Key Points:

- Flying over an area with no nearby lightning activity, the ASIM-MXGS instrument detected a four ms long event with a soft spectrum.
- Observations coupled with simulations suggest that more than 90% of the counts come from a TEB, and the rest from the associated TGF.
- A source TGF with a broad angular distribution and $10^{17.2}$ to $10^{18.9}$ photons can explain the observation.

Abstract

We report the first Terrestrial Electron Beam (TEB) detected by the Atmosphere-Space Interactions Monitor (ASIM). It happened on September 16th, 2018. The ASIM Modular X and Gamma-ray Sensor (MXGS) recorded a two millisecond long event, with a softer spectrum than typically recorded for Terrestrial Gamma-ray Flashes (TGF). The lightning discharge associated to this event was found in the World-Wide Lightning Location Network (WWLLN) data, close to the northern footpoint of the magnetic field line that intercepts the International Space Station (ISS) location. Imaging from a GOES-R geostationary satellite shows that the source TGF was produced close to an overshooting top of a thunderstorm. Monte-Carlo simulations were performed to reproduce the observed lightcurve and energy spectrum. The event can be explained by the secondary electrons and positrons produced by the TGF (i.e. the TEB), even if about 3.5% to 10% of the detected counts may be due to direct TGF photons. A source TGF with a Gaussian angular distribution with standard deviation between 20.6^o and 29.8^o was found to reproduce the measurement. Assuming an isotropic angular distribution within a cone, compatible half angles are between 30.6^o and 41.9^o, in agreement with previous studies. The number of required photons for the source TGF could be estimated for various assumption of the source (altitude of production, angular distribution), and is estimated between $10^{17.2}$ and $10^{18.9}$ photons, i.e. compatible with the current consensus.

Plain Language Summary

Terrestrial Gamma-Ray Flashes (TGFs) are the highest energy natural particle acceleration phenomena occurring on Earth. They are burst of energetic photons associated with thunderstorms, and have a poorly understood production mechanism. When interacting with the atmosphere, TGFs produce secondary electrons and positrons of high energy. A fraction of them can reach Space, and forms a beam under the effect of Earth's magnetic field, so called Terrestrial Electron Beam (TEB). They can be detected over geographical location with no lightning activity. In the past, most of the TEBs have been detected by the Fermi space telescope and the Compton Gamma-ray Observatory. In this article, we report the first detection of a TEB by the Atmosphere-Space Interactions Monitor (ASIM), docked on the International Space Station since April 2018. During this event, no lightning activity was detected below the instrument. The TEB's source lightning was actually found to be located 650 kilometers away from detector, very close to

⁵¹ an overshooting top of a thundercloud. The comparison of the observation with simu-

⁵² lated data made it possible to constrain the geometry of the parent TGF. Our results

⁵³ point towards a relatively wide angular distribution and an intensity of $10^{17.2}$ to $10^{18.9}$

⁵⁴ photons, in agreement with previous studies.

1 Introduction

⁵⁶ Terrestrial Gamma-ray Flashes (TGFs) are short (< 2 ms) bursts of high energy

⁵⁷ ($< 30\text{-}40$ MeV) photons, produced during thunderstorms, between 10 and 15 km alti-

⁵⁸ tude, for events detectable from space. A review of the science of TGFs is presented by

⁵⁹ Dwyer et al. (2012). TGFs were first detected using the BATSE experiment on-board

⁶⁰ the NASA's CGRO spacecraft (Fishman et al., 1994). Later, TGFs were recorded from

⁶¹ space by RHESSI (Smith et al., 2005), AGILE (MCAL instrument) (Marisaldi et al., 2014),

⁶² the Fermi space telescope (GBM instrument) (Briggs et al., 2010; Roberts et al., 2018),

⁶³ BeppoSAX (Ursi et al., 2017) and the Atmosphere-Space Interactions Monitor (ASIM)

⁶⁴ (Neubert, Østgaard, Reglero, Blanc, et al., 2019). ASIM is the only one specifically de-

⁶⁵ signed to detect TGFs from space, using the Modular X- and Gamma-ray Sensor (MXGS)

⁶⁶ (Østgaard et al., 2019). ASIM was successfully launched and docked to the International

⁶⁷ Space Station in April 2018, and started science operations in June 2018. The first re-

⁶⁸ sults from ASIM are presented by Neubert, Østgaard, Reglero, Chanrion, et al. (2019);

⁶⁹ Østgaard et al. (2019), in addition to this article.

⁷⁰ TGFs deposit a large amount of energy in the atmosphere, as a large fraction (typ-

⁷¹ ically $> 97\%$) of the initial bremsstrahlung photons is absorbed before reaching space.

⁷² By colliding with the atmosphere, the photons produce a large quantity of electrons (through

⁷³ Compton scattering and pair production) and positrons (pair production), but only a

⁷⁴ small fraction is able to escape the atmosphere. Most of the escaping electrons are pro-

⁷⁵ duced above ≈ 40 km altitude (Sarria et al., 2015). Once they have escaped, the electrons

⁷⁶ and positrons are then bound to Earth's magnetic field lines and can travel large dis-

⁷⁷ tances inside the magnetosphere (Dwyer et al., 2008; Cohen et al., 2010; Briggs et al.,

⁷⁸ 2011). This phenomenon is called a Terrestrial Electron Beam (TEB). The TGF respon-

⁷⁹ sible for the TEB will be referred as the "source TGF" in the rest of this article. TEBs

⁸⁰ were first reported from measurements of the BATSE/CGRO spacecraft (Dwyer et al.,

⁸¹ 2008). Later, they were detected by the Fermi space telescope (Briggs et al., 2011), one

⁸² event was found in the BeppoSAX satellite data archive (Ursi et al., 2017), and RHESSI

83 also likely detected such an event (see Smith et al. (2006); and Gjesteland (2012), Fig-
84 ure 4.6). The Fermi space telescope could also detect an event identified as both a TGF
85 and a TEB (Stanbro et al., 2019). The duration of TEBs are several times longer that
86 TGFs. This is because the electrons/positrons have a wide range of pitch angles (with
87 respect to the local magnetic field direction) when they are produced and/or escape the
88 atmosphere, which leads to a temporal dispersion after propagating several thousand of
89 kilometers along Earth's magnetic field lines. This phenomenon is illustrated in figure
90 1. For more information about the pitch angle distribution of TEB's electrons, see Sarria
91 et al. (2016). A TEB typically contains 8% to 15% of positrons. All TGFs directed to
92 space produce a TEB, but they are more difficult to detect than TGF. This is because
93 a TGF can be detected by satellites located within a radius of about 800 km around its
94 source, whereas TEBs extend only over a few tens of kilometers around the two point
95 where the magnetic field line reaches the altitude of the satellite (in some cases, the apex
96 of the magnetic field line is lower than the ISS altitude). For example, the first Fermi-
97 GBM TGF catalog presents only 30 TEB candidates among the total of 4135 listed TGF
98 events (Roberts et al., 2018).

99 In this article we report the first TEB event detected by ASIM, using the MXGS
100 instrument. Although the MXGS primary objective is to detect TGFs, a long trigger win-
101 dow (25 milliseconds) was implemented to detect longer events like TEBs. In section 2,
102 we present the ASIM-MXGS instrument and discuss its ability to detect TEBs. In sec-
103 tion 3, we present the event detected on September 16th, 2018. In section 4, we use Monte-
104 Carlo simulation in order to reproduce the event and to constrain its beaming and its
105 source content. We conclude in section 5.

106 ## 2 Instruments and data

107 The Atmosphere-Space Interactions Monitor (ASIM) (Neubert, Østgaard, Reglero,
108 Blanc, et al., 2019) consists of two main instruments : MXGS (Modular X- and Gamma-
109 ray detector) for hard radiation observations and MMIA (Modular Multi-spectral Imag-
110 ing Array) for optical observations (Chanrion et al., 2019). The MXGS instrument con-
111 sists of a Low Energy Detector (LED) and a High Energy Detector (HED). Østgaard et
112 al. (2019) described the instrument in details. The HED is based on twelve bismuth ger-
113 manium oxide (BGO) scintillator crystal bars of 15 x 5 x 3.2 cm^3 interfaced to Photo-
114 multiplier tubes, and is sensitive to energies of $\sim$300 keV to $\sim$40 MeV. It has a total ge-

115 ometrical area of 900 cm^2. The LED consists of an array of cadmium-zinc-telluride (CZT)

116 detector crystals with a total of 16384 pixels, and geometrical area of 1024 cm^2. It op-

117 erates in the energy range of ∼70 keV to ∼400 keV. The LED only operates during nigh-

118 time, and the event reported in this article happened during daytime. MXGS uses 4 trig-

119 ger time windows: 300 μs, 1 ms, 3 ms and 25 ms, this last being specifically implemented

120 to target TEBs. For both detectors, if the recorded number of count exceeds a given thresh-

121 old within one of these time windows, the MXGS instrument triggers, and saves high res-

122 olution data of every single recorded count inside a time frame of approximately ±1 sec-

123 ond around the trigger time.

124 ASIM is mounted to the Columbus module on the International Space Station (ISS)

125 since April 2018. The ISS has been designed to always show the same side to the Earth,

126 meaning that MXGS is always pointing towards the nadir. Let θ be the angle, measured

127 from the ISS, between the nadir and the location of a TGF. All TGF events are expected

128 to come with $\theta < 70^o$. TEB's electrons and positrons are bounded to Earth's magnetic

129 field lines and perform helical motion around it and therefore can hit the space station

130 from any angle of incidence.

131 In order to simulate the response of MXGS to TGF and TEB, we developed a com-

132 plete mass model of the instrument (Østgaard et al., 2019), based on the Geant4 toolkit

133 (Agostinelli et al., 2003; Allison et al., 2006, 2016). It includes all relevant elements around

134 the instrument, in particular the HED, LED, coded mask, shielding and electronics, MMIA,

135 mounting platform, the other mounted instruments, and the Columbus module. By Monte-

136 Carlo simulations we estimated that the effective area of the HED for a typical TEB is

137 about 150 cm^2, which is about 25% of the one for a typical TGF. In this case the effec-

138 tive area is calculated as the geometrical area ($\approx$ 900 cm^2 for HED and $\approx$ 1024 cm^2 for

139 LED) multiplied by the probability of an incident TEB electron to deposit more than

140 400 keV into at least one BGO crystal. This energy deposition can be direct (electrons/positrons

141 hitting the crystal) or indirect. In the indirect case, electrons/positrons emit bremsstrahlung

142 photons by interaction with the surrounding material, that hit at least one BGO crys-

143 tal. Each positron can also be affected by the annihilation process that takes place at

144 the end of each track, when the kinetic energy goes down to zero. For HED, the indi-

145 rect processes are mostly involved during TEB events, because of the shielding around

146 the crystals stops most of the electrons/positrons. The effective area is a function of the

147 energy of the electrons and positrons, and the value given previously is an average over

148 a typical TEB spectrum. In addition to HED, we also estimated that the effective area

149 of the LED detector for TEB detection is about 280 cm^2. It is significantly larger than

150 for HED because direct electron hits are much more likely. It implies that, during a TEB

151 event, the LED could detect twice more particles than the HED. This prediction should

152 be testable with future events, since the LED was not operating for the event reported

153 here.

3 Observation

155 ASIM-MXGS recorded an unusually long event on September 16th, 2018, at 13:14:44.733601

156 (UTC). The event was strong enough to have been triggered by the 3 ms window. The

157 recorded lightcurve is presented in figure 2. The event consists of a pulse of more than

158 2 ms duration. Figure 3.a. shows the geometry of the event on a map. Table 1 gives a

159 summary of the coordinates and times of the interesting points.

160 The data from World Wide Lightning Location Network (WWLLN) was also used

161 for this analysis. It provides lightning timing and location by the use of a network of VLF

162 sensors positioned on the ground around the globe (Hutchins et al., 2012). According

163 to WWLLN, there was no lightning activity below the ISS within a reasonable time win-

164 dow (few minutes) and distance (< 600 km). We could estimate the position of the mag-

165 netic field line footpoint at 45 km altitude (approximately the altitude where most of

166 the electrons that have a chance to escape the atmosphere are produced) in the north-

167 ern hemisphere (see Table 1). This position was obtained from the model presented in

168 Emmert et al. (2010), based on IGRF-12 (Thébault et al., 2015). These geographic co-

169 ordinates were also confirmed by the two other codes, implementing the IGRF-12 model

170 and a Runge-Kutta stepper to propagate the electrons/positrons along Earth's magnetic

171 field (MC-PEPTITA and Geant4-based) that will be presented in section 4. Four WWLLN

172 events were found around this location, within a time frame of less than 140 ms. Two

173 of them are within 6 ms, well within the MXGS absolute timing uncertainty of about

174 20 ms. Since these two events happened within 0.1 ms and are close in location, they

175 probably belong to the same flash. The coordinates of the events are given in Table 1,

176 as events number 3 and 4. They are respectively 13.79 km and 12.69 km away from the

177 northern magnetic field line footpoint at 45 km altitude, knowing that the WWLLN has

178 a generic positioning uncertainty of ± 15 km. The probability of having a WWLLN event

179 in such a narrow time window and position by random chance is extremely low. There-

180 fore these two points are likely close to the location of a lightning flash associated with

181 the TGF that generated the TEB that was recorded by MXGS. In addition, simulated

182 data, presented in section 4, also indicate that the time between the TGF production

183 and the first electron reaching the detector is about 2.3 ms, which is close to travel time

184 at the speed of light along the magnetic field line.

185 As it has been observed previously (see e.g. Briggs et al. (2011); Ursi et al. (2017)),

186 a TEB could, in principle, come from a source TGF located at the magnetic footpoint

187 of the opposite hemisphere. For this event, it is located at $\lambda = -29.920$ °(latitude), $\phi =$

188 -101.044 °(longitude). However, we could not find any WWLLN match near this point

189 within a reasonable time frame. Furthermore, according to simulations, the observed TEB

190 duration in this configuration should be substantially longer than the observation (dis-

191 cussed in next section).

192 Figure 3.a. shows an image of the thunderstorm system located around the north

193 magnetic field line footpoint, obtained by the geostationary satellite GOES-16 and has

194 0.5 km spatial resolution (Advanced Baseline Imager band 2, visible red, centered at 0.64

195 μm). The image was taken around 13:15:30 (UTC), i.e. about 45 seconds after the ASIM

196 trigger. The positions of the three closeby WWLLN events are presented, and all are within

197 6 ms of the ASIM trigger time. They also appear close to an overshooting top of the thun-

198 derstorm system. Overshooting tops correspond to a region with high convective activ-

199 ity, with a high lightning activity in the vicinity, therefore it is not surprising if this re-

200 gion of the cloud generated a TGF.

201 Since this event shows a relatively low flux (i.e. particle count rate), instrumen-

202 tal effects due to pulse pile-up and dead time are weak. It was possible to correct for them

203 and get reliable energy calibration and count rates. MXGS HED and LED data from the

204 ASIM Science Data Centre (in particular lightcurves and spectra) cannot be used for sci-

205 entific analysis without performing mandatory post-processing step (including instru-

206 mental effects corrections, calibration, and forward modeling using the Geant4 mass model),

207 in collaboration with the ASIM-MXGS team. The energy spectrum of the event is pre-

208 sented in Figure 5. The spectrum is actually softer than what is recorded during usual

209 TGF events. The inset in Figure 5 shows a zoom below 780 keV using a finer binning,

210 which reveals a line around 511 keV. This line is broader than the ones detected by the

211 Fermi space telescope (Briggs et al., 2011) due to different instrumental characteristics.

212 A more detailed spectral analysis is presented in section 5.

4 Monte-Carlo simulations of the event

214   Numerical Monte-Carlo simulations were performed to reproduce the recorded lightcurves

215 and energy spectrum of the event. Two models were used to propagate the TGF and sec-

216 ondary particles from the source of the TGF to ASIM: the MC-PEPTITA model (Sarria

217 et al., 2015) and a new model based on the Geant4 toolkit (Agostinelli et al., 2003; Al-

218 lison et al., 2006, 2016). The Geant4-based code is made publicly available (see acknowl-

219 edgments) and presented into more details in appendix A. Both models are able to prop-

220 agate photons, electrons and positrons in Earth's environment, including the atmosphere

221 and the Earth's magnetic field. They include the relevant processes for photons (Comp-

222 ton scattering, photo-electric absorption, pair production, Rayleigh scattering) and elec-

223 tron/positron transport (elastic/inelastic scattering, bremsstrahlung, annihilation). For

224 simplicity, we only show results from the Geant4-based model, as both models showed

225 very consistent results in all the simulations we performed.

226   The simulations start from a time instantaneous photon source, with a bremsstrahlung

227 energy spectrum $\propto 1/\epsilon \times \exp(-\epsilon/7.3\,\mathrm{MeV})$ (Dwyer et al., 2012). The TGF is located

228 at 15 km altitude (later in this section an altitude range between 10 and 16 km is tested),

229 pointing towards zenith, with an opening angle that can be isotropic or Gaussian. The

230 isotropic angular distribution is parameterized by the opening half-angle θ, and the Gaus-

231 sian by the standard deviation σ_θ. The time reference is set to the source TGF produc-

232 tion time, assumed to be located at the coordinates of the northern or southern mag-

233 netic footpoints. Figure 1 illustrates the geometry of the simulation, and explains why

234 TEBs are temporally more dispersed than TGFs, and shows the pitch angle distribution

235 as a function of arrival time that was obtained for this event. For a source TGF located

236 at the north footpoint ($\lambda = 11.076^o$, $\phi = -95.399^o$), it takes about 2.28 ms for a di-

237 rect photon (straight line) to travel from their source to the ISS (located about 650 km

238 away), and the fastest electron/positron arrives about 48 μs later. The pointing angle

239 between the ISS and the TGF source is about 58.4° with respect to nadir. The positron

240 to electron ration of the TEB when it hits the ISS is about 13%. Simulated data indi-

241 cate that 95% of the electron/positron beam is contained in an ellipse of semi-major axis

242 of $\approx$ 88 km and semi-minor axis of $\approx$ 54 km. For simplicity, we will consider in the fol-

243 lowing that the TEB is contained inside a circle, of about 70 km radius.

5 Discussion

245   Figure 2.a. presents a comparison between the observed lightcurve, and the sim-

246 ulations. For all the simulations, except the green histogram, we assumed that the TGF

247 was produced close to the northern footpoint of the magnetic field line that intercepts

248 the ISS location. The simulated TEB lightcurve (electrons/positrons) is compatible with

249 the measurement. Here, the simulated photon lightcurve is arbitrarily scaled to have its

250 maximum (that is located about 2.2 ms) at the same level as the maximum of the elec-

251 tron/positron lightcurve. The real relative amplitude between the two histograms is a

252 function of the beaming angle of the source TGF and is discussed later.

253   TEB events may present a mirror pulse in some configurations. This is because charged

254 particles moving in a converging magnetic field (i.e. a stronger field) are subject to the

255 magnetic mirror "force" and are reflected. For this event, the IGRF-12 model gives a ge-

256 omagnetic field magnitude at the northern footpoint (at 45 km altitude) of 34590 nT,

257 and a weaker field of 29949 nT (-13.4%) at the southern (i.e. opposite) footpoint, hence

258 no mirror pulse is expected. The lightcurve presented in Figure 2 does not present any

259 mirror pulse indeed. There is a small count rate increase around 13 ms, that is consis-

260 tent with background fluctuations. According to our calculation (time of travel along the

261 field line), an hypothetical mirror pulse would be located much later, somewhere between

262 60 and 75 ms.

263   In principle, TEBs could be also detected when they are produced in the opposite

264 hemisphere (i.e. the southern hemisphere in this case). In Figure 2.a., the green histogram

265 presents the lightcurve that would be observed if the TGF had been produced in the south-

266 ern footpoint of the magnetic field line, and shows a signal about 4 times longer that the

267 observation ($\sim$ 20 ms compared to $\sim$ 5 ms). Figure 2.b. shows the same lightcurves

268 as 2.a., but zoomed-in between 2.1 and 3.1 ms. According to the simulation, the signal

269 due to the photons from the TGF (produced $\approx$ 650 km away from the ISS) should be

270 above the background level, and have a t_{90} duration of about 150 microseconds, for pho-

271 tons above 400 keV (reminder: we assume, for now, an instantaneous TGF at source).

272 The pulse due to TGF photons is about 20 times shorter than the one due to the TEB,

273 that lasts about 5 milliseconds. It indicates that some of the direct photons from the TGF

274 may also have been detected. This fraction will depend on the location of the ISS with

275 respect to the center of the electron/positron beam and, more importantly, on the an-

276 gular distribution of the TGF.

277 Figure 4.a. and b. presents the same comparison as before, but assuming several

278 angular distributions for the source TGF. Compared to figure 2, the relative effective ar-

279 eas of MXGS to detect photons (~ 650 cm^2) and electrons/positrons (~ 150 cm^2) is

280 also taken into account. MXGS-HED is actually about 4.33 times more efficient to de-

281 tect signal generated from incoming TGF photons than from TEB electrons and positrons.

282 A change in the TGF angular distribution parameter mostly affects the counts inside the

283 bin of the histogram located between 2.09 and 2.29 ms, containing mainly photons. . A

284 wider angular distribution of the source TGF implies that the relative amount of pho-

285 tons compared to electrons/positrons is increasing. A value of the angular parameter (θ

286 or σ_θ) is considered compatible with the measurement if the photon (red) bin count be-

287 tween 2.09 and 2.29 ms lies inside the 1-σ error interval of the ASIM measurement in

288 the same bin. For the isotropic (within a cone) angular distribution, the observed lightcurve

289 is compatible with the simulations if a half-angle of θ between 30.6^o and 41.9^o is used.

290 For the Gaussian angular distribution, it is for a σ_θ between 20.6^o and 29.8^o. This range

291 is in agreement with previous studies (Dwyer & Smith, 2005; Østgaard et al., 2008; Hazel-

292 ton et al., 2009; Carlson et al., 2011; Mailyan et al., 2016). This scenario implies that

293 about 3.5 to 10 % of the recorded counts by ASIM-MXGS are actually direct TGF pho-

294 tons, that arrive mostly at the beginning of the recorded lightcurve.

295 The previous results have been obtained assuming an instantaneously produced source

296 TGF. But we also investigated the effects of using longer source TGF durations. We found

297 that the constraint on the angular distribution is similar for any source duration $t_{90}^s <$

298 $197\,\mu s$, that corresponds to a recorded $t_{90}^d < 260\,\mu s$ after propagation to the satellite.

299 It is probably the case, because according to the TGF duration distribution obtained from

300 ASIM, $\approx 90\%$ of the t_{90} durations are below $260\,\mu s$ (Østgaard et al., 2019). For longer

301 source durations, it is impossible to constraint the angular distribution using the method

302 presented above. This discussion is presented in more detail in appendix B.

303 Figure 5 presents a comparison between the recorded energy spectrum (background-

304 subtracted) and simulations, using a strategy of forward modeling. Two scenarios are

considered, one assuming that the incoming particles are photons from the TGF, and the other assuming that the incoming particles are the secondary electron/positrons from the TEB. The TGF and TEB spectra are first calculated using the Geant4-based model of TGF propagation in the atmosphere with the assumptions presented previously (see Section 4, and Appendix A). The particles are gathered at 400 km altitude, around the position of the ISS (± 70 km). We verified that the TEB spectrum does not change significantly as a function of radial distance from its center (the corresponding data and figures are presented in the associated data repository, see acknowledgments). The results of this first simulation are then used as input for the ASIM Geant4 mass model (presented by Østgaard et al. (2019)), and a set of simulated MXGS-HED spectra are produced. The quality of the simulated data compared to the observation can be quantified using the reduced chi squared (χ^2_{red}). The χ^2_{red} values obtained for the simulated response to a TGF and to a TEB are 7.2 and 1.13, respectively. Due to the chosen energy binning, there are 7 degrees of freedom, and using an usual 95% probability threshold, it gives a critical value $\chi^2_{red,c}$ equal to 2.01. It means that the TEB model, with $\chi^2_{red} < \chi^2_{red,c}$, is compatible with the measurement, whereas the TGF model, with $\chi^2_{red} > \chi^2_{red,c}$, is not. In addition to the results concerning the lightcurve (previous paragraph), and the geographical and time lightning matches (section 3), we think that it is enough evidence to consider that this event is mostly a TEB, with a small fraction (3.5% to 10%) of photons coming directly from the TGF.

Finally, we can estimate the required photons number N_γ of the source TGF in order to obtain the ≈ 160 counts that were observed by HED. The exact value of N_γ depends on assumptions of the source TGF, mainly the altitude of production and the angular distributions. We performed a series of simulation using the Geant4-based model, with a TGF altitude of production tested between 10 and 16 km, assuming an isotropic distribution of photons within a cone (with parameter the half-angle of the cone, θ, tested from 10° to 50°), or a Gaussian distribution (with parameter the standard deviation σ_θ, tested from 10° to 40°). The results are presented in figure 6.

The derived constraint on the TGF photon number is based on the number of electrons/positrons detected by ASIM-MXGS, and not the number of photons as it is usually done. Most of the electrons/positrons that are detected by ASIM-MXGS are produced between 40 and 100 km altitude, along the Earth's magnetic field line that is intercepting the ISS location. Most of the electrons/positrons (>95% of the total number)

338 are within 70 km radial distance around the field line. By increasing the angular distri-

339 bution of the source TGF, a large fraction the added electron/positrons have no chance

340 to reach ASIM since they are not produced close enough to the field line. In other words,

341 increasing the value of the beaming angle mostly adds new photons that will not con-

342 tribute to the TEB. Therefore the dependence of N_γ on θ (when a source altitude is fixed)

343 can be approximated as being proportional to the solid angle of a cone, i.e. $N_\gamma(\theta) \propto$

344 $\sin^2(\theta/2)$ (θ is a half angle). This was checked to fit quite accurately the profile of $N_\gamma(\theta)$,

345 at a fixed source altitude. At a fixed opening angle, the variation of N_γ with altitude is

346 directly linked to the absorption of the air. The absorption that has to be considered,

347 i.e. that will affect the number of produced electrons/positrons, is happening between

348 the source altitude and about h_l =40 km altitude. The integrated densities H that the

349 TGF photons have to cross before reaching h_l are about 290.41, 215.60, 156.18 and 111.05

350 g/cm^2 for source TGFs at altitudes of 16, 14, 12 and 10 km respectively. The photons

351 get absorbed about 80.5 times more for a source at 10 km altitude, compared to a source

352 at 16 km. This ratio is 14.0 for a source at 12 km altitude, and 3.46 for a source at 14

353 km altitude. The profile of relative absorption can be obtained with $A(h) \propto exp(-H(h)\,\mu/\rho)$

354 and using an effective mass-energy absorption coefficient $\mu/\rho \approx 0.0247\,\mathrm{cm^2/g}$. This value

355 corresponds to the coefficient for air for photons at about 1.7 MeV, that is approximately

356 the average of the assumed source TGF energy profile, if integrated between 60 keV and

357 40 MeV.

358 If the constraints on the angular distributions are considered (discussed before),

359 a value of N_γ of $10^{17.2}$ (high altitude) up to $10^{18.9}$ photons (low altitude) is required to

360 reproduce the particle count measured by ASIM-MXGS-HED (see Figure 6). This range

361 is in agreement with values given by previous studies (Dwyer & Smith, 2005; Dwyer et

362 al., 2012; Cummer et al., 2014; Gjesteland et al., 2015; Mailyan et al., 2016).

6 Conclusions and future work

364 We report the first TEB detected by the MXGS-HED instrument on-board the Atmosphere-

365 Space Interactions Monitor (ASIM). It appeared as an unusually long event (> 2 ms)

366 with a spectrum softer than what is usually seen from TGF events. Tracing of the ge-

367 omagnetic field line from the ISS permitted to estimate a likely geographical position of

368 the TGF that produced the TEB, where three WWLLN matches within compatible time

369 (<6 ms) and distance (<15 km) intervals were found. From geostationary imaging, ob-

370 tained just about 45 seconds after the event, it appears that the TGF was produced in

371 the vicinity of an overshooting top of a thunderstorm.

372 Using Monte-Carlo simulations to reproduce the observed lightcurve and energy

373 spectrum, we show that the event is indeed mostly explained by a TEB, even if 3.5% to

374 10% of the detected flux may be direct TGF photons. A source TGF with a broad an-

375 gular distribution can explain the observation ($\theta \approx 30.6^o - 41.9^o$ for a isotropic within

376 cone distribution, or $\sigma_\theta \approx 20.6^o - 29.8^o$ for a Gaussian distribution). This constraint

377 is valid only if the source TGF has a duration $t_{90}^s < 197\,\mu s$ (that corresponds to a du-

378 ration at satellite altitude of $t_{90}^s = 260\,\mu s$). This is a likely possibility according to the

379 distribution of TGF durations recorded by ASIM, where 90% of the TGFs have a $t_{90} <$

380 $260\,\mu$s (see Østgaard et al. (2019), Figure 2). In addition, the intensity of the source TGF

381 could be estimated for various assumptions of the source (altitude of production, angu-

382 lar distribution), and is between $10^{17.2}$ and $10^{18.9}$ photons. This range is in agreement

383 with previous studies.

384 Here, we have discussed a TEB event detected during the daytime by the HED in-

385 strument alone. Future observations during nighttime have the added promise of simul-

386 taneous detection by the LED and MMIA instruments. It will allow measurements of

387 the low-energy part of the spectrum ($\sim$70 keV to $\sim$400 keV), and hypothetical UV and

388 optical emissions associated with such events.

389 Planned for a launch in 2020, the TARANIS micro-satellite (Lefeuvre et al., 2009),

390 should also detect TEB events. It is primarily designed to detect both TGFs and TEBs,

391 with help of the XGRE and IDEE instruments (Sarria et al., 2017), and will have, in ad-

392 dition, the capability of detecting hypothetical radio emissions from TEBs.

Table 1. Summary table of the time and coordinates of the interesting elements for the ASIM event that happened on 2018/09/16. λ, ϕ and h are latitude, longitude and altitude. All the given coordinates geodetic/geographic, using the WGS84 reference ellipsoid. WWLLN events number 3 and 4 are in a very narrow time (with respect to the event trigger time) and distance windows (with respect to the northern magnetic field line footpoint) and can be considered as good matches for the lightning discharge that produced the source TGF. Due to their very narrow time differences (< 0.1 ms), these two matches probably belong to the same discharge.
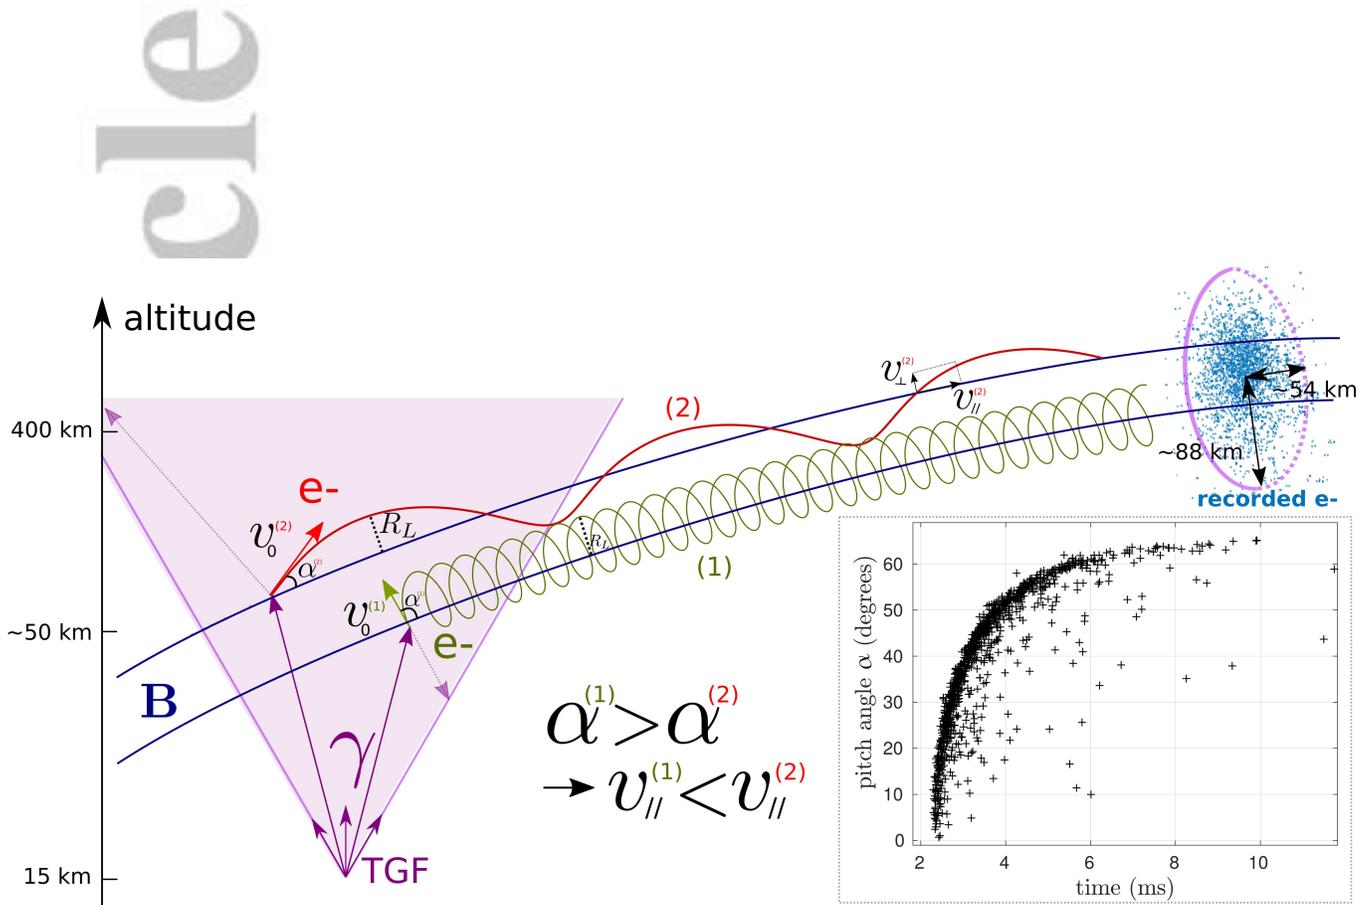

Figure 1. This sketch illustrates why the time distribution for a TEB event is mainly due to the pitch angle α with respect to Earth's magnetic field. Most of the electrons/positrons are relativistic and hence have a speed close to the speed of light. However, they have to follow helical trajectories around the field lines, and the electrons/positrons with larger α will undergo more rotations around the field lines, and with a larger Larmor radius (R_L) at the same electron energy, before reaching the satellite. They have actually a smaller velocity along the field line ($v_{/\!/}$). More energetic electrons will have a larger R_L (as it is proportional to the Lorentz's γ factor). The insert shows the pitch angle as function of arrival time (according to the simulations described in section 4). At the satellite level, most of the electrons will arrive inside an ellipse of 54 km semi-minor axis and 88 km semi-major axis.
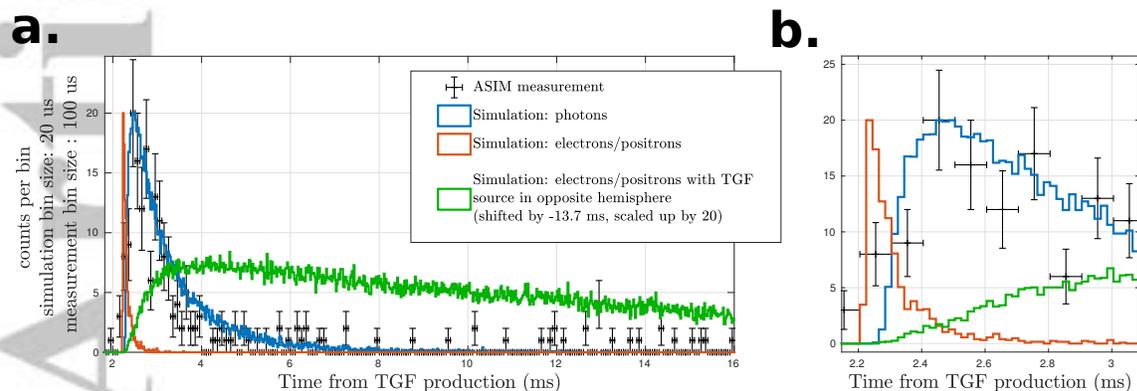

Figure 2. **a.** Comparison between simulated and measured lightcurves for the TEB event. Error bars indicate a 1-σ interval, and are calculated as the square root of the number of counts in each bin. Time 0 is when the source TGF is produced. The signal of the photons (TGF) and electrons/positrons (TEB) are shown. The simulated photon lightcurve (red) is scaled to have its maximum (that is located around 2.2 ms) at the same level as the maximum of the electron/positron lightcurve (blue).

The observed lightcurve matches the electron/positron component (TEB) of September 16th, 2018. The green histogram presents the TEB lightcurve that would be observed if the associated TGF was produced in the southern footpoint of the magnetic field line, and shows a signal about 5 times longer that the observation. It was scaled in amplitude by a factor of 20 and shifted in time by -13.7 ms, to be able to display it inside the same time scale. **b.** Zoomed in between 2.1 and 3.1 ms. The simulations indicate that photons from the TGF could also have been observed, and they should be mostly within the first 0.2 ms of the event. According to this simulation, most of the recorded counts below about 2.3 ms are due to photons.
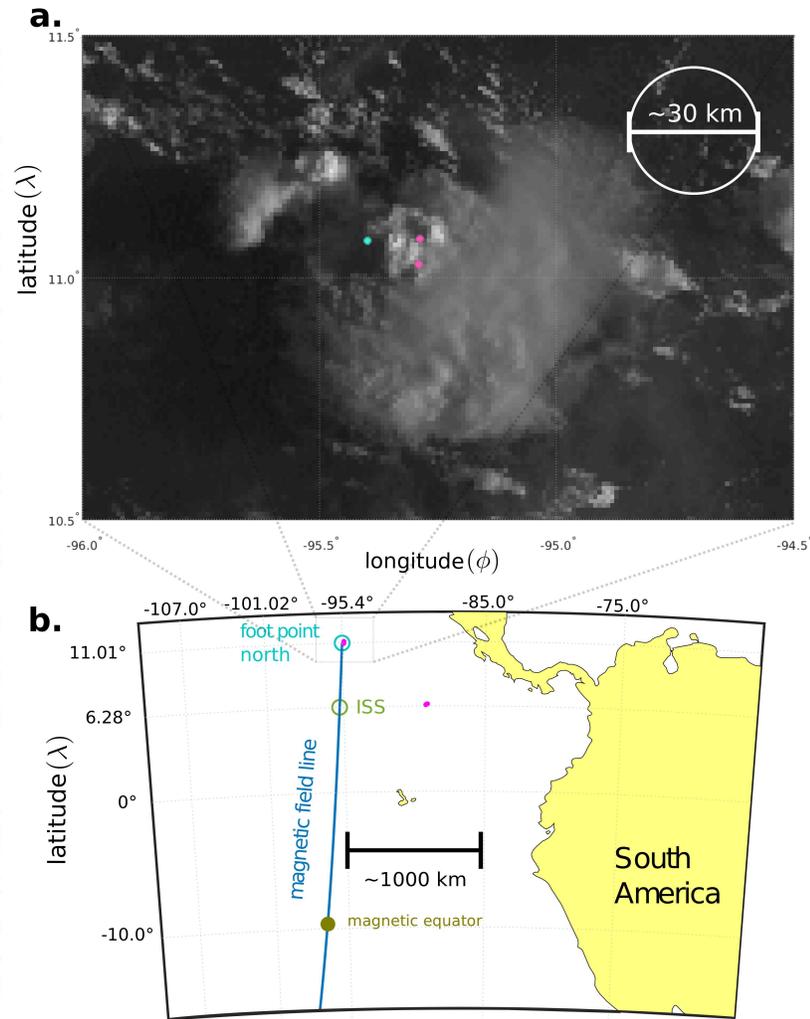

Figure 3. **a.** Image from geostationary satellite GOES-16 on September 16th, 2018, around 13:15:30 UTC (about 45 seconds after ASIM trigger time), zoomed around the north magnetic footpoint region. The image comes from the Advanced Baseline Imager instrument, optical band 2, centered at 0.64 μm, with 0.5 km resolution. The cyan dot gives the position of the footpoint at 45 km altitude of the magnetic field line intercepting the ISS location. The two closest positions obtained from WWLLN are presented as magenta dots, that may correspond to a single discharge. They are within 6 ms of the ASIM trigger time (the MXGS absolute timing uncertainty is about 20 ms) and within 15 km of the northern magnetic footpoint (the WWLLN generic positioning uncertainty is $\pm$15 km). The two points are located close to an overshooting top of the thunderstorm system. **b.** The map shows the positions of interesting points of the event. The ISS (green dot) is located at a latitude $\lambda = 6.28°$ and a longitude $\phi = -95.71°$. The red dot is located at the northern magnetic footpoint of the magnetic field line passing though the ISS (coordinates $\lambda = 10.98°$, $\phi = -95.39°$). The corresponding magnetic latitude is 21.05° (modified apex). The small magenta dots are the position of the lightning discharges obtained from WWLLN sferic detections, within a time frame of 140 milliseconds around the ASIM trigger time.
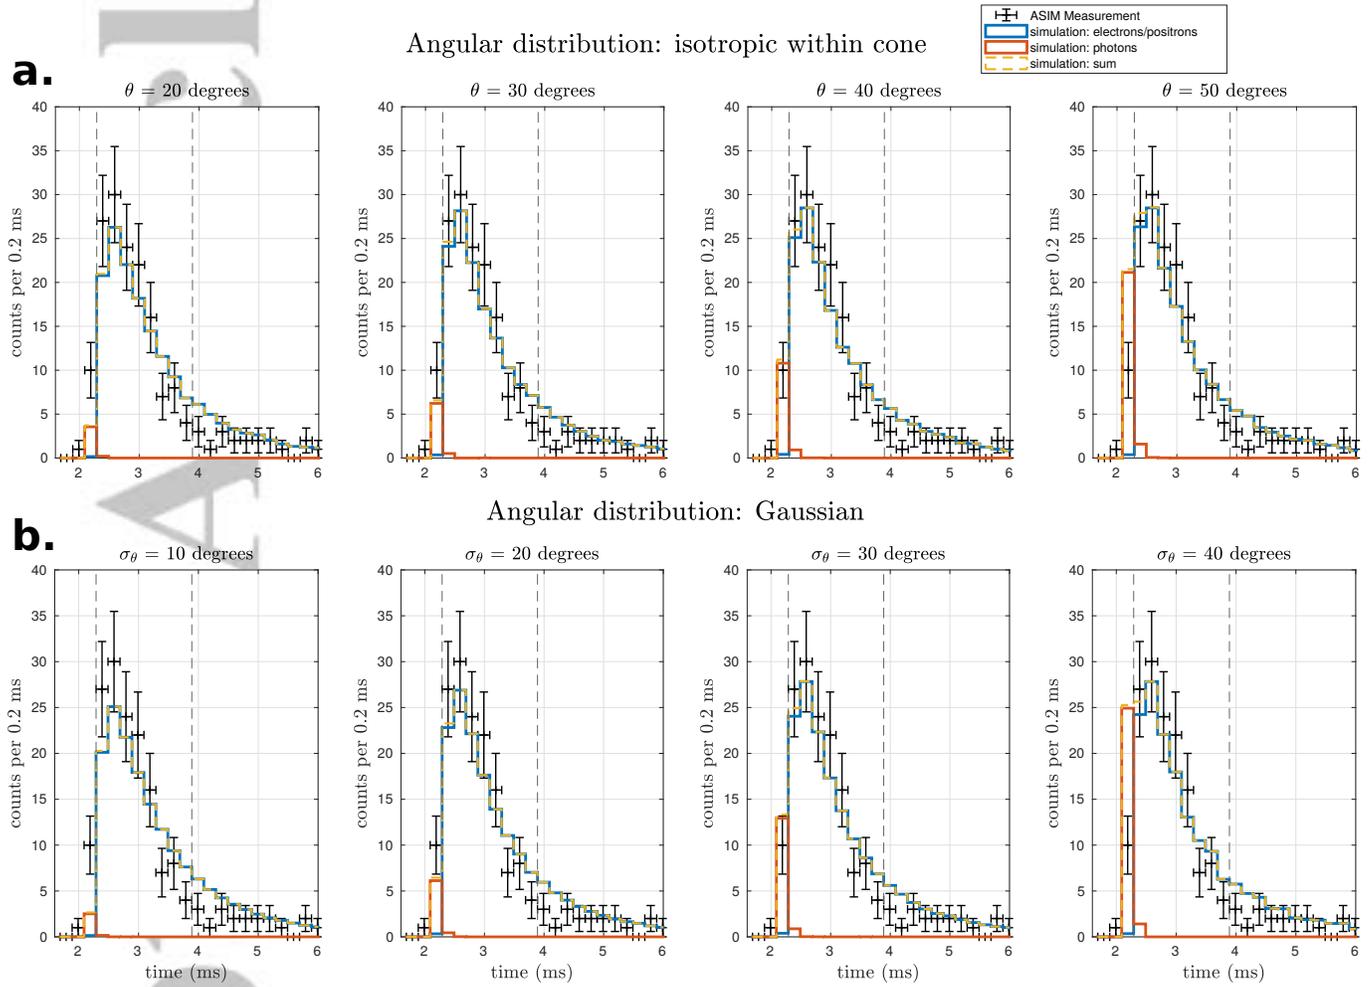

Figure 4. Comparison of the simulated and measured lightcurves, assuming various opening angles of the source TGF. Compared to figure 2, the relative fluxes between electrons/positrons and photons take now into account the efficiency of the detector for the different particles. Error bars indicate a 1-σ interval, and are calculated as the square root of the number of counts in each bin. The simulation is scaled to the measurement to minimize the value of the χ^2. The bins between 2.09 and 3.89 are used to compute it (shown with vertical dashed lines). A change in the source TGF opening angle mostly affects the photon (red) count rate between 2.09 and 2.29 ms. **a.** Isotropic angular distribution inside a cone, with half angle θ. **b.** Gaussian angular distribution with standard deviation σ_θ.
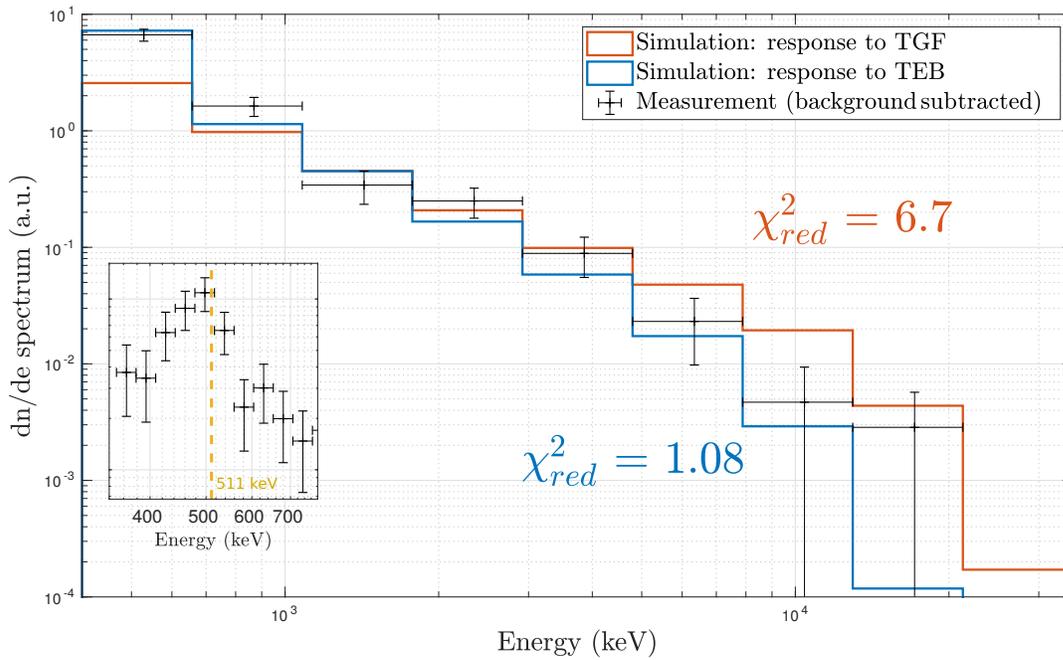

Figure 5. Energy spectrum comparison between the ASIM-MXGS measurement and simulations. The inset shows the recorded spectrum below 780 keV using a finer binning, which reveals a line around 511 keV. Two simulation scenarios were considered: incoming particles are from TGF or TEB. The two simulated spectra are scaled to minimize the values of χ^2_{red}, and the minimum values obtained for each model are indicated.

It is expressed as function of altitude and opening angle, in decimal logarithm. The dotted lines demarcate the parameter space where the angular distribution has been constrained (see figure 4). **a.** Assuming that the source TGF has a isotropic angular distribution inside a cone, with half angle θ. **b.** Assuming a Gaussian angular distribution with standard deviation σ_θ.

Appendix A Geant4-based Monte-Carlo model of TGF and TEB propagation in the atmosphere, ionosphere and magnetosphere.

In order to estimate the response of MXGS-HED instrument for this event, we first needed to generate TGF (photons) and TEB (electrons and positrons) spectra just before they reach the International Space Station. We used a code based on the Geant4 toolkit (Agostinelli et al., 2003; Allison et al., 2006, 2016) to propagate particles in the atmosphere, ionosphere and magnetosphere. The code is available in an online repository, see acknowledgments. The geometry uses 256 exponentially spaced atmospheric layers between 1 and 150 km altitude (the atmosphere is negligible above) of constant density, composed only of N_2 and O_2, for simplicity and better performance. Densities within these layers are calculated with the NRLMSISE-00 model (Picone et al., 2002). The magnetic field of the Earth is modeled using the IGRF-12 model (Thébault et al., 2015). The propagation of photons, electrons and positrons is simulated, including all the relevant processes, which are included in the Geant4 toolkit. Different models can be used (semi-analytical, or database driven like Livermore or Penelope), more-or-less accurate in the low energy part. In the context of photon/electron/positron propagation in air above 50 keV, and without electric fields, they all show similar results as long as the effects of straggling are included (Rutjes et al., 2016), that is the default behavior of Geant4.

The source TGF is assumed to be a point source with adjustable altitude, typically set between 10 and 16 km. The energy spectrum has an exponential distribution proportional to $1/\epsilon \exp\left(-\epsilon/\epsilon_{\mathrm{cut}}\right)$, with a cutoff $\epsilon_{cut} = 7.3$ MeV. The angular distribution is Gaussian with a standard deviation of 30 degrees, and has no tilt. The electrons, photons and positrons are collected at an altitude of 400 km, inside a circle of $R = 80$ km radius around the position of the ISS. The spectra can be built using this data, but to properly build the photon lightcurve, R should be less than 1 km (to avoid artificial time broadening). Figure A1 shows the recorded energy spectra at 400 km altitude. They were then used as an input to calculate the response of the ASIM mass model to the TGF and the TEB. The electron energy spectrum can be fit by an exponential distributions ($\propto \exp\left(-\epsilon/\epsilon_{\mathrm{cutoff}}\right)$, where ϵ is the energy). It results in cut-off energy of $\epsilon_{\mathrm{cutoff}} = 2.88 \pm 0.176$ MeV, that is compatible with the range of 2.3 to 4.6 MeV found by Briggs et al. (2011).
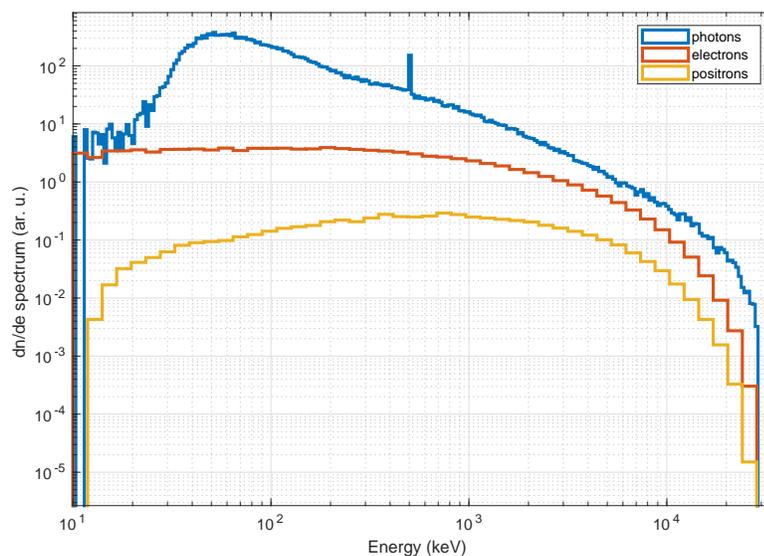

Figure A1. Results of the Geant4-based model simulation. Photon, electron and positron energy spectrum, recorded at 400 km altitude, within 70 km radial distance around the ISS position (i.e. in a plane perpendicular to the local vertical). The photon spectrum uses a finer binning to better represent the 511 keV line when this spectrum is used as input for the ASIM mass model. The source TGF is located at 15 km altitude and has a Gaussian angular distribution centered towards zenith with standard deviation of $\sigma_\theta = 30°$. The amplitude of the spectra shown here is not representative of the fluence ratios (particles/cm^2) of the different particle types.

The amplitude of the spectra shown in the figure are not representative of the fluences (particles/cm^2) of the different particle types. The fluence ratio of positions over electrons arriving to the ISS is about 13% in this case. For other settings of the source altitude or the angular distribution, it can fluctuate between 11% and 16%. The fluence ratio of electrons+positrons over photons arriving at the ISS is dependent on where the satellite is located with respect to the center of the TEB, on the offset between the TEB and the TGF (which depends on the geographical location) and on the angular distribution of the TGF. Figure A2 presents the evolution of this ratio as function of the distance to the center of the electron beam, for an initial TGF with a Gaussian angular distribution with several values of σ_θ.
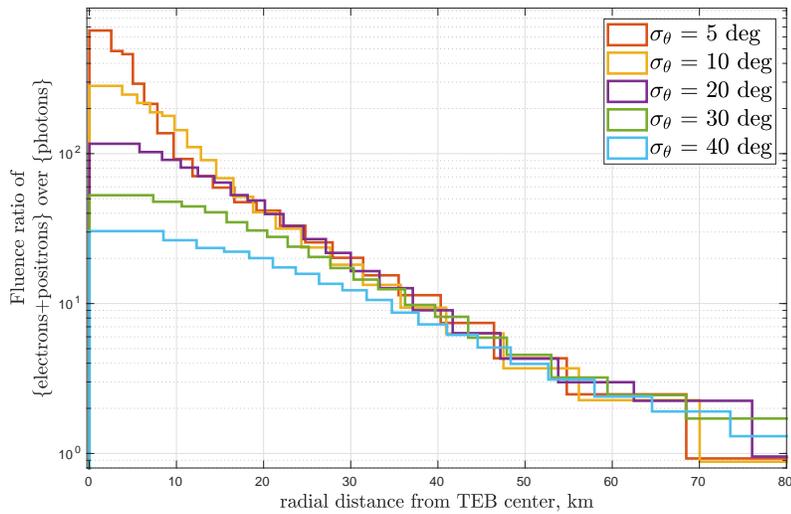

Figure A2. Fluence ratio between electrons+positrons (TEB) and photons (TGF) arriving at the ISS, according to the simulation. In this case, the ISS is located at about 650 km of the source TGF. The fluence ratio is presented as function of the distance between the ISS and the center of the electron beam, for several angular distributions (assuming a Gaussian distribution with parameter σ_θ). The source TGF is located at 15 km altitude. The response of the MXGS detector (i.e. the relative detection efficiency between electrons and photons) is not taken into account here. Note that the real spatial distribution of the leptons is contained inside an ellipse and here the particles are recorded inside rings (circular symmetry) for simplicity.

## Appendix B Effect of longer TGF source durations on the angular distribution constraint.

In this appendix, we provide a comprehensive discussion on the effects of assuming a longer TGF source duration (t_{90}^s) on the constraint on the angular distribution. If the TGF source duration is too long, it will blur (or smear) both the detected TGF and the TEB lightcurves, and could lead to different conclusions regarding the presented constraint on the beaming angle. We want to determine what is the maximum allowed value of t_{90}^d for the conclusions to be still valid.

First, it is important to distinguish between t_{90}^d, the detected TGF duration (when the TGF is detected by a satellite) and t_{90}^s, the source (or intrinsic, i.e. when the TGF is produced), because the propagation in the atmosphere implies a spread (or smearing) of the duration (and this spread is larger if the radial distance between the TGF source point and the sub-satellite point is larger; it also depends on the considered photon energy range). We always have $t_{90}^d > t_{90}^s$. According to the simulation, assuming an instantaneous source ($t_{90}^s = 0$), the detected TGF t_{90}^d duration is about $150\,\mu s$ in this case (the radial distance between the TGF source point and the sub-satellite point is about 650 km). We can model the source TGF duration with a Gaussian (normal) distribution with parameter σ_t^{TGF}. Note that the t_{90}^s duration of the gaussian time profile is directly linked to σ_t^{TGF} by $t_{90}^s = 3.290\,\sigma_t^{TGF}$ (and $t_{50}^s = 1.349\,\sigma_t^{TGF}$). For simplicity, we only show here the results for the Gaussian angular distribution.

Figure B1 presents how the lightcurves are changing with different σ_t^{TGF}. When σ_t^{TGF} is increased, the simulated lightcurves get too much smeared (spread out) compared to the measurement. This effect can be quantified by looking at the reduced χ^2 value between the simulation and the measurement. The value of χ_{red}^2 as function of σ_t^{TGF} is presented in figure B2. Only the bins between 2.29 and 3.89 ms are kept for the χ^2 calculation (that are shown by the dashed vertical lines in Figure B1). An instantaneous TGF source ($\sigma_t^{TGF} = 0$) gives the best fit to the lightcurve, and increasing it gives less accurate ones. However, if we perform a χ^2 test, only σ_t^{TGF} values above 0.242 ms are rejected, using a standard 95% probability threshold.

In section 5, we established a constrain on the beaming angle by assuming that the beginning of the recorded lightcurve (i.e. the bin between 2.09 and 2.29 ms) contains mostly photons. This assumption will not be true anymore after increasing σ_t^{TGF} above a cer-
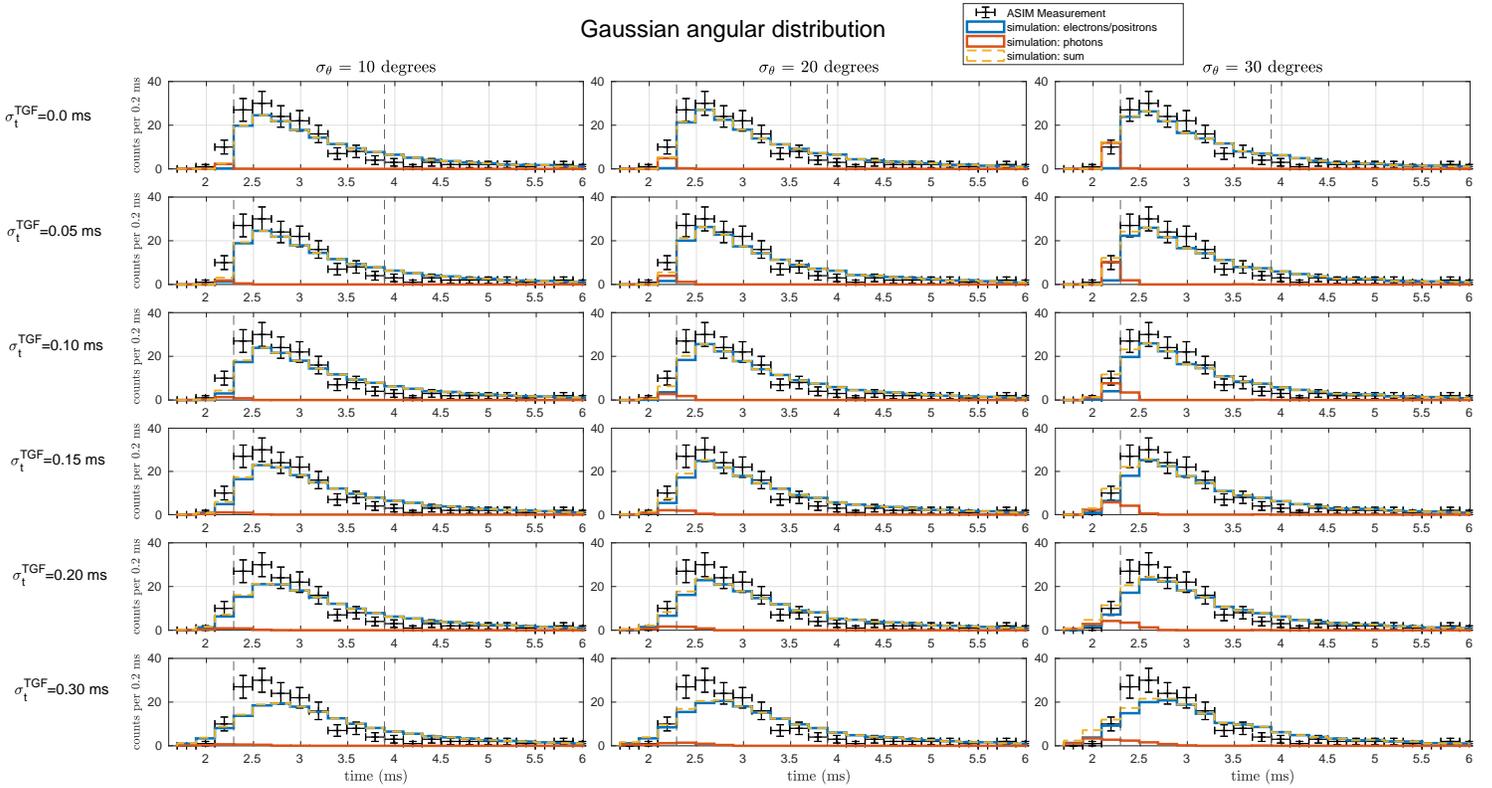

Figure B1. Comparison of the simulated (photons, electrons/positrons, and sum of both components) and measured lightcurves, assuming various opening angles and source duration of the source TGF. Error bars indicate a 1-σ interval, and are calculated as the square root of the number of counts in each bin. The simulations are scaled to the measurement to minimize χ^2. The dashed vertical lines indicate the time interval ($2.29\,\mathrm{ms} < \mathrm{t} < 3.89\,\mathrm{ms}$) where the χ^2 calculation is done (see Figure B2 for the results)

Figure B2. Reduced χ^2 between the simulated and the measured lightcurves, as function of the source duration of the TGF. The red vertical dashed line indicates the critical value ($\chi^2_{red,c} = 2.1$).

tain value. This is because increasing σ_t^{TGF} will smear both the photon and the electron/positron lightcurves (see figure B1). Therefore we must define a threshold for which we consider that the bin between 2.09 and 2.29 ms contains mostly photons. If we set it to 80% (i.e. 4 times more photons than electrons) then the maximum allowed σ_t^{TGF} is $\approx 60\,\mu$s. It corresponds to $t_{90}^s \approx 197\,\mu$s and, according to the simulation, the corresponding observed t_{90}^d should be about $260\,\mu$s (i.e. after propagating the TGF from the source at 15 km altitude to the satellite at $\approx$400 km altitude and at $\approx$650 km arc length distance). For any σ_t^{TGF} between $0\,\mu$s and $60\,\mu$s, the constraint on the angular distribution is about $21^o < \sigma_\theta < 30^o$, with small fluctuations with σ_t^{TGF}. For longer TGF source durations, it is not possible to establish a constraint on the angular distribution. The question is then how likely it is for the specific TGF that we are studying in this paper to have a $t_{90}^d < 260\,\mu$s, as it is impossible to be sure about its real t_{90}^s. However, if we look into other TGF detection by ASIM, and more specifically the distribution of observed TGF t_{90}^d durations (see Østgaard et al. (2019), Figure 2.B.), a large majority ($\approx$ 90%) are below $t_{90}^d = 260\,\mu$s, with a most likely duration around $t_{90}^d = 75$ to $100\,\mu$s. It is therefore likely that the source TGF studied in this article has a t_{90}^d shorter than $260\,\mu$s.
