2004; Merghadi et al., 2020; Paul &

127   Ganju, 2021; Tien Bui et al., 2016; Yousefi et al., 2020); and on other Solar System planetary body (Barrett et al.,

128   2022; Dundar et al., 2019; Hipperson et al., 2020, 2020; Lee, 2019; Palafox et al., 2017; Rashno et al., 2017; Stepinski

129   et al., 2007; S. Wang et al., 2020; Wilhelm et al., 2020); thus may be play a crucial role in exploiting such amount of

130   data.

131   The objectives of these methodologies are mainly of four types listed below and shown in Figure 1.

132
133   **Figure 1.** Comparison between image recognition, image segmentation, object detection and instance segmentation

134   for the specific case of geomorphology mapping.

135   The first methodology displayed in Figure 1 is the I*mage Recognition (ImR)* which classifies the whole image contents,

136   the second, called I*mage Segmentation (ImS)*, classifies each pixel of the image and create segments of adiacent pixels

137   with contiguous classification. The third technique, the O*bject Detection (OD)*, locate the objects using bounding

138   boxes and classifies them separately, while the fourth, the I*nstance Segmentation (InS)* is a combination of the second

139   and the third method, obtaining the segmentation of only the objects identified by the detection.

140   Those architectures may require a tremendous amount of well labeled training data in order to generalize properly the

141   model and avoid overfitting and underfitting problems (Zhang et al., 2021). More detailed descriptions are available

142   in the supporting information Text S1.

143   Such data, are not always ready-to-use for labeling, mostly due to compatibility issues between labeling software,

144   deep learning software and data itself. More specifically, these issues are related mainly to data size and format, and

145   therefore pre-processing tasks have a key role and are mandatory for any approach especially if georeferencing

146   information is required. A more detailed overview is provided in the supporting information Text S3 along with

147   detailed pre-processing steps.

148   Nowadays, Deep Learning methodologies are widely and commonly used as a solution to solve several daily problems,

149   for instance facial recognition features of social networks, Google images search, security surveillance and much

150   more, but also specific problems relative to Earth Observation such as land coverage, crops vegetation monitoring,

151   early warning systems and other (Brust et al., 2019; Hoeser & Kuenzer, 2020; Miyamoto et al., 2018; Redmon et al.,

152   2016; Szegedy et al., 2013; Y. Wu et al., 2019a, 2020; Zhao et al., 2019).

153   In the last two decades a lot of efforts have been made to use Deep Learning to solve planetary mapping problems on

154   Earth (Liu et al., 2004; Paul & Ganju, 2021; Stepinski et al., 2007; Talukdar et al., 2020) as like as on Mars (Hipperson

155   et al., 2020; Nagle-McNaughton et al., 2020; Palafox et al., 2017; Wilhelm et al., 2020) and the Moon (Hu et al., 2021;

156   Silburt et al., 2019; S. Wang et al., 2020) exploring almost all architectures and algorithms with very promising results.

157   In some cases the code used for the analysis is publicly available (Aye et al., 2019; Barrett et al., 2022; Lee, 2019;

158   Silburt, 2017/2019; Wilhelm et al., 2020) and may be used to create preliminary map products.

159   The results obtained with the above-mentioned codes are typically plain images with superimposed the bounding

160   boxes or the segmented area and are in non-georeferenced raster file type formats such as png or jpeg. Those type of

161   results need to be georeferenced before being further processed in GIS software to vectorize manually all the objects

162   or segments and finally obtain a vectorial map that can be published in a geospatial data format such as OGC

163   Geopackage. This newer file format is specific for transferring geospatial information similarly to ESRI shapefiles

164   (ESRI technical document, 1998), but with higher portability and compactness, moreover is an open format and

165   standard-based (Open Geospatial Consortium, 2021).

166   For instance, segmented areas such those that represent geomorphological units, need to be manually digitized as

167   individual shapes in GIS software, with the manual conversion and assignment of the properties of the units in the

168   image.

169   In this setting, geologists and geomorphologists, not familiar with programming languages and interested only in

170   workflows and tools may have a lot of difficulties understanding and using complex machine learning approaches that

171   require higher knowledge in computer science, especially if complete and ready-to-use tools are not available.

172   In this work is presented a first complete working release of *DeepLandforms*, a set of comprehensive and ready-to-

173   use tools specifically developed for planetary mapping.

174   This toolset is a follow-up of the work and tool (Nodjoumi et al., 2021) based on object detection methodology and

175   focused on the usage of You Only Look Once version 5 (YOLOv5) framework (Pham et al., 2020; *Ultralytics/Yolov5*,

176   2020/2021) to detect sinkhole-like landforms on Mars, obtaining a geopackage containing, the centroid coordinates

177   of the bounding boxes, confidence level and classification class for each of the detections. In Figure 2 the map showing

178   both the MGC^3 catalog and the object detection results.

Figure 2. Comparison of MGC^3 catalog and results obtained by using Deep Learning object detection (DeepLandforms-YOLOv5) on a similar dataset (Nodjoumi et al., 2021).

Despite centroid coordinates could be considered a starting point for proper mapping, there is the lack of the spatial dimensionality thus providing only a general localization of the features, even using the coordinates of the detection boxes there is still the lack of a precise localization and definition of the shapes of the landforms. To further improve the previous work, a change of architecture was mandatory, moving from object detection to instance segmentation architecture.

The instance segmentation library selected for this work is the Detectron2 Library, developed and periodically maintained by the Facebook AI Research team, specialized in image segmentation tasks through R-CNN networks. See supporting information Text S2 for additional details on Detectron2 Library.

In this work, the Mask R-CNN network has been considered the only main network since it is specific for object instance segmentation tasks (He et al., 2018).

Mask R-CNN extends Faster R-CNN, class labels and bounding boxes, by adding a third output, the objects masks (He et al., 2018; Massa & Girshick, 2018). A mask can be considered as a method of describing an image in boolean-based representation by using specific filters or functions, meaning that the content of the image will be converted in

194   only two possible values (0-1, on-off, true-false, and so on). See supporting information Text S5 and Figure S1. Each

195   mask is then characterized by internal and external values and can be localized by using image pixel coordinates.

196

2.   DeepLandforms

198   *DeepLandforms* has been developed with the aim of creating a comprehensive set of tools to support a complete

199   workflow for mapping landforms using georeferenced data and producing results in vectorial format. Flowchart of the

200   workflow can be visualized in Figure 3.

201
202   **Figure 3.** Flowchart of the complete workflow on which is based the DeepLandforms toolset.

203   The toolset is composed by four major components, all based on docker open platform (*Docker Overview*, 2021;

204   Merkel, 2014), which is a state of the art, well-known, open-source platform for developing, sharing and running

205 applications as a sandbox service called *containers*, with full support for NVIDIA GPU (CUDA) computing (Luebke,

206 2008). More information on docker available on supporting information Text S5.

207 The first component is the *ImageProcessingUtils* docker container (Nodjoumi, 2021a), a jupyter notebook tool

208 developed for resize, crop, remove black borders, tile and convert images from CUB (Anderson Jeff & Deborah Lee

209 Soltesz, 2003), jpeg2000 and GeoTiff file formats to GeoTiff, jpeg and png file formats maintain georeferencing

210 information in file metadata for GeoTiff or in an ancillary world files for jpeg and png.

211 The second component, is *Labelme* docker container, an open-source tool with graphical user interface for creating

212 segmentation labels (Wada, 2021).

213 The third component is DeepLandforms docker container which includes two jupyter notebook, both built on top of

214 Detectron2 library, *DeepLandforms-Training* and *DeepLandforms-Segmentation*. More detailed description are

215 provided in supporting information Text S6.

216 The fourth component is *Tensorboard* docker container, a simple utility for monitoring the training process.

217 **3. Materials and Methods**

218   3.1. Data

219 The data used in this work are mainly images acquired by image sensors operating in the visible (VIS) and Near

220 InfraRed (NIR) spectrums on board of probes orbiting Mars and the Moon as shown in Table 1.

221

Orbiter	Target	Instrument	Sensor type	Ground Resolution	Images
Mars Reconnaissance Orbiter (MRO)	Mars	High Resolution Image Science Experiment (HiRISE)	Panchromatic VIS+NIR	Up to .30 m/pixel	~1000

222 **Table 1.** The dataset used for training and testing purposes is a combination of three subset samples of global coverage

223 major datasets.

224 This dataset is composed of images by different instruments and space missions downloaded both as Reduced Data

225 Record (RDR) and Experiment Data Record (EDR) format from public space archives such as PDS Geosciences Node

226 Orbital Data Explorer (ODE) (PDS Geosciences Nodes, 2021). EDR images have been processed initially to produce

227 RDR version using USGS Integrated Software for Imagers and Spectrometers (ISIS) (Laura et al., 2021) and then

228 converted into jpeg2000 (JP2) file format or GeoTiff file format using *ImageProcessingUtils* container.

229 Computational requirements of Machine Learning and more in particular of Deep Learning architectures for Computer

230 Vision, apart from the complexity of the architecture, are strictly related to image properties, image bands, resolution

231 (size), dataset size, that have a great impact especially during training of the model. On the other hand, the impact on

232 computation and resources during the usage of the pre-trained model is lower. In comparison, the Mars and Moon

233 high-resolution images from HiRISE and LROC respectively, are enormous in terms of data size, reaching easily

234 50000pixel height resolution at 0.3m/pixel ground resolution (on average). These require a lot more processing in

235 order to make them compatible with Deep Learning tasks or to reduce the computational requirements.

236 A simple and easy approach would be the direct resize of these images but is not always possible because there is the

237 risk of loose object's unique details or even worse introduce apparent similarity between two different objects.

238 A better approach is to divide the images into desired resolution tiles, in this case there is no detail loss but the number

239 of images to be filtered out of irrelevant ones and then labeled increases proportionally of image original and desired

240 resolution. E.g., HiRISE PSP_004715_1855_RED image is 30137x76047 pixels, dividing it into ~512x512 pixels

241 tiles results in more than ~8700 tiles. Even tiling into larger tiles is not always a feasible approach. Moreover, such

242 tiling may result in the loss of contextuality of the objects or introduce difficulties during the labeling tasks since the

243 object may result splitted into multiple tiles.

244 In this situation it is advised to define the requirements of the analysis and evaluate compromises between the

245 approaches of Table 2.

Requirements	Limits	Compromises	Approach
Maintain context	Scaling to very low resolution may lead to huge loss of details	Limit the scaling to maintain discretization capabilities	Scaling approach
Maintain high discretization and avoid object splitting	Larger images produce several tiles proportional to original image and tiles resolution, objects may results split across several tiles	Limit the dimension of the tiles to avoid object splitting and number of tiles low	Tiling approach

246
247 **Table 2.** Comparison between approaches, scaling approach may be better for analysis of features at regional scale,

248 while tilin approach may be preferred for smaller landforms.

249 In the presented use case, a mixed approach has been used: images spatial resolution have been scaled down to 5

250 m/pixel, then the resulting images have been sliced into tiles with 1024 pixel max width or height. To achieve these

251 specific tasks, the docker container named ImageProcessingUtils.

252   3.2. Masks world coordinates

253 As mentioned in the introduction, all results obtained by Mask-R-CNN are image masks described with pixel

254 coordinates. Therefore it is necessary to convert in world coordinates. This operation has been accomplished by

255 developing a function based on a Python library named Rasterio (Gillies & others, 2021) which contains specific

256 modules for spatial data manipulation by using each image affine transform. See Text S4 and Figure S1 in supporting

257 information.

258 **4. Results**

259 Hereby are described the results obtained after re-training Mask-R-CNN models on a custom dataset of HiRISE

260 images containing pit/skylights landforms.

261 All the configuration parameters, the components of DeepLandforms, including the descriptions of the data pre-

262 processing and labeling components, the training and inference jupyter notebooks and the types of results obtainable

263 are available in supporting information Text S3, S4, S5, S6, S7, Table S3, S4, S5.

264 ### 4.1. Pits/Skylight use-case

265 Despite this toolset is not specific to any kind of landforms, the target used as test landform consist of pits/skylights
266 with a comparison with craters.

267 Craters are almost circular to elongated depressions caused by an impact of an object. Dimensions may vary a lot
268 across the solar system and are guided by several aspects such as the presence of an atmosphere, the geology of the
269 area, the velocity and trajectory of the object, the gravity of the planet and more. Commonly, they are characterized
270 by a bulged rim, shallow to steep walls, radial eject marks and a small summit at the center (Evans, 2012; Hargitai &
271 Kereszturi, 2015b; Michikami et al., 2014; Mouginis-Mark, 2004). These characteristics are more visible in craters
272 that are newer, larger, or more in general, that were less subject to recent or present erosional processes, e.g.
273 atmospheric ones in the case of Mars. In later stages of erosion and alteration some characteristics tend to be obliterated
274 or smoothed, resulting in morphologies that resemble pits or skylights.

275 Pit and skylight are depressions of the terrain characterized by an elongated to almost circular shape, flat rims and
276 bottom, walls ranging from almost flat to very steep and in some cases sub-vertical (Cushing et al., 2015; Cushing &
277 Titus, 2010; F. Sauro et al., 2020; U. Sauro, 2016; van der Bogert & Ashley, 2015; Wyrick, 2004). On Earth are
278 commonly caused by the collapse of the top of a subsurface cavity, or by chemical or mechanical erosion of the
279 subsurface sediments, while on other planetary bodies such Mars and the Moon, their formation mechanisms are still
280 debated. As mentioned before, pits and skylights may have different shapes and dimensions on Earth and other
281 planetary bodies (Cushing et al., 2015; Hong et al., 2015; F. Sauro et al., 2020; Sharma & Srivastava, 2021; Whitten
282 & Martin, 2019), yet maintain almost all the characteristics. The classification proposed Figure 4, is an expansion of
283 the classification proposed by Cushing et al (Cushing et al., 2015) and is based only on a qualitative morphological
284 analysis based on visual appearances of the features characteristic of pits and skylight, without taking into account
285 morphometric properties.

286

| Image	ID	Description
	1a	Type 1a – Skylight with possible cave entrance characterized by quasi perfect circular shape, flat rim, no ejecta marks, and almost nonvisible bottom. When visible bottom is present, it is possible to see vertical to overhanging walls by the projected shadows and in some cases piles of debris at the center with conical upward shape. Often found isolated or in proximity of all other types, especially Type-4 and Types-2a-b.
	1a	Type 1b – Pit with possible relation to cave entrance and, or lava tube characterized by quasi circular shape, sub-vertical to vertical walls, almost flat rim, no ejecta marks, almost circular shape, and visible bottom. In some cases, it is possible to see circular marks of darker terrain on the floor, near the sub-vertical walls.
	2a	Type 2a – "Bowl" pit with uncertain connection to lava tubes or dikes characterized by a semicircular shape, almost flat rim, no ejecta marks, sloped walls and visible convex bottom. Often isolated or in connection with Type-3
	2b	Type 2b – Pit with uncertain connection to lava tubes or dikes characterized by a semi elliptic shape, almost flat rim, no ejecta marks, sloped walls and visible convex to flat bottom. Often isolated or in connection with Type-3
	3	Type 3 – Coalescent pits characterized by a mix of characteristics of Type-2a-b. Possible connection to lava tubes or dykes due to the alignment of Type-2a-b.
	4	Type 4 – Pit with possible connection to lava tubes or dikes due to the alignment of multiple similar shapes, characterized by a semicircular shape, almost flat rim, no ejecta marks, shallow to very shallow depth, sloped to sub-vertical walls and visible flat bottom. Often aligned with other Type-4 or in connection with Type-3 and Type-1a-b, rarely isolated.

287

Figure 4. Main types of pits/skylights that can be identified on Mars, also used as classes for labeling training dataset, expanded from a previous work (Nodjoumi et al., 2021).

288   The most consistent and peculiar characteristic among pits/skylights that almost always differ greatly from craters is

289   the presence of a raised rim. As previously mentioned, in craters it's common to find bulge all along the rim, or in a

290   specific direction that usually correspond to the impact trajectory, while rims in pits and skylights are almost

291 completely absent or associated with previously existent landforms that can be visible also in the nearby of the pits
292 and skylights.
293 The best method to evaluate the differences between pit and crater rims, is to manually plot and evaluate Digital
294 Terrain Model (DTM) profiles but, since in most cases DTMs are not always available, it is possible to evaluate them
295 by plotting a profile along the maximum illumination direction of visible images, obtaining a pixel intensity profile
296 that correspond to brightness levels of the pixels, with digital number (DN) with values ranging from 0 (black) and
297 255 (white). Although 16-bit images could provide major details in the shadowed areas, 8-bit images were preferred
298 as their 16-bit counterpart increases computational requirements dramatically and are not completely implemented yet
299 in common Deep Learning techniques for object detection and segmentation. This method is an approximated and
300 indirect estimation of the orientation of the surface and assumes that the substrate is almost homogeneous. Low
301 brightness values correspond to shadowed areas with solar incidence angle near 90°, while high brightness values
302 correspond to lower solar incidence angle. The solar incidence angle is the angle between the solar rays and the normal
303 on a surface and has an absolute range between 0° and 90° (Kalogirou, 2009). This approach is also the core of other
304 works that have the same aim of identifying pits on other Solar System rocky bodies (Lohse et al., 2006; Robinson et
305 al., 2017).
306 Craters brightness profiles can be created using QGIS profile plugin as shown in Figure 5.
307 Profiles can be divided in six main sections, in which there are almost two pairs of paired high peak-bottom brightness
308 sections corresponding to the area of morphological bulge's illuminated and shadowed faces. Those sections can be
309 described as follows:

1) Pre-rim: brightness is almost uniform and visually similar to the surroundings of the landform.

2) 1st Sun-faced rim: inner side of the pit exposed to direct sun's rays opposite of section 2. Divided in two sub-sections:

   a. Lower ramp: brightness increases gradually towards the rim with values up to those of section 1. Not always present in conjunction with 3b.

   b. Higher ramp: brightness increases abruptly, with values equal or major than those of section 1, meaning that the solar incidence angle is decreasing. Not always present in conjunction with 3a.

3) 1st anti-solar rim: side of 1st bulge not exposed directly to sunlight, brightness decreases with values lower than section 1, depending on inclination of the internal bulge and the landforms. Divided in two subsections:

   a. Penumbra: brightness decreases uniformly. Non always present in conjunction with 3b.

   b. Umbra: brightness decreases abruptly, usually completely dark or with DN values near to 0, those values may slightly increase moving near the next rim or increase abruptly. Non always present in conjunction with 3a.

4) 2nd sun-faced rim: side of the 2nd bulge, divided in 4a and 4b, similarly to section 2a and 2b.

5) 2nd anti-solar rim: side of the 2nd bulge, divided in 5a and 5b, similarly to section 3a and 3b.

Post-bulge area: brightness increases up to levels similar to section 1.

Figure 5. Comparison of brightness and DTM profiles for a crater on ESP_070298-ESP_070865 stereo pair, red channel. In blue, an attempt to identify the correspondence of the brightness sections on a DTM derived from photogrammetry of HiRISE stereo pair.

Pits/Skylights brightness profiles, created using QGIS profile plugin, as shown in Figure 6. Additional example in Figure S3 in supporting information.

The profiles are divided in 4 main sections, described as follows:

    1) Pre-pit: brightness is almost uniform with values similar to the surroundings of the landform.

    2) Funnel: brightness decreases with values lower than section 1, depending on inclination of the morphological slope of the surfaces. Divided in two sub-sections:

        a) Penumbra: brightness decreases uniformly. In some cases, brightness may drop abruptly then remaining almost constant or decreasing uniformly with values always higher than DN 0. Non always present in conjunction with 2b.

b) Umbra: brightness decreases abruptly, usually completely dark or with DN values near to 0, those values may slightly increase moving near the next rim or increase abruptly. Non always present in conjunction with 2a.

3) Sun-faced rim: inner side of the pit exposed to direct sun's rays opposite of section 2. Divided in two sub-sections:

a) Lower ramp: brightness increases gradually towards the rim with values up to those of section 1. Not always present in conjunction with 3b.

b) Higher ramp: brightness increases abruptly, with values equal or major than those of section 1, meaning that the solar incidence angle is decreasing. Not always present in conjunction with 3a.

4) Post-pit area: intensity levels become similar or identical to those of section 1.
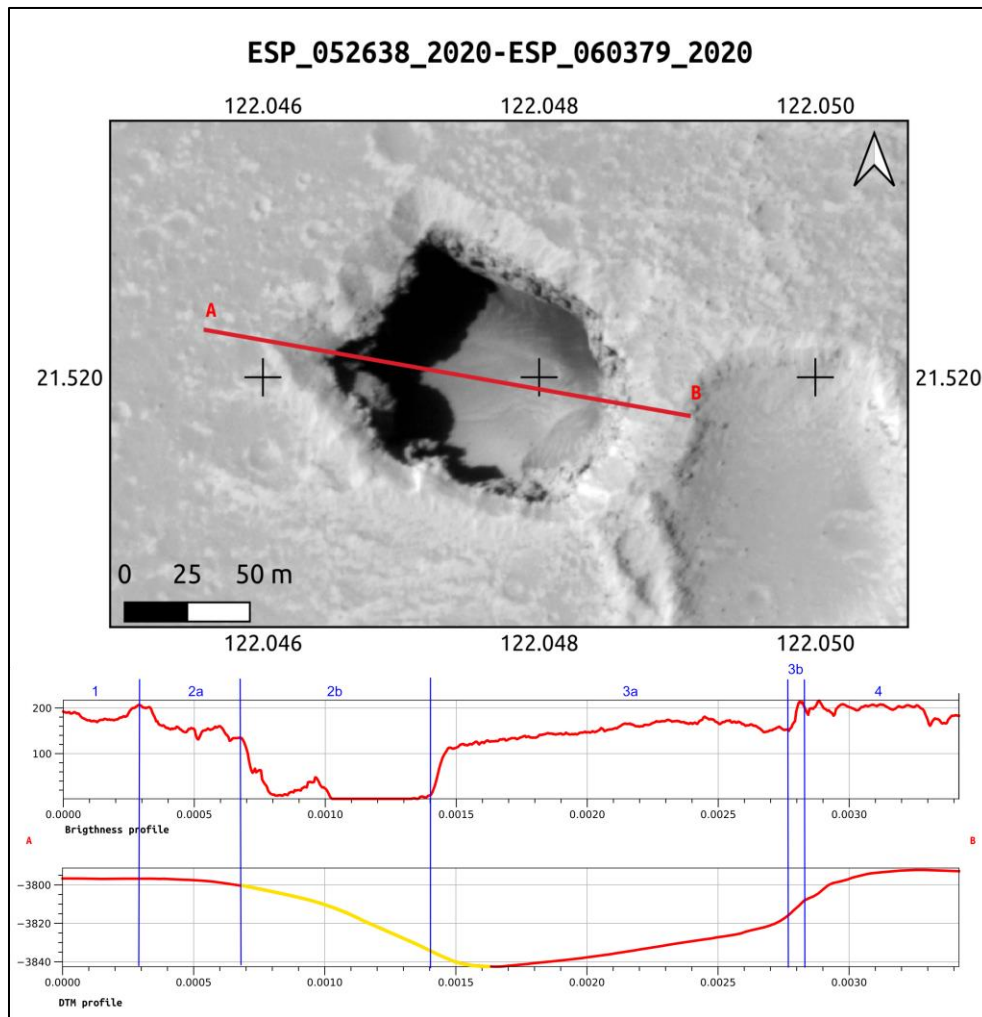

Figure 6. Comparison of brightness and DTM profiles for a Type-1 on ESP_052638_2020-ESP_060379_2020 stereo pair, red channel. In blue, an attempt to identify the correspondence of the brightness sections on a DTM derived from photogrammetry of HiRISE stereo pair. In yellow, the portion of the DTM profile interpolated by the Socet Set ((c) BAE Systems) software. The interpolation is due to lack of usable data in both the images processed using photogrammetry (HiRISE | About HiRISE Digital Terrain Models, 2021).

352   In order to validate all the packages, tools and the complete workflow, an intensive test has been performed on the

353   above-mentioned pit, skylights landforms, including a generic set of craters for references and for testing the capability

354   to discriminate those whose appearance resemble some types of pits.

355   The dataset consists of 89 HiRISE RDR red channel images, see supporting information Table S5. The use of only

356   red channel images is due to the swath of 6 km cross-orbit and 20 km along-orbit at a nominal 300 km nominal orbit.

357   In comparison the Blue-Green and NIR images have a swath resolution of 1.2 km cross-orbit.

358   Those image have been processed using ImageProcessingUtils (Nodjoumi, 2021a) to convert from jpeg2000 file

359   format (JP2) to GeoTiff and then resized to a common 5 m/pixel cell size, and tiled into more usable files with the

360   largest side up to maximum 1024 pixel.

361   All resulting images have been manually examined to filter out those which did not contain any landform relevant for

362   the labeling steps, obtaining 152 images containing at least one type of landform.

363   Then, all the images have been ingested into LabelMe to annotate all the pits, the skylights and some representative

364   craters following the classification showed in Figure 4. At the end of the labeling task, it emerged that the obtained

365   labels were unbalanced, meaning that the dataset does not contain an almost equal number of each class.

366   Since the collection and processing of newer images containing more landforms of the unbalanced classes was not

367   feasible at the time of analysis, a simpler approach was chosen and consist of a reduction of the classes by grouping

368   into similar ones, doing so resulted in only four classes, Type-1, containing -1a and -1b, Type-2, containing -2a and -

369   2b, Type-3, Type-4.

370   After concluding the dataset preparation, several training sessions were performed using DeepLandforms-training

371   notebook, with different parameters and *mask_rcnn_R_50_FPN_3x* as model configuration; to evaluate the stability

372   and scalability and the performance of the tool with the dataset on two different computers.

373   According to Detectron2's model zoo (Y. Wu et al., 2019b), which is a large collection of model configurations and

374   their corresponding pre-trained models and baseline performance values, mask_rcnn_R_50_FPN_3x model

375   configuration is reported to have the best-balanced results/training requirements ratio, see supporting information Text

376   S7 for details on the model configuration. The ranges of the main training parameters are summarized in supporting

377   information Table S3.

378   All the training sessions have been monitored using tensorboard to evaluate the progression and the performance of

379   the trainings and resulted in promising results, despite the small dimensions of the datasets and the not optimized

380   training parameters. As it is possible to see in supporting information Figure S11, the accuracy for bounding boxes

381   and masks reached more than 0.99 after 5000 epochs, with very low ratios of false negatives and false positives and

382   final mean Average Precision values shown in supporting information Table S4 and Figure S9-S10.

383   Those values are mostly in accordance with the average values of the architecture's benchmarks (Y. Wu et al., 2019b),

384   the low values obtained for craters and Type-4 are mainly caused by the low quantities of respective labeled data and

385   the similarities that may occur in some landforms.

386   The obtained model was then used to inference the valid dataset, and then the results were loaded into LabelMe to

387   check if the labeled objects are detected and labeled correctly as shown in Figure 7.
388

Figure 7. Comparison between ground truth labeled image used in training (left) and inferred labeled image (right). The major difference is in the density of the points of the shape, where in the inferred image are way denser than those of the ground truth.

Then the model was used on a partially new set of HiRISE RDR red channel images, in a limited area over the Tharsis Region on Mars.

This region has its central coordinates at 0°N 260°E and was selected three of the largest shield volcanoes in the Solar System are located here, Arsia Mons, Pavonis Mons and Ascreus Mons, moreover in its western area is located the tallest shield volcano in the Solar System, the Olympus Mons. Considering the presence of these large shield volcanoes this region and thus possible intact lava tubes, is the best candidate region to look for possible cave entrances. A previous work by Cushing et al. (Cushing, 2017), identified and published a database containing thousands of pit/skylights landforms, by analyzing manually several Context Camera (CTX) and HiRISE imagery.

This database was used as a control data for all the analyses performed in this and the previous work (Nodjoumi et al., 2021).

The results of the inference performed using DeepLandforms, contained in a geopackage file, was imported in QGIS software, to better inspect the results obtained as shown in Figure 8.

It is possible to see multiple mis-aligned detections of the same landform, this is not properly an error since and is due to presence of two images that are originally acquired from different orbit and not perfectly coregistered or granules relatives to a stereo pair, thus the slightly misalignment, which does not affect the manual validation. To avoid these occurrences, it is necessary to manually check the working dataset for duplicates or use only coregistered data.

In Figure 8, is presented an example of the obtained results, compared to the entries of the MGC^3 database and theresults obtained in the DeepLandforms-YOLOv5 object detection work, showing a very good detection and segmentation of the trained landforms. Moreover, it is possible to see the advantages of the approach proposed in this work. Providing polygon geometries as results, could greatly improve the mapping of specific landforms, especially

413   when looking for unknown occurrences on a wide dataset. More examples are available in Supporting information
414   Figures S4 to S8.

415

416

Figure 8. Example of detection on HiRISE Red channel image and comparison between MGC^3, DeepLandforms-

YOLOv5 object detection and DeepLandforms-Mask-R-CNN instance segmentation. Tables show attributes of fields

in the shapefiles. The offset of MGC^3 points is probably caused by the coordinate conversion of the source MGC^3

csv file into shapefile.

421   Notice that in all the presented images, there is a misalignment between the MGC^3 points and the HiRISE or CTX

422   Images. The cause of this discrepancy has not been identified yet but is probably due to a different reference system

423   used by the authors of MGC^3 or introduced during the conversion from the source MGC^3 csv file to the shapefile

424   file format.

5. Discussion

426   In this work, are presented the mapping results of skylight, pit and pit chains automated mapping using only

427   DeepLandforms, a novel comprehensive toolset based on Deep Learning Computer Vision for object detection and

428   segmentation.

429   Skylight, pits and pit chains are an extremely interesting type of landforms that can be observed on almost all rocky

430   planets and moons of the Solar System.

431   Formation mechanisms are commonly related to volcanic and tectonic processes but are still debated, moreover it is

432   still not clear whether such formation mechanisms are the same on all the planetary bodies in which those landforms

433   are observed, especially since there are very similar and common morphological characteristics among all

434   observations. If it is the case of common formation mechanisms, this implies that there should be shared geological

435   properties and settings among those bodies, thus common geological history.

436   Further on, skylights and some pits may have access to caves as observed on Earth analogues, and hypothesized on

437   Mars and the Moon (Hong et al., 2015), such those found on large shield volcanoes (Léveillé & Datta, 2010; F. Sauro

438   et al., 2020). Presence of accessible caves on other planets and moons has an huge importance for space exploration

439   since those cave may contain traces of life, both past and potentially present, as some extremophile bacteria and other

440   smaller life-form may have found shelter from harsh surface condition and cosmic radiations (NASA, 2021).

441   Moreover, caves are considered as good candidates for future human habitation outposts (Cushing & Titus, 2010;

442   Pipan & Culver, 2019), and also are an excellent window on the subsurface structure, thus providing valuable

443   information for understanding the geological settings and evolution of the area and potential direct access to mineral

444   resources (Blamont, 2014).

445   To explore the above-mentioned targets and objectives, is necessary an accurate and global scale mapping of skylight,

446   pit and pit chains, in order to better understand the spatial distribution of such landforms and correlate their presence

447   with other geological and non-geological features and settings.

448   For instance, since pit chains may be related to the presence of lava tubes or dykes (Ferrill et al., 2011; Whitten &

449   Martin, 2019; Wyrick, 2004), mapping pits could lead to new understandings of lava tube distribution, thus to better

450   knowledge of volcanic processes involved, even across planets and moons. Isolated pits with no surrounding other

451   morphological evidence may indicate the presence of a deep buried lava tube or cavity originating from other

452   processes.

453   It is also possible to compare the distribution of such landforms with structural maps or other features that may be

454   interconnected (Ferrill et al., 2004, 2011).

455   Another advantage is connected to the planetary human mission planning, since the availability of geomorphological

456   maps, even if not at highest resolution possible, may lead to the identification of better scientific targets or path

457   planning in case of rovers.

458   An automated or semi-automated approach as the one proposed in this work, in comparison to the manual mapping,

459   may be a game-changer, providing robust processing workflows for generate high-end data in compliance with the

460   OGC standards, for map productions at planetary scale, with the enormous advantage of relaying the most time-

461   consuming task of data pre-process and first analysis to computer time instead of human-time.

462   Presented results are very promising, despite some issues that must be considered.

463   Despite the very good correspondence of the shapes of the detections and the proper real shape, some refinements

464   may be necessary, as some landforms are not detected at all, or in some cases wrongly classified.

465   Moreover, in some cases there is a detection ambiguity, in which some resulting shapes appear doubled, non-unique

466   or mis-aligned, due to the analysis performed on not co-registered images of the same area, as shown in Figures S4

467   and S8 in supporting information.

468   Poor labeling and bad train configuration parameters can also lead to models not suitable for deployment in production

469   uses, or completely unreliable.

470 To improve those results the first step is to increase the quality and quantity of the training dataset, then tuning the

471 configurations of the architecture used and eventually try different networks that may be more adequate to different

472 landforms.

473 The analysis presented in this work, if expanded to a large dataset, may greatly expand the knowledge of the spatial

474 distribution of skylights, pits, and pit chains, including those already known and described, providing a detailed wide

475 map that can be further integrated with morphometric analyses.

476 All the main blocks of the workflow presented in Figure 3 were performed exclusively on DeepLandforms*'s* modules,

477 data collection was performed using NASA-PDS data archive web services, and results evaluation and comparison

478 was performed using QGIS software.

479 The quality of the obtained results can be improved by increasing the amount of images in the initial dataset and their

480 spatial resolution. This will provide more labels to the model that will better learn the differences among all the studied

481 objects. Hyperparameters of the used network can be also tuned to achieve better results. This applies not only to this

482 specific case but to every object detection and segmentation problem.

483 The major limit of those automated approaches resides in the context-unawareness, meaning that when performing

484 the analyses, all the networks are not performing a context-aware analysis in addition to the object detection and

485 identification. This means that at the time of writing there are not yet architectures, for this kind of tasks, that evaluate

486 the surrounding, the context, of a detection to optimize the identification of the objects present in the area.

487 Recently there are architectures that are capable of such additional analyses, called *Liquid Time-constant Networks*

488 (Hasani et al., 2020) but are still under development.

489 **6. Conclusions**

490 The advantages and improvements in data analysis provided by machine learning are undoubtful and constantly

491 expanding in more and more sectors especially in remote sensing of Earth and Space. With an exponential amount of

492 fast-growing available datasets, newer and faster methods are necessary to perform a continuous stream of analyses,

493 and with a plethora of publications, works, architectures and unconnected tools available, that are mainly *accessible*

494 by everyone, albeit not *usable* by not insiders, is also necessary to make those available for the wider audience,

495 especially those who are involved in the analyses of data but are not specialized in the machine learning.

496 In these settings, DeepLandforms, presented in this work, may be a forerunner, a tentative to lead an easier approach

497 well suitable both for first-time users and advanced users.

498 The major advantages and disadvantages are summarized in Table 3:

Advantages	Disadvantages
Almost ready-to-use	Not compatible to every platform
Semi-automated approach	Require intensive user supervision in the initial phase and during preliminary evaluation
Large data volume processing capabilities	Depends on the machine in which is running
Possibly to use results for further correlation with other data	
Wide adaptability to different landforms	May not be compatible with every landform type, depending on the training data

499 **Table 3.** Tabulated assets and liabilities of the toolset presented in this work.

500   6.1. Further development

501 Further development includes implementation of sliding window to improve further the segmentation of large images

502 without pre-tiling them, the integration with GIS statistics such as the parametrization of the detected shapes, including

503 cross-analysis of different data types such as Digital Terrain Models (DTM) in order to improve the quality of the

504 results including eventually volume estimation, or integration with hyperspectral data to retrieve a mineral

505 composition of the surface.

506 Another development could integrate the workflow with the shape-from-shading technique (Alexandrov & Beyer,

507 2018; Lohse et al., 2006; Micheletti et al., 2015) in order to extract depth and thus volume information where DTMs

508 are not available.

509 Moreover, this toolset is not specific to any planetary body nor specific landforms, thus is compatible with every

510 planet or moon imagery, if provided images are georeferenced and the corresponding reference system is passed to

511 the tool.
